To doctors the most annoying statement a patient can make is that she was told by the agent of her society she was to get a certificate. This has led to much acrimonious talk between doctors and societies, but it is quite easy to see what happens. The agent of the society cannot say yes or no to a question whether a woman is entitled to sick pay. What he does say, often under instruction from his head office, is, "You must get a certificate from your doctor." This phrase is interpreted by the patient to mean that the doctor is bound to give a certificate, and this is what she tells the doctor. Thus a situation which causes much irritation and administrative difficulty all round is really due to a mistake in the interpretation of words not easy to avoid among uneducated people. Sometimes doctors use expressions which patients interpret incorrectly, such as "I will give you a certificate so that you can get your money," or "Take this certificate to your secretary, he will pay you then." The patient assumes that the doctor knows what is due to her, though the agent or secretary may be under orders from head office to stop payment for some administrative infringement or other reason unknown to the doctor.

It is not unknown, however, for agents to go round advising women to claim when pregnant, and then advertising the successful claims in order to encourage recruitment of new members. Fortunately this is not a common proceeding, and most of the bigger societies have given definite instructions to their agents in order to remove any erroneous impression. The real cause of difficulty in competitive areas is a threat of change of doctor. A tired doctor may protest that he can ill afford to risk losing private cases, confinement fees, as well as panel fees, in order to carry out the letter of an Act of Parliament run by a Minister who is always worrying him about records and prescriptions in order to save the funds of some approved society whose officers rarely have a good word to say for his work. It is easy for him to believe that a patient feels much worse than her physical signs show, and to convince himself that it would be wrong to refuse to put her on the panel. In time of course a doctor will realise that a weak attitude leads to panel slavery, and that patients will not retain much respect for a doctor who does not hold to his own judgment in these matters. These cases can usually be handled tactfully so that the doctor gets his own way and the patient is nevertheless satisfied. If the incapacity really is in doubt the case can always be referred to the regional medical officer for a report.

The certificate of post-confinement cases is not so difficult. For four weeks after her confinement she gets maternity benefit and is not eligible for sick pay or disablement benefit. After this period she is not entitled to such benefits unless she is certifiable as incapable of work. In this case a first certificate should be given and not an intermediate one. The commonest causes of such incapacity are backache and anæmia.

The certification of pregnancy cases has given rise to much discussion in approved society circles as well as in medical committees. It has been suggested that no sickness pay should be given during pregnancy, but that a larger maternity benefit should be paid in its place. This would be rather hard on the woman who broke her arm when pregnant, and required funds to help finances to carry on. Again, it has been suggested that sickness pay should only be given for those ailments which are not connected with pregnancy, an almost impossible position for any doctor to determine. The matter is certainly very important. It has recently been brought to the notice of the panel committee for London by the organising assistant secretary in his quarterly report, and not for the first time.

Surcharging

In THE LANCET of Jan. 14th we expressed agreement with the Glasgow critics that "it is a pity there have been no cases of investigation of under-prescribing." By this we intended to convey that there had been no cases tried by panel committees where the charge was under-prescribing as distinct from over-prescribing. But we are informed, and are glad to point out, that regional medical officers do interview practitioners whose average is definitely below the general average. It is usual to find such cases either in country areas where the doctor is a dominating personality, who has little faith in the efficacy of drugs, or in areas in London, like Soho, where a large foreign population does not readily take medicine. Another type of practice where the average is low is that attached or connected with some industrial firm who habitually send their cases to hospital rather than to the panel doctor. It is obviously difficult to prove that a doctor is not giving sufficient medicines, even though his prescriptions may be well below the real average, and that is probably why no cases have yet been taken as far as a panel committee for investigation.

CORRESPONDENCE

MASKED HYPERTHYROIDISM

To the Editor of THE LANCET

SIR,—Dr. J. R. H. Towers is to be congratulated on his paper on Masked Hyperthyroidism and Heart Disease in your issue of Jan. 14th. Those of us who are especially interested in thyroid problems are frequently confronted with the sort of case Dr. Towers describes in which certain phenomena such as tachycardia, wasting, nervousness, and tremor are present, but the thyroid gland is not visibly enlarged.

Dr. Towers, I am sure, does not need to be reminded that many goitres not visible are nevertheless palpable owing to their abnormal consistence, or to the fact that in a muscular neck a thyroid gland of two to three ounces in weight may not be visible, yet if the muscles are relaxed it may be felt. It is also true that the thyroid gland may be enlarged, yet neither inspection nor palpation, even by those skilled in this branch of medicine, reveal the fact. The normal thyroid gland weighs in the young adult, when it is at its maximum size, about four-fifths of an ounce, but a gland twice or even thrice this weight may be neither visibly nor palpably enlarged. Where Dr. Towers might, I think, enlighten us further is by giving details of the weights of thyroid tissue removed in those cases submitted to operation, and also by informing us as to the histological structure of the extirpated tissue. This would help to solve the problem whether thyrotoxicosis ever occurs with a thyroid gland which is normal in size or normal in structure, or both. I am convinced that the contrary proposition is true—viz., that thyrotoxicosis never occurs in association with a thyroid gland which is normal in size, still less in one which is normal in structure.—I am, Sir, yours faithfully,

Harley-street, W., Jan. 24th, 1933. CECIL A. JOLL.

THE MIGRATION OF "MALTA FEVER"

To the Editor of THE LANCET

SIR,—In the discussion on Prof. W. E. Hume's paper on Undulant Fever at the Royal Society of Medicine on Jan. 24th, I submitted that undulant fever was new to Malta when first heard of in the fleet in 1856, and Dr. E. W. Goodall asked where it had been before that. Perhaps you will let me answer now—in South Russia. Surgeon Captain S. F. Dudley tells us it was then new to the fleet, and there is no trace of it among the diseases of Malta recorded by that careful physician, John Hennen, in medical charge there from 1821–25. An expedition was made to Kertch, at the foot of the Sea of Azof, during the Crimean War, and troops returning thence to Malta, on board men-of-war, seem to have infected the ships, and perhaps the island. It is doubtful if any reports of this disease were made from South Russia before the Great War, but several have appeared since, from Baku,[1] from Batoum[2] and from Rostoff, at the upper end of the Sea of Azof in 1931.[3] Brucella septicæmia is clinically so indefinite in men that it is not likely to be diagnosed unless attention is specially directed to it. It was recognised at Rostoff in 1925, but epidemic abortion of cattle it was caused particular concern. The first human *abortus* case was at last recognised in a veterinary surgeon, for three years concerned with epidemic abortion (loc. cit., ref. 3, p. 237).

Br. abortus and *melitensis* fevers—they seem scarcely distinguishable—are widely spread. We heard on the 24th that they are notifiable in France and Germany, cases are always being reported in new places; Prof. Hume told us of 17 unexpectedly found in the North of England, and Surg.-Lieut. Commander S. G. Rainsford[4] says that 20 per cent. of normal serums in Ireland agglutinate *Br. abortus*. So this septicæmia is almost as widespread, if not so virulent, as appendicitis, of which hardly anyone had heard 50 years ago. And other diseases have been known to migrate—yellow fever from West Africa to the West Indies, and in 1848 to South America (Bahia); malaria to Mauritius from India. Cholera, plague, and influenza migrate quite commonly, syphilis recently invaded Uganda, sleeping-sickness and chigoe were brought from West to East

OBITUARY

SIR WILLIAM TAYLOR, K.B.E., C.B., F.R.C.S.I.

REGIUS PROFESSOR OF SURGERY, UNIVERSITY OF DUBLIN

WE regret to announce the death of Sir William Taylor, Regius professor of surgery in the University of Dublin, which occurred suddenly on Sunday last, Jan. 29th, in the sixty-second year of his age. He had shown no signs of illness, and the news of his death came as a shock to his friends.

Sir William Taylor was born in Donegal and was educated at the Strabane Academy, the medical schools of the Irish Royal Colleges, and the University of Dublin. He qualified with the double diploma of the colleges in 1893, having proved himself a distinguished student by securing the gold medal in operative surgery and the Mayne scholarship. Later, at the University of Dublin, he graduated in Arts and took the M.B. degree in 1901, having previously secured the F.R.C.S. Irel. In 1898 he was appointed assistant surgeon to the Meath Hospital, where he had formerly been interne, and two years later full surgeon to the institution. He was consulting surgeon to this hospital at the time of his death, so that he had given it life-long service. He soon established a well-earned reputation as an operating and consulting surgeon, and some of his experiences formed the subject of valuable communications to the *Transactions* of the Royal Academy of Medicine in Ireland and to the *British Medical Journal.* Elected to the Council of the Royal College of Surgeons in Ireland in 1914, he became vice-president, and two years later president, his term of office coinciding with the middle period of the war. On the outbreak of the war he was appointed, with the rank of colonel A.M.S., consulting surgeon to the Forces in Ireland, a position which he held for six years. He was one of the surgeons to the Dublin Castle Red Cross Hospital, and in 1917, at the request of the War Office, he organised a hospital in France, selecting the staff from men too old for ordinary service. The staff consisted almost entirely of members of the visiting staffs of the Dublin hospitals, every hospital being represented, and the " 83 (Dublin) General Hospital " at Boulogne did admirable work at the closing period of the war. Taylor himself spent three months at the hospital, and his energy and skill were recognised with the C.B. in 1917 and the K.B.E. in the following year. Since that time his deep concern for the condition of ex-Service men has been expressed in many directions, and he was a notable figure among the group of Irishmen who went to Belgium and France to unveil memorials to their dead countrymen.

SIR WILLIAM TAYLOR

[*Photograph by Elliott and Fry*

In 1923 Sir William Taylor became surgeon to Sir Patrick Dun's Hospital, in succession to Prof. Edward Henry Taylor, whom he also succeeded in the Regius professorship, the chair which he was occupying at the time of his death. He recently visited Canada and the United States and was received there warmly, the University of McGill making him an honorary LL.D., and the American College of Surgeons an honorary fellow. He was president of the Association of Surgeons of Great Britain and Ireland in 1924-25, and was elected president of the Royal Academy of Medicine in Ireland in 1927. In addition to his posts at the Meath Hospital and Sir Patrick Dun's Hospital, he was consulting surgeon to the Coombe Lying-in Hospital, the Steevens Hospital, and the Dental Hospital of Ireland. He was a D.L. for the county of Dublin, and held high rank in the Masonic Order. Few men can have combined so many important posts or acquitted themselves in their multifarious obligations with greater ability.

Sir William Taylor married, in 1898, Katharine, daughter of the late Dr. Hamilton Walker, and is survived by one daughter and three sons.

Our Dublin correspondent writes: " William Taylor was not only a leading surgeon in Dublin, but he was one of the outstanding personalities in the profession. Clear-headed, forcible, direct, he had made his way by his natural gifts of intelligence and character. As a surgeon he was careful in his diagnosis and confident in his judgment; in operation cool, quick, resourceful. Such a thing as 'nerves' was unknown to him. It was characteristic of him that he chose to perform major operations on his own family rather than refer them to other surgeons. As a teacher he was clear, precise, and entertaining. In public professional affairs he took a leading part, and his qualities of common-sense, quickness of understanding, and directness were of great value in shortening many a discussion and in expediting business. He had strong likes and dislikes, and he took no trouble to conceal either."

WILLIAM BLACK JONES, M.D. Lond.

William Black Jones, whose death is announced in Cardiff on Jan. 27th, at the age of 68, was well known in connexion with medical hydrology. He received his medical education at St. Bartholomew's Hospital, and qualified with the English double diploma in 1892. He graduated in the same year as M.B., B.S. in the University of London with honours in obstetrics and surgery, and acted as house surgeon and assistant in the throat department at St. Bartholomew's. He proceeded to the M.D. degree in 1894, and shortly afterwards began a long connexion with the Spa at Llangammarch. The waters of this spa contain barium to a somewhat unusual extent, and the fact was brought to the attention of the medical profession by Lauder Brunton, who suggested that the therapeutical properties of barium might be employed with advantage in certain cardiac disorders. Accordingly a considerable study of the matter was made at Llangammarch by various experts, but the spa, however, now relies for its reputation on the value of its mild saline waters in digestive catarrhs. While at Llangammarch Black Jones made some interesting meteorologic studies; one upon the measurement of sunshine at our health resorts attracted considerable attention, bringing home to the medical profession in England that they were behind their continental brethren in demonstrating the amenities of their own health resorts.

Dr. Black Jones had retired from practice when he died. In addition to his post at Llangammarch, he was at one time M.O.H. for the combined Builth Wells and Colwyn urban and rural districts, and J.P. for Brecon. He was consequently a well-known man, and his death is widely regretted.

CHRISTOPHER MARTIN, M.B. Edin., F.R.C.S. Eng.

WE regret to announce the death of Mr. Christopher Martin, the well-known gynæcologist, which occurred at his residence at Edgbaston, Birmingham, on Jan. 28th, after a long period of indifferent health.

Christopher Martin was born at Stockton-on-Tees in 1866 and educated at the Middlesbrough High School, whence he proceeded to the University of Edinburgh. Here he graduated M.B., C.M. in 1887, with first-class honours. He became resident surgeon at the Royal Maternity Hospital, and was for a time demonstrator of anatomy at the Edinburgh School of Medicine. He continued his studies at St. Bartholomew's Hospital and took the F.R.C.S. Eng. in 1891, having already formed his valuable professional connexion with that forceful curious character, Lawson Tait.

MR. CHRISTOPHER MARTIN

[*Photograph by Beaufort*

Christopher Martin had been introduced to Lawson Tait by Sir A. R. Simpson, whose house surgeon he had been in Edinburgh. Tait, some 20 years previously, with the vigorous coöperation of Mr. Arthur Chamberlain, and in the face of opposition from the Birmingham General and Queen's Hospitals, had founded in Birmingham a special hospital for women. To this hospital, now the Midland and Birmingham Hospital for Women, Martin was appointed assistant surgeon, and shortly afterwards entered into partnership with Tait, of whose professional and social life he later wrote an interesting record which was recently reviewed in our columns (THE LANCET, 1932, i., 1264). Tait's was a meteoric career, and his surgical prowess, which brought him so swiftly to the top, failed to sustain him there. Shortly after Martin joined him Tait resigned his many important appointments and retired into private life. But by this time Martin had secured by his own good work a high place in his special department of medicine. He was appointed assistant to the professor of gynæcology in Queen's College, Birmingham, and gynæcologist to the Birmingham General Dispensary, and the experiences of his large practice, institutional and private, were put out in practical papers on abdominal surgery and gynæcology, some of which were published in our columns, notably one on the treatment of myomata. He was one of the first in England to perform a total hysterectomy, and was successful also in extensive plastic operations for advanced cases of carcinoma involving the whole vagina. In 1902 he delivered the Ingleby lectures at the University of Birmingham upon the retention of the menses, and shortly afterwards became president of the Midland Obstetric and Gynæcological Society. Increasing calls upon him made no difference to his abiding interest in the Hospital for Women, with the progress of which he had been bound up since his first appointment to the institution more than 40 years ago, and it is in this connexion in particular that he has established a claim to permanent recollection in the city. He was one of the first fellows of the British College of Obstetricians and Gynæcologists.

Christopher Martin was married in 1920 to Miss Mary Clarke, M.B., Ch.B. Birm., who had been anæsthetist to the Hospital for Women, and held other medical appointments in Birmingham hospitals. He is survived by his widow.

Mr. Frederick Edge, a personal friend of 40 years' standing, writes: "On Christopher Martin's arrival at Birmingham with his mother I became acquainted with her to whom he always admitted how much he owed. He lived with her when he was a student in Edinburgh, while she possessed a wide knowledge of medical affairs, acquired as matron of the Middlesbrough Hospital, a post which she obtained when she was left a widow. The devotion of mother and son was striking. . . . On the many journeys which I made abroad, to France and Belgium, with Martin and other medical friends, he was a great guide, always producing excellent maps and notes on all points of historic interest, so that we came back carrying bags bursting with articles collected by the way. Martin could never do enough to please and entertain the party, and he always brought the tools necessary to remove the appendix of anyone who should require his assistance. The suffering of the incurable always aroused Martin's particular pity, and he was associated with the late Prof. Taylor in instituting the Taylor Memorial Home for Incurables, of which institution he was chairman until the end of his life. He always thoroughly enjoyed the renewal of old friendships, and with Dr. Douglas Stanley originated in Birmingham an Edinburgh Graduates' Dinner. He was chairman of the Gertrude Myer Home for Convalescents, and he enjoyed the organisation of picnic excursions for nurses and students. His was a truly generous nature."

INFECTIOUS DISEASE

IN ENGLAND AND WALES DURING THE WEEK ENDED JAN. 21ST, 1933

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 16 (last week 18); scarlet fever, 1950 (last week 1739); diphtheria, 821; enteric fever, 12; acute pneumonia (primary or influenzal), 3781 (last three weeks 2017, 2816, and 3456); puerperal fever, 27; puerperal pyrexia, 139; cerebro-spinal fever, 61 (last two weeks 38 and 47); acute poliomyelitis, 2; acute polio-encephalitis, 1; encephalitis lethargica, 10; dysentery, 6; and ophthalmia neonatorum, 75. No case of cholera, plague, or typhus fever was notified during the week.

The number of cases in the Infectious Hospitals of the London County Council on Jan. 24th–25th was as follows:—Small-pox, 40 under treatment, 4 under observation (last week 48 and 3 respectively); scarlet fever, 1676; diphtheria, 1612; enteric fever, 9; measles, 270; whooping-

Dr. John Harry Hebb, C.B.E., has been appointed Director-General of Medical Services in the Ministry of Pensions, in succession to Sir Lisle Webb. Dr. Herbert Lightstone, D.S.O., will succeed Dr. Hebb as Deputy Director-General.

Society of Chemical Industry

At a meeting of this society to be held at 8 P.M. on Monday, Feb. 6th, in the Chemical Society's Rooms, Burlington House, London, W., Dr. E. C. Dodds, Courtauld professor of biochemistry in the University of London, will read a paper on Hormones.

St. George's Hospital

The medical school committee will hold a post-graduate course for old St. George's men from noon on Friday, Sept. 29th, to noon on Monday, Oct. 2nd, 1933, and a small committee has undertaken the arrangements. No details have been worked out yet, but the course will consist of lectures and demonstrations, chosen to meet the needs of general practitioners. The course will be followed on Monday, Oct. 2nd, by the general meeting of the school for the annual prize-giving and dinner, and a week-end ticket will cover the programme.

Ideas and suggestions from old St. George's men should *be sent to Dr. Anthony Feiling, dean of the medical school.*

Research Fund for Mental Disorders

Through the medium of the council of the British Medical Association, Mrs. R. G. Burden, of Clevedon Hall, Clevedon, Somerset, warden of the National Institutions for Persons Requiring Care and Control, has announced her desire of making available for the encouragement and prosecution of research into mental problems and disorders the sum of £10,000. It is the donor's desire that the present director of medical services at Stoke Park Colony, Stapleton, Bristol (*Prof. R. J. A. Berry*), *shall be in a position of responsibility* with regard to the research work to be undertaken. In view of the national importance of such research active steps are being taken to form a committee of management and direction fully representative of the public interests.

Fellowship of Medicine and Post-Graduate Medical Association

The fourth lecture in the series on practical problems in medicine and surgery will take place at 11, Chandos-street, Cavendish-square, London, W., at 4 P.M. on Tuesday, Feb. 7th, when Mr. Martin *Oldershaw will lecture on the* Significance of Bleeding as a Symptom in Gynæcology. A course of eight demonstrations on the Interpretations of Pyelograms is being given by Dr. G. R. Mather Cordiner, beginning on Wednesday, Feb. 8th, at 8 P.M. There will be a week-end course in physical medicine at the London Clinic and Institute of Physical Medicine on Saturday, Feb. 11th, and Sunday, Feb. 12th, when all-day instruction will be given. Forthcoming courses include an evening course at the National Temperance Hospital, Feb. 20th to March 17th; a course in medicine, surgery, and the specialties at the Prince of Wales's Hospital, Feb. 20th to March 4th; and in practical pathology at the Brompton Hospital, Feb. 20th to March 4th. All courses, lectures, and demonstrations arranged by the Fellowship are open only to members and associates. Further particulars may be had from the Secretary of the Fellowship at 1, Wimpole-street, London, W. 1.

Grants for Research

The trustees of the Ella Sachs Plotz Foundation are anxious to make known the resources of their fund for the advancement of scientific investigation. The Foundation seldom or never offers stipends to investigators, nor does it provide apparatus and materials which are ordinarily part of laboratory equipment. Its special purpose is to give grants for the purchase of apparatus and supplies needed for special investigations and for the payment of unusual expenses incidental thereto, including technical assistance. At present research is favoured which bears on medicine or surgery, and the trustees endeavour to assist workers in various countries who are trying to solve identical or related problems. Thus a considerable number of grants have been made in the last few years for studies on nephritis, while internal secretion and infection have also [illegible] not to so great a degree. In the [illegible] nce the Foundation has made 179 [illegible] have been aided in 23 countries. The [illegible] ranged from 100 to 500 dollars each. Applications for assistance during the coming year should arrive before May 1st, including statements about the nature of the research, the amount of money wanted, and the objects on which it will be spent. The secretary of the executive is Dr. Joseph C. Aub, Corliss P. Huntington Memorial Hospital, Boston, Mass., U.S.A.

The New Freemasons' Hospital

The report for 1932 presented to the annual meeting last week stated that although the dedication-stone of the new building at Hammersmith was laid only in May last by the Duke of Connaught, and a new wing has since been decided upon, the whole of the structure has been completed, along with the lighting and warming, and the interior work is well on the way to completion. The scheme has twice been enlarged, first from 120 to 144, and now to 180 beds. During the past year 687 patients passed through the present hospital in the Fulham-road, 329 of whom were a charge on the Samaritan Fund, against the previous highest figure of 270. Of this number 13 were cases from overseas, one being sent by aeroplane from Khartoum for an urgent operation. Although there have been many extras in connexion with the new building, the contract figure of £313,000 has not been exceeded. The new building will, it is expected, be open for the reception of patients in September or October.

Medical Diary

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

SOCIETIES

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

TUESDAY, Feb. 7th.—5.30 P.M., ORTHOPÆDICS. (Cases at 4.30 P.M.) Demonstration. Mr. E. I. Lloyd: Tilting Table for a Hip Operation in Children. Cases. Mr. G. R. Girdlestone: 1 and 2. Unusual Abnormalities of the Body of the Vertebræ. Mr. J. M. Turner: 3. Dyschondroplasia. 4. Hæmophilia with Tuberculous Abscess in Abdominal Wall and Arthritis of Hip. 5. Hæmangiectatic Hypertrophy of the Calf. Mr. C. Lambrinudi: 6. Pes Calcaneus. Mr. Philip Glynn: 7. Fractured Neck of the Femur treated with Smith-Petersen Pins. Mr. A. Rocyn Jones: 8. Madelung's Deformity. Other cases will be shown. 8 P.M., PATHOLOGY. Laboratory Meeting at the Lister Institute of Preventive Medicine, Chelsea Bridge-road, S.W.

FRIDAY.—5.30 P.M., CLINICAL. (Cases at 4.30 P.M.) Cases. Mr. H. A. T. Fairbank: 1. Congenital Enlargement of One Arm. Mr. J. P. [illegible] Epithelioma of Anus [illegible] H. H. Woollard: 4. My[illegible] X Rays. Mr. Harol[illegible] Pouch. Dr. H. S. St.[illegible] Dr. Francis Bach: 7 [illegible] successfully treated. Dr [illegible] Enlargement of Parotid Glands of 16 years' duration, with Xerostomia. 10. Chronic Enlargement of Parotid Glands with Intermittent Exacerbations. 11. Chronic Œdema of Legs, with large Turgid Hands. 12. Dystonia Musculorum, probably of Encephalitic Origin. Dr. H. V. Morlock: 13. Chronic Spontaneous Pneumothorax treated by Intrapleural Injection of Silver Nitrate. 14. Repeated Hæmoptysis caused by *a Benign Bronchial Neoplasm.* Dr. G. Gregory Kayne: 15. Retrosternal Goitre and Amyotrophic Lateral Sclerosis. Other cases will be shown. 8.30 P.M., [illegible] apers. Miss Ida Mann: On [illegible] Membranes on the Posterior [illegible] Mr. J. Cole Marshall: Safar's [illegible] of Detachment of the Retina with Diathermy. Mr. N. Bishop Harman: A New Hand Slit-lamp. Mr. J. Foster: Method of Transferring Scotomata and Fields from a Scotometer Chart to a Perimeter Chart.

SOUTH-WEST LONDON MEDICAL SOCIETY.

WEDNESDAY, Feb. 8th.—9 P.M. (at the Bolingbroke Hospital, Wandsworth Common), Dr. A. Moncrieff: Coughs in Childhood.

WEST KENT MEDICO-CHIRURGICAL SOCIETY.

FRIDAY, Feb. 10th (at the Miller Hospital), Mr. P. H. Mitchiner: Should One Wait and See in Acute Appendicitis?

MEDICAL SOCIETY OF INDIVIDUAL PSYCHOLOGY, 11, Chandos-street, Cavendish-square, W.

THURSDAY, Feb. 9th.—8.30 P.M., Dr. W. J. O'Donovan: Pathomimia Cutanea.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, Lincoln's Inn-fields, W.C.

MONDAY, Feb. 6th.—5 P.M., Mr. H. P. Winsbury-White: Paths of Infection between the Genital Organs and the Urinary Tract. (Hunterian lecture.)

WEDNESDAY.—5 P.M., Mr. Stanford Cade: Radiation Treatment of Cancer of the Mouth and Pharynx. (Hunterian lecture.)

FRIDAY.—5 P.M., Mr. H. J. Burrows: Tissue Culture in its Relationship to Surgical Pathology. (Hunterian lecture.)

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, London, W.

MONDAY, Feb. 6th, to SATURDAY, Feb. 11th.—ST. JOHN'S HOSPITAL FOR DISEASES OF THE SKIN, Leicester-square, W.C. Post-graduate Course in Dermatology. Afternoon instruction in the Out-patient Department daily; lectures at 5 P.M. on Tues. and Thurs.—ROYAL FREE HOSPITAL, Gray's Inn-road, W.C. Demonstration on Antenatal Diagnosis and Treatment, by Dame A. Louise McIlroy, 5 P.M. Frid.—CHELSEA HOSPITAL FOR WOMEN, Arthur-street, S.W. A Course in Gynæcology. Mornings and/or afternoons daily.—HOSPITAL FOR CONSUMPTION, Brompton, S.W. A Course in Diseases of the Chest. All day instruction given.—LONDON CLINIC AND INSTITUTE OF PHYSICAL MEDICINE, [illegible] Course in Physical [illegible] Feb. 12th. All day [illegible] NDON, 11, Chandos-street, Cavendish-square, W. Lecture on the Significance of Bleeding as a Symptom in Gynæcology, by Mr. Martin Oldershaw, on Tues., at 4 P.M. (Free to Members and Associates of the Fellowship.)—FELLOWSHIP OF MEDICINE, 1, Wimpole-street, W. A Series of Demonstrations on the Interpretation of Pyelograms will be given by Dr. G. R. Mather Cordiner Wed. at 8 P.M., and Sat. at 3 P.M.

ROYAL NORTHERN HOSPITAL, Holloway-road, N. (Intensive Week.)

MONDAY, Feb. 6th.—2.15 P.M., Mr. F. D. Saner: Some Aspects of the Treatment of Acute Suppuration. 3.15 P.M., Mr. Frederick Roques: Anæsthetics in Obstetric Practice.

TUESDAY.—2.15 P.M., Mr. McNeill Love: Some Common Diseases of Joints. 3.15 P.M., Dr. Bruce Williamson: Demonstration of Cases (unselected).

WEDNESDAY.—2.15 P.M., Dr. Bernard Schlesinger: Chorea. 3.15 P.M., Dr. Henry C. Semon: The Drug Rashes.

THURSDAY.—2.15 P.M., Dr. A. Lisle Punch: The Value of Lipiodol in Diagnosis. 3.15 P.M., Mr. E. Wolff: Common External Diseases of the Eye.

FRIDAY.—2.15 P.M., Dr. G. R. Mather Cordiner: Radiological Dyspepsias. 3.15 P.M., Mr. E. I. Lloyd: The Semilunar Cartilages of the Knee.

MIDDLESEX HOSPITAL MEDICAL SCHOOL, Mortimer-street, W.

TUESDAY, Feb. 7th, and the following THURSDAYS and TUESDAYS at 5 P.M., Prof. Samson Wright: Physiology of the Nervous Systems (six lectures).

ST. MARK'S HOSPITAL, City-road, E.C.

THURSDAY, Feb. 9th.—4 P.M., Mr. C. N. Morgan: Surgical Anatomy of the Anal Canal and Rectum.

CENTRAL LONDON THROAT, NOSE, AND EAR HOSPITAL, Gray's Inn-road, W.C.

FRIDAY, Feb. 10th.—4 P.M., Mr. W. G. Scott Brown: Œsophageal Obstruction.

ST. PETER'S HOSPITAL FOR STONE, Henrietta-street, W.C.

WEDNESDAY, Feb. 8th.—3 P.M., Mr. F. J. F. Barrington: Treatment of Senile Enlargement of the Prostate.

LONDON SCHOOL OF DERMATOLOGY, St. John's Hospital, 49, Leicester-square, W.C.

TUESDAY, Feb. 7th.—5 P.M., Dr. H. C. G. Semon: Diseases of the Buccal Mucous Membrane.

THURSDAY.—5 P.M., Dr. H. Haldin-Davis: Pruritus. Prurigo. Lichenification.

ST. MARY'S HOSPITALS, Manchester.

FRIDAY, Feb. 10th.—4.15 P.M., Post-graduate Lecture (at the Whitworth-street West Hospital), Dr. Lacey and Dr. Addis: Antenatal Demonstrations.

LONDON JEWISH HOSPITAL, Stepney Green, E.

THURSDAY, Feb. 16th.—4 P.M., Mr. S. I. Levy: Lecture-Demonstration. Enlarged Prostate and its Treatment.

KING'S COLLEGE HOSPITAL MEDICAL SCHOOL, Denmark-hill, S.E.

THURSDAY, Feb. 9th.—9 P.M., Dr. Graham Hodgson: The Radiology of the Accessory Nasal Sinuses.

ROYAL INSTITUTE OF PUBLIC HEALTH, Queen-square, W.C.

WEDNESDAY, Feb. 8th.—4.30 P.M., Dr. W. S. C. Copeman: A Scheme for Industrial Rheumatism.

SOUTH-WEST LONDON POST-GRADUATE ASSOCIATION.

WEDNESDAY, Feb. 8th.—4 P.M., Mr. Terence Millin: Endoscopic Diathermy as applied to the Obstructing Prostate.

GLASGOW POST-GRADUATE LECTURES.

TUESDAY, Feb. 7th.—3.30 P.M. (in the Faculty Hall, St. Vincent-street), Mr. A. MacLennan: Post-Hospital Treatment of Deforming Lesions.

WEDNESDAY.—4.15 P.M. (at the Royal Samaritan Hospital for Women), Dr. D. McIntyre: Gynæcological Cases.

Appointments

LEWIS, IVOR, M.D., M.S. Lond., has been appointed Medical Superintendent of the North Middlesex Hospital.

RYCROFT, B. W., M.D., Ch.B. St. And., D.O.M.S., Ophthalmic Surgeon (Second) to the Royal Northern Hospital.

Vacancies

For further information refer to the advertisement columns

Archway Hospital, Archway-road, Highgate, N.—Asst. M.O. £250.

Ayr County Hospital.—H.S. £150.

Bath, Royal United Hospital.—Two Surgeon Dentists.

Birkenhead General Hospital.—Hon. Orthopædic Surgeon. Res. Sen. H.S. At rate of £150. Also Second H.S., H.P., and Cas. O. Each at rate of £100.

Birmingham, Canwell Hall Babies' Hospital.—Res. M.O. At rate of £250.

Birmingham, Selly Oak Hospital.—Cas. O. At rate of £200.

Bolingbroke Hospital, Wandsworth Common, S.W.—Asst. Gynæcologist.

Bootle General Hospital.—H.P., Two H.S.'s, and Cas. O. All at rate of £150.

Bradford Children's Hospital.—H.S. £100.

Bristol General Hospital.—Hon. Asst. Phys.

Cardiff City Mental Hospital, Whitchurch.—Sen. Asst. M.O. £570.

Colchester, Essex County Hospital.—H.P. £150.

Coventry, Coventry and Warwickshire Hospital.—H.S. to Aural and Ophthalmic Depts. At rate of £125.

Croydon County Borough.—Asst. M.O.H. for Obstetrics. £750.

Derby County Mental Hospital, Mickleover.—Deputy Med. Supt. £600.

East Ham Memorial Hospital, Shrewsbury-road, E.—Hon. Surg. to Ear, Nose and Throat Dept. Also Res. M.O. At rate of £200.

East Sussex Public Assistance Committee.—District M.O. &c. for Hove, &c. £60. Also District M.O. for Aldrington, &c. £85.

Edinburgh, General Board of Control for Scotland.—Medical Deputy Commissioner. £726.

Fulham Hospital, St. Dunstan's-road, Hammersmith.—Asst. M.O. £250.

Gloucester County and City Mental Hospitals.—Jun. Asst. M.O. £350.

Gravesend and North Kent Hospital.—Jun. H.S. £100–£150.

Grosvenor Hospital for Women, Vincent-square, S.W.—Chief Asst.

Hackney Hospital, High-street, Homerton, E.—Res. Asst. M.O. £350.

Hampstead General and North-West London Hospital, Haverstock-hill, N.W.—Cas. M.O. for Out-patient Dept. At rate of £100.

Hastings, Royal East Sussex Hospital.—Sen. and Jun. H.S.'s. At rate of £200 and £150 respectively.

Highgate Hospital, Dartmouth Park Hill, N.—Asst. M.O. £250.

Hospital for Sick Children, Gt. Ormond-street, W.C.—H.P. and H.S. Each at rate of £100.

Hull Royal Infirmary.—Third H.S. At rate of £150.

Ilford, [illegible] of £100.

India, [illegible]

Leeds G[illegible] At rate of £100. Also Hon. Ophth. Surgeon.

Leicester Royal Infirmary.—Hon. Asst. Radiologist.

London Hospital, E.—Med. First Asst. and Reg. £300.

London Jewish Hospital, Stepney Green, E.—H.S. At rate of £100.

London Lock Hospital, 91, Dean-street, W.—Surg. Reg. £100.

Manchester, Ancoats Hospital.—Hon. Asst. Phys.

Miller General Hospital, Greenwich-road, S.E.—Hon. Asst. Physician.

Ministry of Health, Whitehall, S.W.—Vacancy. £833.

New End Hospit[illegible] Asst. M.O. £250.

Northwood, Mou[illegible] S. At rate of £150.

Norwood Childre[illegible] M.O. £250.

Nottingham Gene[illegible] rate of £150.

Paddington Gree[illegible]—Hon. Surgeon to Ear, Nose a[illegible]

Portsmouth, St. [illegible] hird Asst. Res. M.O. £250.

Royal Northern Hospital, Holloway, N.—Obstetric H.S. At rate of £70.

Royal Surgical Aid Society, Salisbury-square, E.C.—Hon. Ophth. Surg. 50 guineas.

St. Alfege's Hospital, Vanbrugh-hill, S.E.—Res. Asst. M.O. £350.

St. Benedict's Hospital, Church-lane, Tooting, S.W.—Asst. M.O. £250.

St. George-in-the-East Hospital, Raine-street, Wapping, E.—Asst. M.O. £250.

St. Giles' Hospital, Brunswick-square Camberwell, S.E.—Res. Asst. M.O. £350.

St. Luke's Hospital, Sydney-street, S.W.—Asst. M.O. £250.

St. Mary Abbot[illegible]*d, Kensington, W.*—Temp. Asst. [illegible]

St. Mary Islingto[illegible]*, N.*—Res. Asst. M.O. £350.

St. Mary's Hospital for Women and Children, Plaistow, E.—Hon. Ophthalmic Surgeon.

Stoke-on-Trent, North Staffordshire Royal Infirmary.—Asst. H.P. £125.

Sunderland, Royal Infirmary.—Sen. H.S. £200.

Swansea County Borough.—Asst. M.O. £500.

Victoria Hospital for Children, Chelsea, S.W.—Temporary Phys. to Out-patients.

West London Hospital, Hammersmith-road, W.—Asst. Phys. for Diseases of Children.

West Riding of Yorkshire C.C.—School Medical Inspector. £500.

Westmorland County Hospital, Kendal.—H.S. At rate of £200.

The Chief Inspector of Factories announces vacancies for Certifying Factory Surgeons at Leeds (West), East Farsley, and at Tuxford (Nottingham).

NOTES, COMMENTS, AND ABSTRACTS

IONIZED IODINE

(THE MOLSON IONIZED IODINE COMPANY, 34B, GABRIEL'S-HILL, MAIDSTONE)

AN investigation of the properties of the preparation ionized iodine (Molson brand) has been undertaken by THE LANCET and the results are as follows:—

The composition of this solution as given on the label sent out on the bottles is—

	Parts.		Parts.
Iodine	7·91	Ammonium	1·02
Chlorine	10·04	Hydrogen	0·05
Potassium	2·89	Salicylic acid	2·00
Sodium	1·16	Chlorophenols	2·00
Magnesium	0·76	Total	27·83

One part of this mixture is dissolved in 115 parts of 10 per cent. glycerol.

Quantitative analysis on the same basis gives the following results, a table calculated in percentages from the above figures being added for purposes of comparison.

	Found. (Parts per cent.)	Calculated. (Parts per cent.)
Iodine	0·2429	0·2440
Chlorine	0·3117	0·3240
Potassium	0·0920	0·0910
Sodium	0·0366	0·0362
Magnesium	0·0230	0·0237
Hydrogen	0·0016	0·0015
Ammonium	0·0315	0·0318
Salicylic acid	0·0628	0·0624
Chlorophenols	0·0621	0·0624
Total	0·8642	0·8770

The solution is clear to the naked eye, microscopically, and under conditions of dark-ground illumination. Some of the constituents are in a colloidal form, and can be separated by the addition of alkali and subsequent acidification. Attempts to redissolve the precipitate thus formed, and at the same time maintain a neutral or faintly acid reaction, were not successful. The constituents which separate in this way are salicylic acid and chlorophenols; no attempt to separate and characterise the various chlorophenols present was attempted.

The preparation is isotonic, and the lowering of freezing point (Δ) is −0·52° C.

Ionized iodine is faintly acid in reaction, having a pH value of 2·5 and a titratable acidity equivalent to 12·35 c.cm. of N/10 caustic soda per cent.; 4·45 c.cm. of this is accounted for by the salicylic acid present, the remainder probably being in the form of mixed hydrochloric, hydriodic, hypochlorous, and hypoiodous acids. Calculated as hydrochloric acid, this figure would be equivalent to a concentration of hydrochloric acid of 0·0209 per cent., or approximately 0·06 per cent. of the ordinary concentrated solution.

Iodine is present to the extent of 0·0617 per cent. in a free state, whilst the total content is 0·2429 per cent. The difference between free and combined iodine (0·1812 per cent.) is in an inorganic state, there being none of this element in organic combination. The mode of combination is complicated, as chloro-iodine compounds, hydriodic acid, hypoiodous acid, iodic acid, and iodides can all be detected in the solution.

Chlorine is present in combination (1) with iodine, (2) as inorganic chlorides, (3) as hydrochloric acid, (4) in traces as hypochlorous acid and possibly as chloric acid or its salts, and (5) as cyclic organic compounds in the form of chlorophenols. The amount available as a free combining agent can be deduced from its action on unsaturated organic compounds and from the oxidising properties of the solution. Estimated in this way, the combining power was found to be equivalent to approximately 0·02 per cent. of free chlorine.

The preparation has a powerful oxidising action on both inorganic salts (such as ferrous salts) and on organic compounds, many dyestuffs for example being bleached. This action is due partly but not wholly to the free iodine present, as when this element is rendered inactive by the addition of sodium thiosulphate oxidising properties still remain. The total amount of oxygen available which can be accounted for by the free iodine is 0·0038 per cent., whilst experimentally there is available 0·0110 per cent. This difference is due to the various iodo- and chloro- acids mentioned above. On account of this powerful oxidising action the solution is corrosive when in contact with metals for any length of time, and after long periods it will destroy organic material such as cork, silk, and wool; for this latter action to occur, however, contact with the preparation must be for some weeks.

ACTION ON PROTEIN

The solution does not precipitate blood albumin, globulin, or fibrinogen. Serous effusions, provided that they do not contain any mucus, are similarly not affected. Mucus is precipitated by the solution in its natural state, but not if it is previously rendered alkaline, the precipitating agent being the acid and not any of the other constituents. The free iodine present is slowly taken up by protein solutions (so that the mixture gradually loses most of its colour) to form additive compounds as the element cannot be recovered subsequently in an inorganic state. In the presence of weak alkali the iodine is very rapidly absorbed, and cannot be liberated again on subsequent acidification. If the preparation is left in contact with a protein such as gelatin, and is then poured off after the visible iodine is absorbed, it still possesses iodising and oxidising properties, so that when it is again placed in contact with gelatin, iodine (and chlorine) pass into the protein and combine with it as before until the whole of the available supply is used up. In a similar manner, if a slab of gelatin is placed in contact with the solution it will be stained with iodine to a depth proportional to the length of time of contact; for a considerable depth below the visible stain, however, both iodine and chlorine, as additive organic compounds, can be detected showing that iodo-chloro compounds of considerable penetrative power are present. These iodo-chloro compounds, which penetrate deeply in this manner, combine with the protein and are not recoverable wholly in the inorganic form in which they were originally present.

ACTION ON RED BLOOD CORPUSCLES AND HÆMOGLOBIN

The effect on hæmoglobin solutions is to form a mixture of acid hæmatin and methæmoglobin. This change occurs when the concentration of the antiseptic in the solution exceeds 1·8 per cent., and takes place almost instantaneously when a concentration of 4 per cent. is reached. When whole blood (oxalated) is used this action is not observed until at least an equal volume of antiseptic is added and no decomposition of hæmoglobin takes place. This is due presumably to the fact that whole blood is sufficiently well buffered to overcome the free acid present in the antiseptic, whilst the protein combines with the free and combined iodine and chlorine and prevents their oxidative action on the pigment.

No hæmolysis of red blood corpuscles occurs even after 24 hours when washed cells are suspended in the undiluted antiseptic, but naturally takes place with solutions diluted with water, but not when normal saline is used. No alterations in the volume of the cells takes place under the same conditions, as determined by hæmatocrite measurements. When washed cells are used for these determinations an almost immediate conversion of their contained hæmoglobin as described above takes place, but this is not observed when whole (oxalated) blood is used.

ACTION ON LEUCOCYTES

The shape and staining reactions, both of cytoplasm and nucleus of all types of white blood corpuscles, are not altered by contact with the antiseptic. This applies to blood films made and stained in the ordinary way with Leishman stain after treatment of the dried film for five minutes with the undiluted antiseptic, and also to films made from oxalated blood and blood taken directly into the solution and subsequently stained. Effects upon the opsonic index were not determined.

BLOOD COAGULATION

Blood coagulation is not delayed, and the clot formed in the presence of the antiseptic possesses normal firmness and is normally retractile. This property was tested on oxalated blood with subsequent addition of an amount of calcium chloride sufficient to restore a normal ionic calcium content to the mixture. When mixed with an equal quantity of antiseptic clotting is delayed, but not more than in a control preparation in which normal saline replaced the antiseptic, the delay in both cases being due to dilution only. When only small quantities of antiseptic are used—e.g., up to one-tenth of the volume of the blood—no delay was observed. Similar tests on scarified areas of skin showed that the blood oozing through on to dressings moistened with ionized iodine clotted in a normal manner, and also that dressings applied in this way did not adhere to the wounds.

DIFFUSION EXPERIMENTS

Diffusion across collodion membranes takes place readily, all the constituents passing through. When dialysed against water, inorganic chlorides and iodides can be detected on the other side of the membrane in from two to five minutes, depending upon the thickness of the membrane and its method of preparation—i.e., on its degree of porosity. Free iodine appears shortly afterwards, then chloro-compounds (inorganic), and, finally, the salicylic acid and chlorophenols; some retention within the membrane itself appears to take place with the latter compounds.

Diffusion across solid slabs of gelatin has been described above, where free iodine was shown to be retained whilst the other constituents diffused more readily. Similar experiments using omentum as a semipermeable, natural membrane showed that the free iodine was retained almost completely within the membrane, whilst the other constituents diffused through readily, the dialysate possessing antiseptic and oxidising properties, although these were considerably less than is the case with the undiluted product.

Rapid diffusion occurs in agar-agar plates: if a cotton-wool pad well soaked in the antiseptic and contained in the end of a short open glass tube is placed in the centre of a freshly inoculated Petri dish, diffusion towards the edge of the dish is sufficiently rapid to prevent the growth of organisms excepting perhaps at the extreme periphery. The rate of diffusion and the dilution taking place depend amongst other factors on the thickness of the agar plate, the percentage amount of agar present, and the amount of antiseptic used. The inhibiting action is not so marked when serum-agar is used, due probably to the fact that unsaturated compounds are present which remove the active iodine and chlorine by forming additive bodies.

ANTISEPTIC POWER

Tested on *B. typhosus*, *Staphylococcus aureus*, and hæmolytic streptococci it was found that cultures of these organisms could be killed in 2½ minutes by the antiseptic diluted with an equal amount of water. About half of this antiseptic power is due to the free iodine present, as when this element is eliminated by the addition of sodium thiosulphate the above organisms required treatment with the undiluted antiseptic for 2½ minutes before their growth was inhibited. The presence of sterilised (boiled) fæces, blood-serum, or ascitic fluid does not materially affect the antiseptic properties of the preparation.

Control experiments with standard phenol solutions showed that the test organisms were killed in a similar period by 2½ per cent. (1 in 40) carbolic acid.

LETHAL ACTION, AND ACTION ON MUCOUS MEMBRANES

Approximately 12 c.cm. per kilo of body-weight were found to be lethal when injected intravenously into rabbits. This action is due largely to the free iodine present; when this is removed by means of thiosulphate the preparation is toxic only in very large doses. When injected subcutaneously and intraperitoneally no toxic effects were observed with doses of 20 c.cm. per kilo of body-weight.

When applied continuously—e.g., for two hours—to mucous membranes, a coagulation of superficial mucus takes place, followed by histological evidence of increased glandular activity on the part of the mucus-secreting glands, and a mild polymorphonuclear leucocyte infiltration. No coagulation of tissues occurs. When applied for a short while only—e.g., for five minutes—no histological changes can be observed apart from the superficial coagulation of mucus. Repeated applications daily for a period of 14 days resulted in a mild submucous polymorphonuclear infiltration.

No changes in ordinary skin could be observed after daily applications for 14 days.

DEODORISING ACTION

The preparation has a very marked deodorising action on such pathological material as fæces, pus, and decomposing urine.

RHEUMATISM AS A PUBLIC BURDEN

THE urgency of rheumatism as an industrial problem is the theme of a course of lectures now in progress at the Royal Institute of Public Health. Presiding at the first meeting, Sir Arthur Stanley said that he was glad to see that this matter was being taken up in academic circles. "Frankly," he said, "I had always thought that the medical profession was rather bored with it. But even the medical profession is moving with the times."

The first lecture was given on Jan. 18th by Dr. Langdon Brown, Regius professor of physic in the University of Cambridge, and the second on Jan. 25th by Dr. Fortescue Fox, chairman of the Ligue Internationale contre le Rheumatisme. The evolution of medicine, Dr. Fox said, seems to show that the problem of the epidemic is on its way to solution, that acute diseases are on the whole becoming less prevalent, and that we are reaching an era of chronic disease. This is a new problem, requiring new ways of approach; the objective is to save health rather than lives.

Reports submitted to the recent international rheumatism congress in Paris showed, said Dr. Fox, that the incidence of rheumatism is maximal in outdoor occupations, especially those with hard labour and exposure to cold. In Sweden, G. Kahlmeter found that the permanent invalidity considerably increased between 1918 and 1928, and now exceeds that from pulmonary tuberculosis. About 30,000 arthritic persons are now disabled in Sweden (6 per cent. of the population) at a charge upon the State more than twice as great as that for tuberculosis. J. van Breemen has analysed the occupations of 3000 patients in Holland (Amsterdam), and states that men in outdoor work have from three to five times more rheumatic abnormality than those occupied indoors. A report from Germany suggests that nearly 75 per cent. of industrial workers over 40 years of age suffer from some form of rheumatism. The report for the rheumatism committee in the Soviet Republics emphasised the great importance of chill, and gave figures showing a great reduction of invalidity in factories where this risk was minimised. An analysis of 19,000 cases treated at the chief spa hospitals in England confirmed the main conclusions of the other reports: "Those most affected are, in men, the strenuous manual workers exposed to damp, and, in women, housewives and home workers."

Dr. Fox believes that many contributory factors are now taking a fixed place in the constellation "Rhuma." There is no disease, he thinks, for which a single cause is more impossible; at the same time it is common to find a dominant cause, and the vicious circle can be broken only at this point, and in favouring circumstances. He attributed much importance to the production of chronic chill by repeated exposure to uncompensated cold. Rheumatoid, the "British arthritis," was often connected with chill; osteo-arthritis, on the other hand, was related to mechanical trauma (injury).

Further lectures in the series are being given by Dr. C. W. Buckley, Dr. W. S. C. Copeman, and Miss Margaret Edminson. Particulars may be had from the institute, 23, Queen-square, London, W.C.1.

INSTRUCTION ON NURSING PROCEDURES

THERE are many procedures on the borderland between medicine and nursing of which the doctor is often content to assume that the nurse has mastered the practical details, and thus issues his orders in general terms. This detached attitude may have its dangers, for not all private nurses have been recently trained. It is wise to be prepared to give precise instructions. An extraordinarily comprehensive little manual,[1] compiled primarily for practising nurses, will meet a need which the doctor may have felt also. Its author, Miss Powell, better known as Sister Hope, of the medical side of St. Bartholomew's Hospital, has provided a concise summary of the requirements of almost every medical emergency, and has included notes on the dietaries appropriate for various conditions. Miss Powell does not advocate any procedure, but mentions the occasion for which it may be ordered, and then tells the nurse exactly how to carry it out. Her style is simple, direct, and vivid, and her little book will be more often consulted by doctors and nurses than are many weighty tomes.

HOSPITAL LIBRARIES

ON Jan. 25th a well-attended meeting, organised by the London and Home Counties Branch of the Library Association, on "Hospital Libraries" was held in the Nurses' Home of the Middlesex Hospital. Miss Frost, librarian to the public library at Worthing, presided. Mrs. R. Beddington, hon. librarian to the Middlesex Hospital, spoke of the system employed in hospital libraries. The Middlesex could claim to be one of the first hospitals to have a patients' library, since one had existed there before the war. As the result of many years' experience she emphasised the need for the right type of librarian and for a simple system of handling books. "In the past," she said, "hospital libraries were suffered to exist; now they are looked upon as part of the curative work of the hospital." Mrs. Richmond said that at Guy's no patients' library had existed before 1931; now there were eight librarians, 4800 books, and four trolleys. The wards were visited three times a week. In the paying wards a charge of 2*d.* a volume was made. Special facilities were given for the nurses to use the library. In most hospitals librarians worked in the afternoons, but at Guy's the routine of the distribution fitted in better with the routine work of the wards if it was done in the mornings. Mr. Bedwell, house governor to King's College Hospital, said that historically hospital libraries could be traced to the time when hospitals were monastic foundations, the monks being concerned with the advancement of learning equally with the care of the sick. In England St. Bartholomew's was the foremost example; the present library of the medical school of that hospital was developed from the library mentioned in the records of 1667. In England he knew of no medical school directly concerned with the provision of books for patients, but in the Royal Victoria Hospital, Montreal, a library was staffed and largely financed by women medical students, and was available for the administrative staff as well as for the patients. Mr. Bedwell laid stress on the importance of libraries for nurses and on the greater possibilities of library service in hospitals. Mr. Bolton described the plan in force at the Watford Peace Memorial Hospital. A small stock of public library books was kept in that hospital and was renewed when necessary. In this way a high standard of books in good condition was maintained; the work was carried out by ex-library assistants.

THE YOUNG AERONAUT

Dr. Killick Millard, the well-known medical officer of the city of Leicester, has taken to flying at the age of 62, with such a rejuvenating effect upon himself that he has publicly recommended doctors to prescribe flying for their patients, as a substitute for sending them abroad. He holds that flying might be an ideal treatment for people in need of a change, while in his view this method of transit has become practically safe if only plain aeronautics are indulged in.

HORMONES AND MENSTRUATION.—In a leading article with this title in our issue of Jan. 21st, reference was made to a report on a synthetic œstrus-exciting compound by Mr. J. W. Cook, D.Sc., Prof. E. C. Dodds, and Mr. C. L. Hewett. This report appeared in *Nature* of Jan. 14th (p. 56), and not Jan. 7th as stated in our article.

Births, Marriages, and Deaths

BIRTHS

HALL.—On Jan. 25th, at Wilbraham-place, S.W., the wife of Dr. J. H. Hall, of a daughter.

HOSFORD.—On Jan. 28, at "Cairnton," Stormont-road, Highgate, the wife of R. W. P. Hosford, F.R.C.S., of a son.

LLOYD.—On Jan. 25th, at Bentinck-street, W., the wife of W. Ernest Lloyd, M.D., of a son.

LYNN.—On Jan. 25th, in London, the wife of Lieut.-Colonel Rigby Lynn, D.S.O., I.M.S., of a son.

SCHNEIDER.—On Jan. 27th, at Southampton, to Dorothy (née Green), wife of John Erhard, M.B., B.S. (Lond.)—a daughter.

MARRIAGES

KERR—NEVIN.—On Jan. 25th, at Carr's Lane, Birmingham, James Arthur Kerr, B.Sc., M.D., D.P.H., of Glasgow, to Catherine Dorothea Nevin, B.A., younger daughter of the late Dr. A. M. Nevin, of Sparkhill, Birmingham.

LAWSON—EVANS.—On Jan. 24th, at St. Paul's, Onslow-square, William Thomson Lawson, M.B., Llangadock, to Phyllis Marguerite, only daughter of the late H. Dawkin Evans, Esq., and of Mrs. Evans, Iscoed, Ferryside.

DEATHS

COWEN.—On Jan. 23rd, in London, Edward James Cowen, M.B., T.C.D., aged 78.

ELPHICK.—On Jan. 27th, at Newton House, Kirkcaldy, Harry Noel Keyes Elphick, M.C., B.A. (Oxon.), M.R.C.S., L.R.C.P. Lond., aged 36 years.

EVANS.—On Jan. 24th, suddenly, at The Cottage, Lansdowne-road, Worthing, Thomas Evans, M.D., late Medical Superintendent, Archway Hospital, Highgate.

FLANEGAN.—On Jan. 22nd, Henry James Flanegan, F.R.C.S., of "The Grange," Wellesley-road, Clacton-on-Sea, and Eyrecourt, Co. Galway.

JONES.—On Jan. 27th, at Penderi, Creigiau, Cardiff, William Black Jones, M.D., J.P., formerly of Builth Wells, aged 68.

MARTIN.—On Jan. 28th, at George-road, Edgbaston, Birmingham, Christopher Martin, M.B., C.M., F.R.C.S.

OWENS.—On Jan. 29th, at Longstratton, Norfolk, Charles Arthur Owen Owens, M.D., V.D., J.P., in his 88th year.

SORAPURE.—On Jan. 29th, in a nursing-home at Bournemouth, Victor Edgar Sorapure, M.B., F.R.C.S. Edin., of 17, Wimpole-street, London.

TAYLOR.—On Jan. 29th, in Dublin, Sir William Taylor, Regius Professor of Surgery in Dublin University, aged 61.

WALL.—On Jan. 28th, Maximilian Christian Wall, M.R.C.S.Eng., of Fore-street, Edmonton, N.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

ADDRESSES AND ORIGINAL ARTICLES

DE MINIMIS *

BY WILFRED TROTTER, M.S. LOND., F.R.C.S. ENG., F.R.S.

SURGEON TO UNIVERSITY COLLEGE HOSPITAL

I

THE familiar saying from which I have taken my title and my text tells us that the law does not concern itself with very small matters—*de minimis non curat lex.* If this aphorism gives an authentic glimpse of the legal mind, it tells us also that that enigmatic organ differs sharply in at least one particular from the mind of science. For it is characteristic of science not to value things by their size or according to their apparent importance in the eye of common sense. The scientific world is a democracy of facts where the inhabitants are of equal standing and there is no table of precedence. Indeed the progress of knowledge has been in great part the discovery of the importance of small things and the exaltation of the insignificant. The great development of the medical sciences in the last sixty years has got most of its strength from such a continued revelation of the minute. At its beginning was the demonstration of the meaning of bacteria in disease, about its middle the discovery of the vitamins, in its recent stages the study of the viruses. All these have been concerned with things or substances of which the effective action has been in spite of sizes or amounts excessively small. The theory of microbic disease displaced supposed causes of what we may call naked-eye size—cold and wet, damps, miasmas, and infected airs. For them it substituted bodies at that time almost inconceivably small—the veritable minims of nature. I use that term "minims of nature" to express the smallest imaginable dose of life, not only because in that sense it has good authority behind it—no less, for example, than that of John Milton—but because in this company it must come to our ears with a homely sound. Perhaps we may regret that the pioneers of bacteriology did not revive it instead of inventing in 1878 the term microbe out of misused Greek. If they had been content with established English a pleasant link would have been left between the language of pharmacy and that of pathology. We might well also have been grateful to be able to speak of the viruses as "minims of nature" when we learn that there are among them living particulate and formidable agents so small as to surpass by little the individual *molecules* of hæmoglobin.

The theory of deficiency disease introduced to pathology a principle as wholly new as did the microbe. Like that it involved an immense change of scale and the demonstration that what might be called the naked-eye view of the constituents of the living body was inadequate. But the new principle was of a different kind from that necessary to found bacteriology. No pursuit of the old climatic and sanitarian theories of disease with whatever thoroughness could have led to the doctrine of microbic pathology without the revolutionary inquiries of Pasteur which disclosed an unsuspected mode of existence. On the other hand dietetics failed to disclose the vitamins because inquiries had not been exact and exhaustive enough. The problem of the vitamins was in fact a residuary problem. The dietetic field had been harvested and even gleaned except for what seemed a few inconspicuous remnants that for a long time it was agreed to ignore. Yet it was these very residues that were to yield the richest harvest of all. This peculiarity makes the solution of the vitamin problem of special interest to the student of scientific method. It is therefore as the leading recent case of a problem of the residuary type that I have reminded you of it, for I propose to call your attention in some little detail to that class of problem and its significance for the theory of method.

The economic value of working-over rejected residues has often been proved by the mining engineer and the metallurgist; similarly the need for vigilance in securing complete exhaustion of raw materials has shown its value to the chemist and the pharmacist. These lessons may usefully serve as metaphorical injunctions in the prosecution of scientific research itself. Time after time it has been shown in the latter activity that the humblest residual phenomena have concealed great secrets. In order to give this point all the salience I can, I shall go outside the field of medicine, and even of the biological sciences, to that of inorganic chemistry, and shall venture to recall to you the familiar and even hackneyed story of the finding of argon and the other inert gases of the air.

II

In the last quarter of the eighteenth century the study of the elementary gases was being pursued in England with much activity. Among those who were thus engaged we chiefly remember to-day the names of Priestley, Watt, Black, and Cavendish. Of these, Henry Cavendish was perhaps the ablest investigator as he was certainly the most extraordinary man. He was a millionaire and the grandson of a duke; yet his mode of life was hermit-like and spartan, his manner shy to the extent of oddity, and though he was a great experimenter, the publication of his researches was notably careless and hesitating. This last characteristic left his reputation for long far below his merits, but to give a measure of his real quality we need only recall that he was the first to demonstrate the constitution of water by hydrogen and oxygen and its synthesis from those elements.

Sometime before 1785 Cavendish was studying the separation of nitrogen from the air. He used the method of passing a stream of electric sparks through a glass tube containing air mixed with excess of oxygen. The nitrogen and oxygen combined to form an oxide of nitrogen which was absorbed by a solution of caustic potash, while the oxygen was removed by another absorbent. When, therefore, the process was complete and all the nitrogen oxidised, his tube should have been empty of any gas. But the result was different and I will quote his description of it, using however the modern terms for the gas concerned. After these processes he says, "a small bubble of air remained unabsorbed which was certainly not more than 1/120 of the [nitrogen] let up the tube. So that if there is any part of the [nitrogen] of our atmosphere which differs from the rest and cannot be reduced to nitrous acid we may safely conclude that it is not more than 1/120 part of the whole." That bubble, of course, was argon. Cavendish had seen it, but argon remained undiscovered. If curiosity was aroused at any time during the next century by this ambiguous residue in Cavendish's eudiometer, it has left no record; and we may be sure that any questionings were invariably stilled by the comfortable assumption of experimental error.

---

* Delivered before the Guild of Public Pharmacists on Jan. 18th.

III

It was over a hundred years later, in the last decade of the nineteenth century, that the meaning of this residue was explained, but the residue itself had first to be rediscovered by a wholly different line of approach. Chiefly owing to the work of Cavendish and his contemporaries, inorganic chemistry had experienced a continuous and successful development; but it had now fallen, as those of us who were students then can remember, on rather hard times. It had reached one of the flat periods to which all purely experimental sciences seem to be subject. The inspiration derived from its founders, after burning brilliantly for so long, was dying down. Ideas were few and—an even more ominous sign—were apt when they were at all speculative to be deprecated in the name of science. This dread of speculation, and the disguise of it as scientific austerity, are characteristic symptoms shown by an experimental science when its life is running thin. Such phenomena were, for example, apt to appear in the discussion of one of the few speculative conceptions that had found any kind of currency among chemists—the once famous "Prout's hypothesis." William Prout, it may be of interest to recall here, was a doctor as well as a chemist, and the discoverer of the presence of free hydrochloric acid in the gastric juice. As early as 1815 he enunciated the view that there must be a simple numerical relation between the atomic weights of hydrogen and the other elements, and that hydrogen was a sort of elementary substance that in some way entered into the composition of the others. Even on the evidence then to be reckoned with, this was a sensible and not very recondite guess, but in the next seventy or eighty years it produced from time to time a surprising amount of indignant criticism. It must of course be admitted that to those who had comfortably settled down to the view that each element is made up of irreducible indivisible billiard balls of a special kind, it was an irritating and repulsive dose. By them it was naturally criticised as a flighty departure from scientific rectitude, and I can remember the feeling some of my teachers gave me that it was a little disreputable even to entertain such an idea. Yet it was true; and it gave the hint that was to begin an energetic revival and extension of inorganic chemistry.

The hint was taken by a man whose personality (fortunately preserved for us by his son in a notably graphic memoir) would in itself justify the recall of the events that ensued. The third Lord Rayleigh was born into a family of country squires and landowners, and in many respects was thoroughly representative of his class. He was as strong a Conservative, as sound a church-goer, and as firm an upholder of the established order as his position and convictions demanded. He was brought up among the assumptions of a world which seemed to itself endowed and established for ever, and which is still indestructibly preserved for us in the annals of Middlemarch and Barchester. The main physical circumstance of his youth was the profound security of rural England, where the mild landscape and the deeply rooted village looked humbly to the Great House standing side by side with the church. Experience shows that a type and an environment such as this are not among the richer sources of our scientific masters. But they permitted Rayleigh, as they had permitted Henry Cavendish, to become one of the leading physical investigators of his day; and they perhaps reinforced, in the case of Rayleigh, the caution, the patience, and the stable judgment in which he conspicuously excelled.

It was these last gifts that were to be of decisive value when in 1882 he yielded, as many physicists had done before, to the siren song of Prout's hypothesis, and made up his mind to decide once for all whether, if every precaution that even his patience could suggest were taken, it might not be possible to show that a simple arithmetical relation did obtain between the atomic weight of hydrogen and those of the other elementary gases. This involved the weighing of these gases under exact conditions, and was of course an enormously laborious task. After some years the work on hydrogen and oxygen was completed, but though it failed to bring the atomic weight of the latter nearer to the hoped for 16 than 15·882, we find him in 1892 at work on nitrogen which had promised to be technically a less arduous affair. Things went well with this, and he was comparatively soon in possession of a stable weight for the gas that satisfied his exacting standards. He might well have supposed his task was done, but in fact he was innocently approaching its crisis. He had been weighing nitrogen got from air and therefore, as we now know, mixed with the heavier argon. This would be discovered only if the weight obtained were compared with the weight of nitrogen got from chemical decomposition and therefore free from argon. He stood thus at the parting of two courses of infinitely different significance. A good and consistent series of weights had been obtained; any man might have been satisfied with such a result. Down that road lay a moderate satisfaction and relief from a long and inexpressibly tedious research, but nothing else. He might, on the other hand, decide that he must confirm his results by work on nitrogen got from another source than air. Down that road, all unsuspected, lay heavy labours and anxieties, but also lay the finding of argon and consequences beyond any dream. There cannot have been many more critical moments in the history of science.

IV

It is a natural impulse of historians to make a good deal of what are called the turning points of history. At these nodes in the story of the past there is apt to be a concentration of issues on a single hour or on a single man, an intensification of meaning that gives dignity even to the trivial, a heightened illusion of free will in the actors. All these combine to endow the vague historic plungings of mankind with an air of design and æsthestic structure, so that it is but a poor historian who does not make an effective scene of Cæsar at the Rubicon, or Charles Edward at Derby. The history of knowledge has not been much recognised as yielding moments of an equal intensity, perhaps because its high occasions are undecorated by trumpet or banner and call to mind no sound of marching feet. But to the ear in tune with the finer vibrations of reality, science has had its crises which give a not less authentic thrill, and here was one of them. We watch Rayleigh at this turning point in the history of science with a confidence that is derived from our knowledge of his character as much as from our knowledge of the sequel. His caution and patience and judgment now had their unique opportunity. He decided that nitrogen prepared from chemical combination must also be weighed to confirm the weight obtained from atmospheric nitrogen, and he was soon brought up against a clear and unshakable discrepancy between the two results; the chemical nitrogen was ½ per cent. lighter than the atmospheric nitrogen. It is not necessary to follow the steps of the toilsome research by which it was proved that the excess weight of the atmospheric nitrogen was due to mixture with an unknown constituent of the air. At the end it became clear that this unknown gas was the "small bubble of air" which had "remained unabsorbed" in Henry Cavendish's eudiometer, and whose enigmatic presence had stood in the background of chemistry inviting curiosity in vain for over a hundred years. It was composed of the inertest substance in the physical world. In the intellectual world however it produced a veritable series of explosions. Argon led to helium and neon; helium pointed the way to the mode of disintegration of the radio-active atom, neon to isotopes and the meaning of the periodic succession of the elements. It is therefore no departure from rational moderation to say that this historic "bubble of air" was one of the most pregnant residues in the whole history of chemical analysis.

Whatever intrinsic interest this old story may possess, I should not have ventured to tell it except as a classical illustration of the significance of residuary phenomena in the history of science. That general lesson must surely provoke us to ask what application of it we can make in the departments of knowledge with which we are more specially concerned. I propose therefore to consider briefly certain aspects of medicine to which it may be relevant.

V

The fundamental activity of medical science is to determine the ultimate causation of disease. That statement sounds like a complete commonplace and should be one. We may perhaps, however, feel some doubt whether we all of us keep it in mind as clearly as we might. The brilliancy and the practical value of the great discoveries that have elucidated the processes of disease tend a little to obscure the fact that many of them tell us nothing about ultimate causation. Thus we are apt to speak of the treatment of myxœdema by thyroid extract or the treatment of diabetes by insulin as if the primary pathological state were affected by the remedy instead of being merely compensated for. As a matter of fact, when we come to survey more attentively the general state of medical science we cannot but be struck by the slight extent to which much recent progress—as, for example, that on the relation of internal secretion to the production of symptoms—has enlightened us in the matter of ultimate causes. A great deal of this work, though of course of the greatest value, has been on what we may call the physiological level, and has scarcely penetrated to fundamental pathology.

It may be interesting to glance over in a summary way the actual situation as regards our knowledge of the causation of disease. At present we can enumerate only six agents:—

Injury.
Malformation.
Defect of diet.
Poisoning.
Parasitic infection.
Neoplasm.

Of these it will be noticed that two—malformation and neoplasm—are not to be regarded as primary in a strict sense, since in time they will almost certainly be resolved into other factors. Setting aside, therefore, the pathological phenomena deriving from these two, we may say that we have for the explanation of the whole of the rest of disease only four principles—injury, defect of diet, poisoning, and parasitic infection. Let us now approach the situation from another aspect. The diseases known to us fall into three groups: first, those that can be assigned with certainty to one of the four causes we have enumerated; secondly, those which have been assigned with more or less probability to one of these; and thirdly, those of which the cause is unknown. The rate at which fresh diseases pass over from the third group to the first, and are found to be due to one of the known kinds of cause, is nowadays slow, and tends necessarily, other things being equal, to become slower. The question thus inevitably arises whether a time may not come and how far away it is, when the application of known principles to the explanation of disease will be at a standstill. Another way of putting the same question would be to ask how far it is likely that the further extensive explanation of disease depends on the discovery of some totally new principle comparable with the microbe or the vitamin. Consider such common and serious diseases as exophthalmic goitre, diabetes, and disseminate sclerosis. They have been under investigation a long time and with an increasing refinement of method, yet, however much we may have learnt of their mechanism, we still know nothing about their ultimate causation. Are they likely to be brought under causal mechanisms we already know, or are they and other diseases in a similar situation, like the residuary "bubble of air" in Henry Cavendish's eudiometer, awaiting for their explanation some radical fresh development? In answer to these questions we cannot make even a plausible guess.

In the last sixty years two wholly new causes of disease have been discovered—microbic infection and vitamin deficiency. The first of these explained a group of diseases which carried a certain broad clinical resemblance, so that a very acute clinician, in the days before bacteriology, might well have been able to guess that whatever their causes they were of the same general order. The case was strikingly different with the diseases explained by vitamin deficiency. In their clinical manifestations these were remarkably miscellaneous, and showed differences of the widest kind, such as, for example, those between rickets, beri-beri, and scurvy. No clinician, however alert, could have guessed that these were due to cognate causes. Furthermore, the deficiency diseases seem actually to mimic the diseases caused by other agents; consider, for example, the resemblance between vitamin-B deficiency and alcohol poisoning, each with its acute cerebral symptoms and chronic peripheral neuritis, and the resemblance of scurvy to an infection. The discovery of deficiency diseases has thus disclosed that allied causes may produce clinical effects showing no hint of any kind of relation, and has thus made it more difficult than ever to infer from clinical phenomena any suggestion as to new prime agents of disease.

VI

I should have hesitated to indulge in these extended reflections about residuary phenomena in relation to science in general and medicine in particular, if I had intended to abandon the subject in the complete blind alley into which it seems to have led us. It is true that we can form no reasonable opinion whether the great mass of disease still remaining unexplained will be cleared up by the more thorough exploitation of principles already known to us, or whether its final elucidation will be in any or in great part made by the discovery of some new kind of cause. Engaging as that problem must be to any philosophic student of medicine, it must remain for the present in the region of insoluble conjecture, but its interest may have a useful property if it sends us for some hint of guidance back to the history of science. If we may be allowed to return for a moment to a topic on which we have perhaps already too inordinately dwelt, we shall recall that the discovery of argon was due to Rayleigh's determination to carry the measurement of the known phenomena to a finer point than had yet been reached. In his branch of knowledge the saying that science is measurement was already familiar and manifestly true. As an indirect result of his work the idea can now be carried much further, and we can say that, at least in the atomic world, all quality is quantity. In such a doctrine we seem to be very far from the biological sciences, and still further from anything that could ever be recognisably human. Nevertheless it may remind us that the need and use for exact measurement in those sciences have steadily increased and must continue to do so.

Up to the present time medicine has almost wholly avoided the burden of measurement. Its field is so rich and various that qualitative methods of inquiry have proved at least adequate. Signs, however, are beginning to be perceptible that perhaps the main harvest of those methods has been gathered. If these omens are fulfilled, a time will come when an exact and exhaustive numerical exploration of the facts of disease will have to be undertaken. When we contemplate the practical success and the continued progress of medicine we are apt to overlook the fact that it is without precise data. Consider merely the distribution of health and disease in relation to topography, climate, race, sex, and age. Our knowledge of these fundamentals is a series of the vaguest approximations; if we had really exact knowledge of them it is quite probable that many problems of causation now insoluble could be solved by inspection. A similar lack of real exactitude is present in our knowledge of normal functions such as the pulse-rate, temperature, reflexes, sleep, appetite, right-handedness, weight and muscular strength, and above all, in our knowledge of the extent to which these functions are capable of adaptation.

It is obvious that to obtain information of the required precision on matters such as these is altogether beyond the range of the individual worker. Thus our final conclusion must necessarily be that if medicine is to acquire a secure foundation of exact and measured data, it can do so only as the result of inquiries far more widespread and coördinated than have yet come within the range of practical contemplation.

The considerations we have surveyed have led us through a course of which the windings may not have shown any very clear relevance to this occasion. Our conclusion, however, could not have been reached in circumstances more appropriate. The only branch of medicine which has always and with increasing intentness and success pursued the ideal of exact measurement is pharmacy. I do not think there can be any reasonable doubt that the future of the parent subject to a large extent depends on how far she is able to adopt the characteristic method of her daughter.

HORSESHOE KIDNEY

AN ACCOUNT OF FIVE CASES

By Arthur Jacobs, F.R.F.P.S. Glasg.
UROLOGIST, GLASGOW ROYAL INFIRMARY

The term horseshoe kidney implies a fusion of the kidneys across the vertebral column. The connecting isthmus varies from a narrow fibrous or parenchymatous bridge to complete fusion along the mesial borders.[1] In the majority of cases the isthmus runs between the lower poles, averages in width 4 to 5 cm., and crosses in front of the aorta and vena cava at the level of the fourth or fifth lumbar vertebra. Each kidney has its own pelvis and ureter, the latter passing ventral to the isthmus and terminating, as a rule, in the normal position in the bladder. The incidence, as obtained from autopsy records, is 1 in every 643 cases.[2] As would be expected, the statistics taken from operations show a much higher ratio, because pathological changes are especially apt to arise in this form of anomaly. In 2424 operations[3] on the kidney reported from the Mayo Clinic, 17 cases of horseshoe kidney were found. Since publishing a report of horseshoe kidney[4] two years ago, I have met with five further cases. I think an account of these will serve a useful purpose, for the records of many observers bear witness to the great difficulty of diagnosing this condition. In the series of 17 cases from the Mayo Clinic, Judd, Braasch, and Scholl[3] diagnosed the anomaly pre-operatively only eight times. According to Lazarus,[5] a correct diagnosis was made in only 12 cases out of 108 operations on horseshoe kidneys collected by Loeffler; in 1 out of a series of 3 by Rathbun; and all the 9 cases reported by Oraison and Gayet were diagnosed on the operating table.

CASE REPORTS

CASE 1.—A man, aged 23, was referred to the urological department of the Glasgow Royal Infirmary complaining of increasing difficulty in urination of three years' duration. He also suffered from generalised abdominal pains and a frequent feeling of abdominal distension. On three occasions during one day, eight months previously, he had passed blood in his urine.

Cystoscopy showed some injection of the trigonal vessels but no other vesical abnormality. A mediumly concentrated dye appeared at the right ureteric orifice five minutes after an intravenous indigo-carmine injection. No dye appeared from the left orifice after eight minutes' observation. A No. 10 ureteric catheter was passed into the right ureter as far as the renal pelvis without difficulty, but it was found impossible to insinuate either a No. 10 or No. 9 catheter farther than 1 cm. up the left ureter. A pyelogram was therefore made of the right kidney only, 17 c.cm. of sodium iodide being injected before any renal uneasiness was produced. The skiagram (Fig. 1) showed a bizarre-shaped, slightly dilated pelvis lying very close to the middle line, the lowest calyx pointing downwards and medialwards. A horseshoe kidney was diagnosed. A further attempt was made later to catheterise the left ureter, but was not successful. An intravenous urographic examination was therefore made, using as the medium 100 c.cm. of 40 per cent. uroselectan. This revealed a marked dilatation in the left segment, which it was decided to resect.

At *operation* in July, 1930, the approach was made through an extraperitoneal lumbar incision. The upper pole, which did not appear to be unusually low, was isolated. The isthmus consisted of parenchymatous tissue, was about 4 cm. in width, and crossed in front of the great vessels. The ureter ran anterior to it. After dividing the latter, the posterior surface of the kidney was freed. The pedicle consisted of two separate groups of vessels, one going to the upper pole and the other to the hilum. These were clamped, divided, and ligatured. The isthmus was now cleared to near the midline and there divided in a wedge-shaped manner. Two mattress catgut sutures were inserted through the stump, about three-quarters of an inch from its end, and a series of interrupted catgut sutures was inserted so as to approximate the edges. This resulted in a complete cessation of bleeding. The wound was closed up to a small tube, delivered through the upper end of the incision. Some urinary leakage through the tube began two days after operation; otherwise the patient had an uninterrupted convalescence. The wound healed by first intention except at the site of drainage, whence a slight urinary discharge continued up to the time of dismissal from hospital, three weeks after operation. This discharge ceased within a few weeks.

A communication from the patient, received in June, 1932, stated that he was unable to report personally as he had just started work after being four and a half years idle. He also wrote: "I now feel in the best of health. I have never had a pain nor a day's illness since the operation and feel as strong as ever I felt in my life."

FIGS. 1 2 3

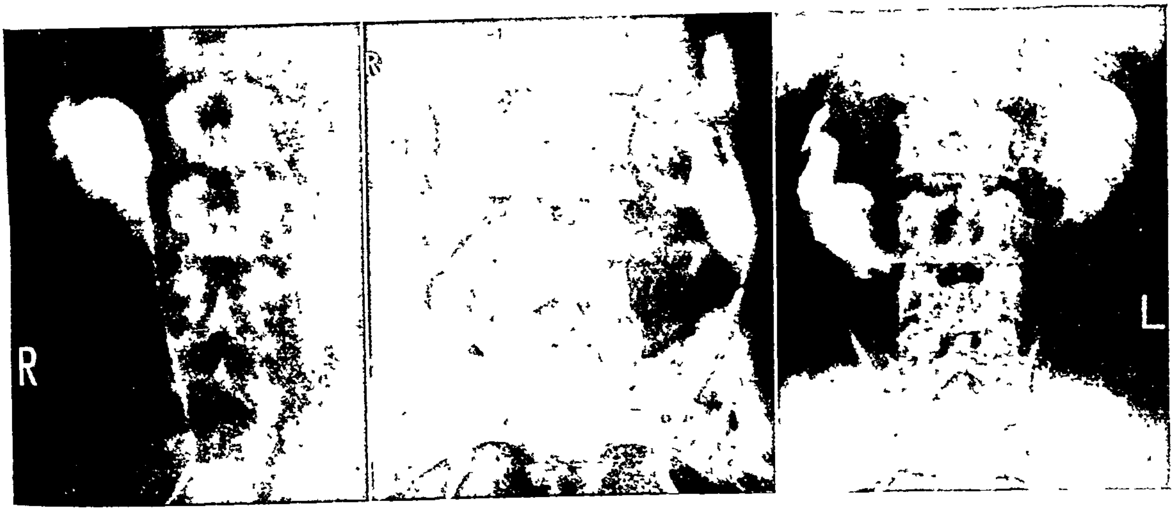

FIG. 1.—Ascending pyelogram of the right kidney of Case 1. The pelvis lies close to the vertebral column, and the lowest calyx, pointing downwards and medialwards, is in apparent contact with a vertebral body.

FIG. 2.—Bilateral ascending pyelogram of Case 2. All the calyces point medialwards, except the upper. Note the calcareous shadow lying lateral to the root of the upper calyx on the right side.

FIG. 3.—Bilateral ascending pyelogram of Case 3. Note how the upper calyces overlap the pelvis on the left side.

CASE 2.—A woman, aged 28, employed as a carpet-weaver, was referred to the department in December, 1930, complaining of urinary frequency of six months' duration. She required to urinate about every two hours during the day and had to rise once or twice at night.

Chemical examination of the urine was negative. A skiagram of the urinary tract showed a calcareous shadow in the right renal area, which was thought to be a gland. Cystoscopy showed a well-marked trigonitis. The ureteric orifices were normal in appearance and position. A medium blue dye appeared from each ureteric orifice four minutes after an intravenous indigo-carmine injection. Both ureters were catheterised without difficulty and a bilateral pyelogram made (Fig. 2). The pelves were markedly elongated and low, and abutted on the vertebral column. All the calyces except the upper pointed medialwards. The upper ends of the ureters curved outwards from and then inwards to the vertebral column. The calcareous shadow seen in the preliminary skiagram was contiguous with the root of the upper calyx on the right side, and it was decided to explore the right segment.

Operation.—Under a general anæsthetic an extraperitoneal lumbar incision was made. The upper pole occupied a position only slightly above the level of the iliac crest. The diagnosis of horseshoe kidney was confirmed by tracing an isthmus of parenchymatous tissue from the lower pole across the midline in front of the great vessels. The right ureter was seen to cross the front of the isthmus. A hard nodule was felt on the inner border of the exposed segment, adherent to the upper part of the hilum. An incision was made directly over it, and what proved to be a calcareous gland was removed. A small tube was brought out through the upper end of the incision and the wound closed. Convalescence was uneventful, and the patient left hospital three weeks after operation with the wound closed. When seen in June, 1932, she stated that she was enjoying excellent health. There had been no recurrence of the nocturia since operation, and during the day she could go for four to five hours.

CASE 3.—A man, aged 32, was referred to the department in September, 1931, complaining of pain in the upper lumbar region, more particularly on the left side. The patient was a miner, and his disability, he stated, had started six months previously, following a rack whilst at work. A radiological examination had been made at his local hospital, and a shadow in the left renal area was thought to be a calculus. Intravenous pyelography had also been carried out at the same institution, and the radiologist there had reported "ballooning" of the left shadow and "abnormal outline" of the right.

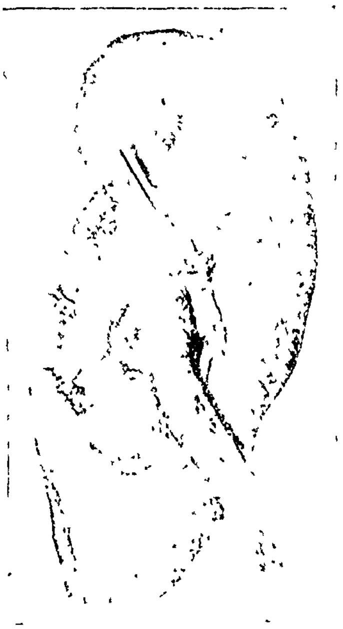
Physical examination of the abdomen was negative. Cystoscopy was negative, and both ureteric orifices were normal in appearance and situation. A catheter was passed up each ureter as far as the renal pelvis, without meeting any obstruction, and 15 c.cm. of sodium iodide were injected into each side before any renal uneasiness was produced. The appearance of the pyelogram (Fig. 3) was typical of a horseshoe kidney. The pelves had a bizarre shape and lay close to the midline. The left one was slightly dilated. Most of the calyces pointed medialwards and, in the left segment, the upper calyces were seen to overlap the pelvis. The ureters curved outwards from and then inwards to the vertebral column on each side. No surgical intervention was advised, as it was considered that the symptoms were probably due to the back strain. A communication from the patient in July, 1932, stated that he had resumed light work, but suffered from frequent attacks of excruciating pain across the small of the back.

CASE 4.—A man aged 34, a miner, was referred to the department in December, 1931. His complaint was of urinary frequency and dysuria of three months' duration. He needed to rise about every hour during the night, and during the day was "always going." For three weeks before his examination he had felt a constant ache in the left lumbar region. Since the onset of the symptoms he had lost a stone in weight.

There was tenderness on palpation of the left lumbar region. The urine contained albumin and pus, and tubercle bacilli were identified without difficulty. Plain radioscopy of the urinary tract was negative. On cystoscopic examination a more or less generalised cystitis was found, and the bladder capacity was reduced to 130 c.cm. The ureteric orifices looked normal. A weak dye appeared at the right ureteric orifice five and a half minutes after an intravenous indigo-carmine injection, and concentrated a minute and a half later. No dye appeared from the left after eight minutes' observation. At a subsequent cystoscopy the right ureter was catheterised one and a half hours after a urea meal, and the secretion from the right kidney collected for urine analysis and for examination of the urea content. No pus cells or tubercle bacilli were found in it, and the urine urea was 2·3 per cent. The examination was completed by making an intravenous pyelogram, using for this 20 c.cm. of uroselectan B. This showed a typical horseshoe kidney appearance. The pelves had peculiar elongated shapes, were situated lower than usual, and the left shadow lay over the transverse processes. On each side some of the calyces pointed downwards and medially. The upper, inner calyces on the left side had a moth-eaten appearance. A diagnosis of tuberculosis in the left segment of a horseshoe kidney was made, and a resection decided on.

Operation was performed under spinal anæsthesia, using 18 c.cm. of percaine. The extraperitoneal lumbar approach was used and the peritoneum reflected towards the midline. The perinephric fat looked healthy, and when it was opened the upper pole was exposed and freed without difficulty. A broad isthmus of parenchymatous tissue was found running in front of the great vessels, and a dilated, hypertrophied left ureter ran anterior to it. The latter was traced downwards to a point about three inches below the level of the isthmus and there divided and ligatured. A true vascular pedicle was found entering the hilum, and was clamped and divided. A small vessel running upwards into the isthmus was also seen and divided. It was now easy to free the left segment and the isthmus, and to mobilise the latter to beyond the midline. Here a sulcus was recognised encircling the isthmus. A stay-suture was introduced on its right side; the isthmus was divided through it in a perpendicular manner and the left segment was removed (Fig. 4). There was very little bleeding. Using the stay-suture to overcome the retraction of the isthmus, a mattress-suture of catgut was passed through the stump about half an inch from its end and tied. This effectively controlled the oozing. The edges of the stump were approximated, as well as possible, by a series of six interrupted catgut sutures. The abdominal wound was closed in two layers, a tube being delivered through the upper end. The perfect relaxation obtained by the spinal anæsthetic greatly facilitated the operation, particularly when dealing with the isthmus.

FIG. 4

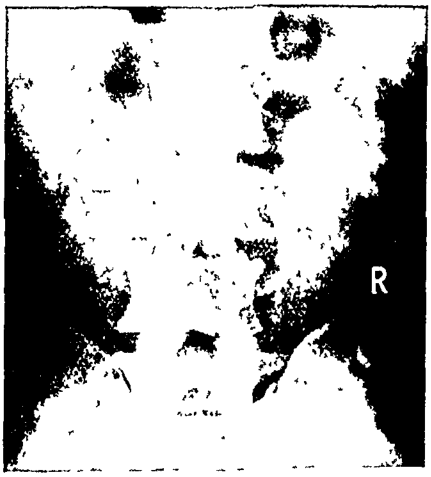


Photograph of the resected segment from Case 4. The upper pole is the seat of a large ulcero-cavernous focus, indicated externally by a large boss. Note the dilated thickened ureter passing in front of the isthmus. Glass rods have been placed in the two vessels passing to the hilum.

For the first two days after the operation the patient was troubled with flatulence. This was relieved by enemata. The tube was removed on the fourth day. On the eleventh day a purulent, sanguinous discharge appeared at the site of the drainage and, later, the middle portion of the wound broke down. A specimen of urine taken from a 24-hour collection, ten days after operation, was negative for tubercle bacillus, and a guinea-pig killed six weeks after inoculation from the same specimen was negative for tubercle. There was a very quick improvement in the rate of urinary frequency, the patient being able to hold his water for three to four hours within a few days of the operation. He was transferred for a period of sanatorium treatment three weeks after operation, with a purulent discharge still coming from the wound. A report from his doctor in August, 1932, stated that the wound was granulating, but was not quite healed. There was no urinary discharge from it. The frequency was three- or four-hourly during the day, and twice at night.

CASE 5.—A man aged 28, a labourer, was referred to the department in April, 1932, complaining of recurring attacks of left renal pain of nine weeks' duration.

FIG. 5



Intravenous pyelogram of Case 5. The pelvis of the right segment appears more dilated than that of the left, the side of the ureteric calculus.

Chemical examination of the urine was negative, and a preliminary radioscopy of the urinary tract proved negative for calculus. A catheter passed up the left ureter was obstructed at 20 cm., however, and a radiogram taken with the catheter in situ showed a small stone at its tip. Sodium iodide (20 c.cm.) was injected into the renal pelvis without causing any uneasiness, and the resulting pyelogram showed a typical horseshoe kidney appearance, with slight dilatation of the pelvis and clubbing of all the calyces. An intravenous pyelogram (Fig. 5) was later made, using 20 c.cm. of uroselectan B. This pyelogram confirmed the diagnosis of a horseshoe anomaly, but showed a greater degree of dilatation in the right pelvis than in the left.

Operation.—Under spinal anæsthesia (percaine 14 c.cm.) an extraperitoneal exposure was made through a curved lumbar incision. The isthmus was seen to consist of thick parenchymatous tissue. The ureter lay anterior, and a stone could be felt within it, about an inch below the lower border. The renal pelvis was seen to be slightly dilated. The stone was removed through a small vertical incision in the ureter, which was then closed by two Lembert-like catgut sutures. A small drainage-tube was brought out through the lower end of the lumbar wound. There was no urinary leakage and the tube was removed on the second day. The patient was dismissed to the convalescent home on the twelfth post-operative day, with the wound completely healed.

DIAGNOSIS

In the presence of renal disease requiring operative intervention, the pre-operative knowledge of the existence of a horseshoe anomaly is a tremendous advantage, particularly in approach. To those experienced in the interpretation of pyelograms, diagnosis should, in most cases, be easy. The only other condition familiar to me which might give rise to confusion is an anomaly of rotation. When this occurs in an excessive degree, the convex border is mesial and the pelvis faces laterally. The pyelogram of such a kidney would show the calyces directed towards the spinal column. As, however, both kidneys are not usually rotated, the pyelogram of the partner kidney would be likely to have a normal appearance. The important diagnostic features of a horseshoe kidney pyelogram are as follows:—

(a) The shadow lies closer to the midline than in the normal, and is usually lower.

(b) The pelvis and calyces are of a bizarre shape.

(c) One or more of the calyces on each side points towards the midline or downwards, and some of the calyces may overlap the shadow of the pelvis.

(d) The upper end of the ureter curves outwards from and then inwards to the vertebral column.

Pyelography is the only reliable diagnostic method. A plain radioscopy might be suggestive by indicating a loss of outline of the psoas shadow, and failing to visualise one or other of the renal poles. There is no syndrome of symptoms and signs characteristic of horseshoe kidney.

SURGICAL TECHNIQUE

Diseases involving a horseshoe kidney should be treated in the same manner as similar diseases in kidneys normally formed. If resection of the affected segment is necessary this involves cutting through the isthmus, which is usually composed of parenchymatous tissue. Most urologists agree that the extraperitoneal lumbar approach is preferable to the abdominal route. By this method there is less likelihood of infecting the peritoneum, especially when dealing with a tuberculous or suppurative lesion, or when there is a possibility of urinary leakage after the operation. It is my custom to make an incision starting about an inch below the costovertebral angle. This is carried downwards and slightly forwards to a point about midway in the costo-iliac space, whence it is made to pass forwards parallel with the iliac crest. The muscles and fasciæ are divided in the line of the incision, which can be prolonged as far towards the midline as seems necessary to give a free exposure of the isthmus. The complete muscular relaxation obtained by spinal anæsthesia greatly facilitates the access. Methods of dealing with the isthmus have been described under Cases 1 and 4, in which resections were carried out.

STARCH FERMENTATION BY THE "GRAVIS" TYPE OF DIPHTHERIA

BY J. S. ANDERSON, M.D. ABERD., D.P.H.
MEDICAL SUPERINTENDENT OF THE LEEDS CITY HOSPITALS

BROTHERTON PROFESSOR OF BACTERIOLOGY IN THE UNIVERSITY OF LEEDS

IN a report on diphtheria types published in THE LANCET Wright and Rankin [1] refer to difficulties they have met with in detecting the fermentation of starch by diphtheria bacilli. One of the general conclusions suggested by their paper is that "gravis" strains of the diphtheria bacillus are either absent or very rare in the Edinburgh area. Inasmuch, however, as they do not state definitely whether the gravis strains which they had received from Leeds did or did not ferment starch in their hands, the general impression left by their paper is far from clear.

They maintain that filtered solutions of starch should be used for fermentation tests because starch is readily hydrolysed when its solutions are heated for the purpose of sterilisation. Our own experience has been entirely at variance with this finding. But in view of this statement it seemed desirable to re-examine the behaviour of starch solutions when heated in a variety of ways.

In the work already published (Anderson, Happold, McLeod, and Thomson [2]) on this subject, the method invariably used has been to add sterile autoclaved 5 per cent. solution of British Drug Houses soluble starch to serum peptone water previously sterilised by repeated steaming at 100° C., in amount necessary to bring the final concentration of starch in the medium to 1 per cent. Latterly [3] we have often worked with serum peptone water in which the starch solution was incorporated before commencing the sterilisation by intermittent heating. Such media have never shown any acid reaction when the types of diphtheria bacilli described as "mitis" or "intermediate" are grown in them for a week or more, and inasmuch as both these types of strain attack maltose, which is one of the products of hydrolysis of starch, it scarcely seemed likely that any appreciable hydrolysis of the starch was taking place under the conditions described.

OBSERVATIONS ON FERMENTATION

The point, however, has been raised, and is important for the differentiation of gravis strains. Results obtained both before and after the publication of Wright and Rankin's paper are the following:—

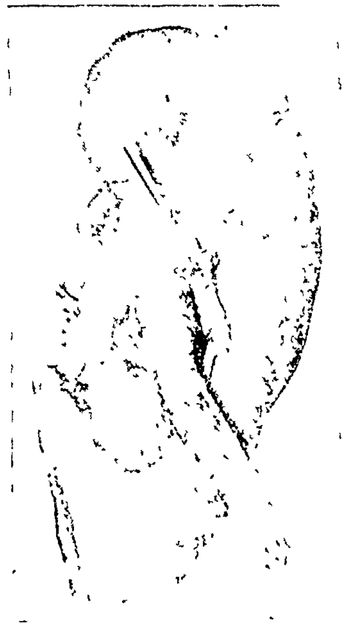
Fermentation of starches of different origin.—The following products were used: (B.D.H.) maize, wheat, potato, and rice starches. These were dissolved in boiling water, autoclaved at 115° C. for 20 minutes as 5 per cent. solutions, and then added in the required amount to serum peptone water (pH 7·8) previously sterilised by intermittent steaming. Four strains previously determined to be starch-fermenting, and eight non-starch-fermenting strains were grown on all four products. All four gravis strains fermented all the specimens of starch with clotting of the proteins of the serum peptone water within 36 hours; whereas none of the other strains had produced any change of reaction after a week's incubation.

Effect of heat sterilisation at different reactions.—One per cent. solutions of starch in 0·1 per cent. Na_2HPO_4 and 1 per cent. peptone of the following reactions, pH 6·0, 7·2, 7·5, and 8·2 were prepared; these were autoclaved for 20 minutes at 115° C. These media, after the necessary adjustments of reaction, were tested for growth and fermentation with various diphtheria strains. No change in the fermentative effects exerted by gravis and other diphtheria strains was observed. This was equally the case when heated serum was added to produce freer growth of the bacteria.

The detection of the products of hydrolysis in complex media by chemical methods cannot readily be made a very delicate observation owing to the reducing action of some component of the peptone; but we failed to find any difference between tubes with and those without starch. Further, the examination of an autoclaved aqueous 5 per cent. solution of starch by Fehling's and Benedict's methods gave no evidence of hydrolysis. If, however, unheated serum is added to any one of these starch-containing media, and it is then inoculated with diphtheria bacilli and of the urinary tract was negative. On cystoscopic examination a more or less generalised cystitis was found, and the bladder capacity was reduced to 130 c.cm. The ureteric orifices looked normal. A weak dye appeared at the right ureteric orifice five and a half minutes after an intravenous indigo-carmine injection, and concentrated a minute and a half later. No dye appeared from the left after eight minutes' observation. At a subsequent cystoscopy the right ureter was catheterised one and a half hours after a urea meal, and the secretion from the right kidney collected for urine analysis and for examination of the urea content. No pus cells or tubercle bacilli were found in it, and the urine urea was 2·3 per cent. The examination was completed by making an intravenous pyelogram, using for this 20 c.cm. of uroselectan B. This showed a typical horseshoe kidney appearance. The pelves had peculiar elongated shapes, were situated lower than usual, and the left shadow lay over the transverse processes. On each side some of the calyces pointed downwards and medially. The upper, inner calyces on the left side had a moth-eaten appearance. A diagnosis of tuberculosis in the left segment of a horseshoe kidney was made, and a resection decided on.

Operation was performed under spinal anæsthesia, using 18 c.cm. of percaine. The extraperitoneal lumbar approach was used and the peritoneum reflected towards the midline. The perinephric fat looked healthy, and when it was opened the upper pole was exposed and freed without difficulty. A broad isthmus of parenchymatous tissue was found running in front of the great vessels, and a dilated, hypertrophied left ureter ran anterior to it. The latter was traced downwards to a point about three inches below the level of the isthmus and there divided and ligatured. A true vascular pedicle was found entering the hilum, and was clamped and divided. A small vessel running upwards into the isthmus was also seen and divided. It was now easy to free the left segment and the isthmus, and to mobilise the latter to beyond the midline. Here a sulcus was recognised encircling the isthmus. A stay-suture was introduced on its right side; the isthmus was divided through it in a perpendicular manner and the left segment was removed (Fig. 4). There was very little bleeding. Using the stay-suture to overcome the retraction of the isthmus, a mattress-suture of catgut was passed through the stump about half an inch from its end and tied. This effectively controlled the oozing. The edges of the stump were approximated, as well as possible, by a series of six interrupted catgut sutures. The abdominal wound was closed in two layers, a tube being delivered through the upper end. The perfect relaxation obtained by the spinal anæsthetic greatly facilitated the operation, particularly when dealing with the isthmus.

FIG. 4

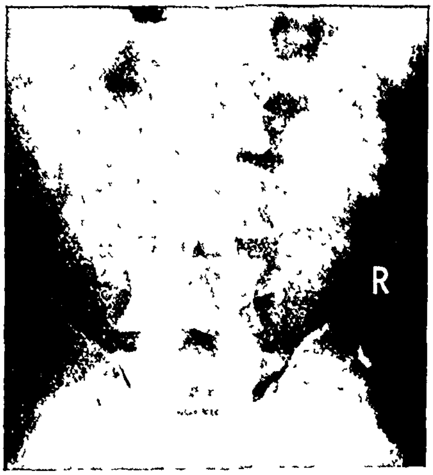


Photograph of the resected segment from Case 4. The upper pole is the seat of a large ulcerocavernous focus, indicated externally by a large boss. Note the dilated thickened ureter passing in front of the isthmus. Glass rods have been placed in the two vessels passing to the hilum.

For the first two days after the operation the patient was troubled with flatulence. This was relieved by enemata. The tube was removed on the fourth day. On the eleventh day a purulent, sanguineous discharge appeared at the site of the drainage and, later, the middle portion of the wound broke down. A specimen of urine taken from a 24-hour collection, ten days after operation, was negative for tubercle bacillus, and a guinea-pig killed six weeks after inoculation from the same specimen was negative for tubercle. There was a very quick improvement in the rate of urinary frequency, the patient being able to hold his water for three to four hours within a few days of the operation. He was transferred for a period of sanatorium treatment three weeks after operation, with a purulent discharge still coming from the wound. A report from his doctor in August, 1932, stated that the wound was granulating, but was not quite healed. There was no urinary discharge from it. The frequency was three- or four-hourly during the day, and twice at night.

CASE 5.—A man aged 28, a labourer, was referred to the department in April, 1932, complaining of recurring attacks of left renal pain of nine weeks' duration.

FIG. 5



Intravenous pyelogram of Case 5. The pelvis of the right segment appears more dilated than that of the left, the side of the ureteric calculus.

Chemical examination of the urine was negative, and a preliminary radioscopy of the urinary tract proved negative for calculus. A catheter passed up the left ureter was obstructed at 20 cm., however, and a radiogram taken with the catheter in situ showed a small stone at its tip. Sodium iodide (20 c.cm.) was injected into the renal pelvis without causing any uneasiness, and the resulting pyelogram showed a typical horseshoe kidney appearance, with slight dilatation of the pelvis and clubbing of all the calyces. An intravenous pyelogram (Fig. 5) was later made, using 20 c.cm. of uroselectan B. This pyelogram confirmed the diagnosis of a horseshoe anomaly, but showed a greater degree of dilatation in the right pelvis than in the left.

Operation.—Under spinal anæsthesia (percaine 14 c.cm.) an extraperitoneal exposure was made through a curved lumbar incision. The isthmus was seen to consist of thick parenchymatous tissue. The ureter lay anterior, and a stone could be felt within it, about an inch below the lower border. The renal pelvis was seen to be slightly dilated. The stone was removed through a small vertical incision in the ureter, which was then closed by two Lembert-like catgut sutures. A small drainage-tube was brought out through the lower end of the lumbar wound. There was no urinary leakage and the tube was removed on the second day. The patient was dismissed to the convalescent home on the twelfth post-operative day, with the wound completely healed.

DIAGNOSIS

In the presence of renal disease requiring operative intervention, the pre-operative knowledge of the existence of a horseshoe anomaly is a tremendous advantage, particularly in approach. To those experienced in the interpretation of pyelograms, diagnosis should, in most cases, be easy. The only other condition familiar to me which might give rise to confusion is an anomaly of rotation. When this occurs in an excessive degree, the convex border is mesial and the pelvis faces laterally. The pyelogram of such a kidney would show the calyces directed towards the spinal column. As, however, both kidneys are not usually rotated, the pyelogram of the partner kidney would be likely to have a normal appearance. The important diagnostic features of a horseshoe kidney pyelogram are as follows:—

(a) The shadow lies closer to the midline than in the normal, and is usually lower.

(b) The pelvis and calyces are of a bizarre shape.

(c) One or more of the calyces on each side points towards the midline or downwards, and some of the calyces may overlap the shadow of the pelvis.

(d) The upper end of the ureter curves outwards from and then inwards to the vertebral column.

Pyelography is the only reliable diagnostic method. A plain radioscopy might be suggestive by indicating a loss of outline of the psoas shadow, and failing to visualise one or other of the renal poles. There is no syndrome of symptoms and signs characteristic of horseshoe kidney.

SURGICAL TECHNIQUE

Diseases involving a horseshoe kidney should be treated in the same manner as similar diseases in kidneys normally formed. If resection of the affected segment is necessary this involves cutting through the isthmus, which is usually composed of parenchymatous tissue. Most urologists agree that the extraperitoneal lumbar approach is preferable to the abdominal route. By this method there is less likelihood of infecting the peritoneum, especially when dealing with a tuberculous or suppurative lesion, or when there is a possibility of urinary leakage after the operation. It is my custom to make an incision starting about an inch below the costovertebral angle. This is carried downwards and slightly forwards to a point about midway in the costoiliac space, whence it is made to pass forwards parallel with the iliac crest. The muscles and fasciæ are divided in the line of the incision, which can be prolonged as far towards the midline as seems necessary to give a free exposure of the isthmus. The complete muscular relaxation obtained by spinal anæsthesia greatly facilitates the access. Methods of dealing with the isthmus have been described under Cases 1 and 4, in which resections were carried out.

LECTURER IN BACTERIOLOGY

AND

J. W. McLeod, M.B. Glasg.
BROTHERTON PROFESSOR OF BACTERIOLOGY IN THE UNIVERSITY OF LEEDS

In a report on diphtheria types published in The Lancet Wright and Rankin[1] refer to difficulties they have met with in detecting the fermentation of starch by diphtheria bacilli. One of the general conclusions suggested by their paper is that "gravis" strains of the diphtheria bacillus are either absent or very rare in the Edinburgh area. Inasmuch, however, as they do not state definitely whether the gravis strains which they had received from Leeds did or did not ferment starch in their hands, the general impression left by their paper is far from clear.

They maintain that filtered solutions of starch should be used for fermentation tests because starch is readily hydrolysed when its solutions are heated for the purpose of sterilisation. Our own experience has been entirely at variance with this finding. But in view of this statement it seemed desirable to re-examine the behaviour of starch solutions when heated in a variety of ways.

In the work already published (Anderson, Happold, McLeod, and Thomson[2]) on this subject, the method invariably used has been to add sterile autoclaved 5 per cent. solution of British Drug Houses soluble starch to serum peptone water previously sterilised by repeated steaming at 100° C., in amount necessary to bring the final concentration of starch in the medium to 1 per cent. Latterly[3] we have often worked with serum peptone water in which the starch solution was incorporated before commencing the sterilisation by intermittent heating. Such media have never shown any acid reaction when the types of diphtheria bacilli described as "mitis" or "intermediate" are grown in them for a week or more, and inasmuch as both these types of strain attack maltose, which is one of the products of hydrolysis of starch, it scarcely seemed likely that any appreciable hydrolysis of the starch was taking place under the conditions described.

OBSERVATIONS ON FERMENTATION

The point, however, has been raised, and is important for the differentiation of gravis strains. Results obtained both before and after the publication of Wright and Rankin's paper are the following:—

Fermentation of starches of different origin.—The following products were used: (B.D.H.) maize, wheat, potato, and rice starches. These were dissolved in boiling water, autoclaved at 115° C. for 20 minutes as 5 per cent. solutions, and then added in the required amount to serum peptone water (pH 7·8) previously sterilised by intermittent steaming. Four strains previously determined to be starch-fermenting, and eight non-starch-fermenting strains were grown on all four products. All four gravis strains fermented all the specimens of starch with clotting of the proteins of the serum peptone water within 36 hours; whereas none of the other strains had produced any change of reaction after a week's incubation.

Effect of heat sterilisation at different reactions.—One per cent. solutions of starch in 0·1 per cent. Na_2HPO_4 and 1 per cent. peptone of the following reactions, pH 6·0, 7·2, 7·5, and 8·2 were prepared; these were autoclaved for 20 minutes at 115° C. These media, after the necessary adjustments of reaction, were tested for growth and fermentation with various diphtheria strains. No change in the fermentative effects exerted by gravis and other diphtheria strains was observed. This was equally the case when heated serum was added to produce freer growth of the bacteria.

The detection of the products of hydrolysis in complex media by chemical methods cannot readily be made a very delicate observation owing to the reducing action of some component of the peptone; but we failed to find any difference between tubes with and those without starch. Further, the examination of an autoclaved aqueous 5 per cent. solution of starch by Fehling's and Benedict's methods gave no evidence of hydrolysis. If, however, unheated serum is added to any one of these starch-containing media, and it is then inoculated with diphtheria bacilli and incubated, it is found that all types of strain produce fermentation. The starch is split by the diastase of the serum on incubation at 37° C., and the mitis and intermediate types of diphtheria bacilli which cannot attack unaltered starch readily produce acid from the products of its hydrolysis.

We must therefore say that we are completely at a loss to understand the difficulty in determining starch fermentation which Wright and Rankin describe. The only three likely sources of error which we have been able to determine are :—

(1) The addition of unheated serum to the medium.
(2) The use of a soluble starch in which the treatment with acid has been carried too far, and resulted in partial hydrolysis.
(3) The use of fluid media with a basis of meat extract, since all diphtheria bacilli can split acid from some of the compounds in meat extract.

The media recommended in our original paper fulfil the two essential requirements—free growth of the bacilli and constant reaction in the absence of added fermentable substance.

TYPE OF ORGANISM AND CLINICAL FINDINGS

A general summary of the views which we advanced a year ago and of the criticisms of these views recently brought forward appeared as an annotation in the same issue of THE LANCET as Wright and Rankin's paper. Without doubt the classification of diphtheria bacilli along the lines which we have suggested must be established ultimately on the corroboration of those findings by other workers, and in other places.

We believe, however, that it is a mistake to suggest that the only evidence available in favour of this conception is that obtained in Leeds.

From the papers of Parish, Whatley, and O'Brien,[4] and of Wright and Rankin, and from our own observations, it appears that gravis infections have played an important part—i.e., have been the most frequent type of infection in Berlin, Frankfort, Cork, Hull, and Leeds, in all of which places diphtheria has recently been severe and in some cases remarkably formidable; whereas in London, Scotland, and Copenhagen, where starch-fermenting strains are rare, diphtheria has been relatively mild. The case death-rate in the centres where gravis infections have been common has fluctuated between 8 per cent. and 20 per cent.; whereas in those areas where they are uncommon no case death-rates exceeding 6 per cent. have been recorded recently.

It is rather too readily assumed that severe outbreaks of diphtheria may be explained away on the ground of insufficient or tardy serum therapy. It may be that here and there an unusually high death-rate from diphtheria can be explained in this way, but it seems to us altogether improbable that this will be the explanation of a high death-rate persisting over a considerable period in a community of some size. The whole tendency is in the other direction, for there is an unusual atmosphere of alarm in connexion with inflammations of the throat, and many practitioners send suspected cases of diphtheria to the fever hospital without waiting for a bacteriological report.

The following figures, based on the experience of diphtheria in Leeds, illustrate this point. In 1928 diphtheria was mild, mortality 3·3 per cent.; in 1931 it was severe, mortality 9·2 per cent.; and the following Tables are compiled from the records of the Leeds City Hospital. Table I. shows the duration of the illness before antitoxin treatment was commenced.

It is commonly assumed that when antitoxin treatment is commenced *within* 96 hours of the onset, there is a reasonable chance of recovery. The average duration of illness before the administration of antitoxin in fatal cases was 4·1 days in 1928 and 3·0 days in 1931.

TABLE I

Duration of illness before commencement of antitoxin treatment.	Percentage of all cases.			
	1928.		1931.	
Under 24 hours	2·7	67·5	4·4	75·2
24 hours – 48 hours	21·6		23·3	
48 „ – 72 „	23·2		27·9	
72 „ – 96 „	20·0		19·6	
Over 96 hours	32·5		24·8	

The proportion of early to late deaths in diphtheria in the two years is given in Table II.

TABLE II

Duration of illness before commencement of antitoxin treatment.	Percentage of deaths.	
	1928.	1931.
Under 96 hours	46·1	68·2
Over 96 „	53·9	31·8

SIGNIFICANCE OF THE LEEDS FINDINGS

There is a tendency on the part of those who criticise the differentiation of gravis and mitis types of the diphtheria bacillus to assume that the finding of a number of fatal cases of mitis infection on the one hand, and of mild gravis infections on the other, disposes of the claim which we have put forward. It is desirable, therefore, to state afresh what we consider to be the significance of the findings which we have made in Leeds.

For the last two years the form of diphtheria bacillus predominant in Leeds has been a starch-fermenting form, growing with marked pellicle formation and coarse granular deposit in broth, and the results of serum treatment in cases due to this type of bacillus have been disappointing. Examination of diphtheria strains, 46 obtained from Berlin, and 1, described as the only form occurring in Posen, has shown that in these areas also the gravis type of diphtheria bacillus is common. It has been assumed, therefore, as probable that this is the type of diphtheria bacillus specially responsible for the very grave epidemics of diphtheria so resistant to serum treatment that have been reported from the continent of Europe during the last three or four years. By contrast, the next most numerous type of diphtheria bacillus in Leeds, which is a non-starch-fermenter, grows abundantly on the usual bacteriological media, and produces a uniform and usually copious turbidity in broth, has not till now in our experience produced death in any case which has been admitted to hospital soon enough to receive serum treatment. It has been assumed as probable that the findings in Leeds, as far as the contrast between the gravis and mitis types of diphtheria are concerned, would prove to be of general application.* That assumption is not invalidated by determining that (*a*) in some areas the bacteriology of diphtheria is quite different from that in Leeds—e.g., that the intermediate form present to the extent of 5 per cent. in Leeds is the most numerous type in Glasgow; nor that (*b*) some mitis infections coming under treatment *late* in the disease have died, as, for instance, those quoted in the Edinburgh paper.

---

* It is scarcely likely that no death in 100 cases of serum-treated mitis infection will often be recorded as it has been in Leeds—this is probably exceptional. We do expect, however, that a low death-rate will prove to be the rule in the mitis type of infection.

Extensive investigations of diphtheria along the lines of the classification which we have suggested are now in progress in several centres outside Leeds, and a more convincing verdict on this subject should result. Meanwhile, however, it has seemed desirable to us to state that we see no reason at present to modify the main conclusions already published on this subject.

Throughout Yorkshire infections with the gravis bacillus are now common, and often extremely formidable, and although there is no immediate prospect of a serum therapy better adapted to these infections, we would emphasise that the nasal carriers appear to be very important agents in spreading such infections, and might well be more effectively controlled than they are at present. Rapid discrimination between the gravis strains and other diphtheroid bacilli of the nose is considerably facilitated by the use of the medium which we have introduced.

We have pleasure in thanking the Medical Research Council for a grant for expenses, and also for a personal grant made to two of us.

ANÆSTHESIA IN TROPICAL SURGERY

By C. GRANTHAM-HILL, M.B. CAMB., F.R.C.S. EDIN.
SENIOR SURGEON TO THE KHARTOUM HOSPITAL

THE difficulty of obtaining good general anæsthesia for surgical operations has always been one of the constant trials of medical work in the tropics. This difficulty is particularly marked in a country such as the Anglo-Egyptian Sudan, in which there are great variations of temperature and humidity, a shortage of experienced medical staff, and a backward and primitive race supplying the majority of the patients. There is, amongst native Sudanese patients, an almost universal dread of losing consciousness under an anæsthetic, a dread compounded of fear of the unknown and a belief that the soul actually leaves the body and may have difficulty in finding it again. There is sometimes also a tincture of doubt as to what mutilation may be in store for the unconscious and helpless patient. The relief with which the information that an operation can be performed without loss of consciousness and without pain is received by such patients contributes greatly to that hopeful outlook which is of such enormous value in the treatment of the African native.

The technical, as apart from the psychological, difficulties of general anæsthesia may be summarised as follows:—

Chloroform, the most dependable of available anæsthetics, is nevertheless dangerous in unskilled hands, and few native medical officers become really dependable in its use. Further, its toxic effect in prolonged anæsthesia is a very real danger, particularly in view of the commonness of hepatic and renal deficiencies in tropical patients.

Ether is very unreliable owing to the great variation in its rate of evaporation following atmospheric changes. It loses bulk rapidly in hot weather, and is apt to explode. Its use needs considerable skill, especially when in combination with chloroform, for the relative strength of the two drugs is continually changing as the ether evaporates. Closed ether appliances seldom survive the climate for more than a few months, on account of the loss of elasticity of the rubber bags or connexions. Ether readily causes bronchial irritation in hot, dry weather. The most useful mode of administration is by the rectum mixed with olive oil.

Nitrous oxide.—Both nitrous oxide and oxygen are impossibly expensive, as they have to be obtained from Europe, and the cylinders lose half their contents in transit.

Ethyl chloride is definitely dangerous unless given in measured quantity from a rubber bag, which rapidly loses elasticity.

Avertin has the very grave objection that skilled attention is needed for at least half an hour before operation, and often for 24 hours after it. It is therefore almost ruled out as a routine anæsthetic in the primitive conditions of nursing found in most parts of this country.

The solution of many of these difficulties has been found to lie in the increasing use of local and spinal anæsthesia; the following are the most striking of the many advantages.

(1) The minimum of shock with the maximum of relaxation.

(2) The almost complete absence of post-anæsthetic vomiting. This is of great value both from a physical and a psychological aspect. The patient usually sleeps well, and can take fluids and solid diet much earlier than after general anæsthesia.

(3) Preparatory and after-treatment are simplified. Many cases can be admitted and sent home on the day of operation, thus economising beds.

(4) One skilled assistant the less is needed.

(5) The coöperation of the patient during the operation is often of great assistance—e.g., a timely cough in locating a hernial sac and the movement of fingers in a tendon suture.

These advantages are, of course, familiar to all surgeons, but work at a distance from the refinements of skilled assistance and nursing lends them such added value as to warrant the emphasis used.

SPINAL ANÆSTHESIA IN ABDOMINAL OPERATIONS

Spinal anæsthesia is the anæsthesia of choice for major abdominal operations on patients who are not profoundly shocked, cachectic, or very old; in other words, for those who are reasonably good "risks," and can tolerate the inevitable drop in blood pressure. After considerable experience of stovaine, novocain, and spinocaine, we have found neocaine, given by the method described by Koster and Kasman,[1] the most reliable. Over 200 operations have been done under this anæsthetic in the Khartoum and Omdurman Hospitals without any untoward event referable to the drug, and with uniformly satisfactory results. Briefly, the method used is as follows:—

After a preliminary injection of morphia, the interval between the first and second, or second and third lumbar vertebræ is punctured with a fine needle and a quantity of cerebro-spinal fluid is drawn off and mixed with the crystalline neocaine in the glass ampoule in which it is supplied. The solution is then injected slowly through the needle which has been left in place.

For an adult of average weight: 10 mg. of neocaine in 4 c.cm. of fluid give anæsthesia up to the umbilicus; 15 mg. of neocaine in 6 c.cm. of fluid give anæsthesia up to the costal margin; 20 mg. of neocaine in 8 c.cm. of fluid give anæsthesia up to the clavicle.

Immediately after injection the patient is placed in the Trendelenburg position to counteract the cerebral anæmia which follows the invariable drop in blood pressure, and the operation may start within five minutes. Complete anæsthesia lasts for about an hour; if the operation is not completed within this time, novocain may be injected into the peritoneal edges, or a little chloroform given. If there is nausea or retching the head of the table is still further lowered and, if they persist, ephedrine is injected, though this is not often needed. After return to the ward, the head should be kept low until the pulse has recovered its volume. No cases of headache have occurred in this series. This is attributed to the use of a fine needle. The following case illustrates some of the advantages of this form of anæsthetic.

---

[1] Koster, H., and Kasman, L. P.: Surg., Gyn., and Obst., 1929, lix., 6.

A male native, aged 35, was admitted with a history of sudden onset two hours previously of epigastric pain of an agonising character, with vomiting and collapse. For two years previously there had been intermittent pain when the stomach was empty. There was board-like rigidity of the upper abdomen, a subnormal temperature, and a pulse-rate of 80, the pulse being of fair volume.

A preparatory injection of morphia, gr. ¼, had little effect upon the pain, but 15 mg. of neocaine in 6 c.cm. of cerebro-spinal fluid intrathecally produced complete relief from pain and a flaccid abdomen in five minutes. The patient retched once or twice while the abdomen was being opened, but subsequently went to sleep; a perforation in the posterior wall of the duodenum was closed, and a gastro-jejunostomy was performed under advantageous circumstances. Except for some paralytic ileus on the second and third days, the patient made an uneventful recovery.

A constant feature in abdominal cases thus anæsthetised is the contracted state of the intestines (except where there is paralytic or obstructive ileus); the abdominal contents not required can be packed away with ease, thus facilitating intra-abdominal manipulations.

LOCAL ANÆSTHESIA IN ABDOMINAL OPERATIONS

In abdominal work local anæsthesia is most useful: (1) in operations not entailing much handling of viscera—e.g., straightforward appendicectomies, colostomy, ventral hernia; (2) in cases where, owing to shock or debility, the patient is a doubtful risk under spinal or local anæsthesia; and (3) in infants. The technique, in outline, consists in:—

(1) Infiltrating the line of the incision by sub- or intracuticular injection of 1 per cent. novocain, made up with fresh adrenaline, 5 drops to the fluid ounce.

(2) Blocking the cutaneous nerves by a zone of infiltration into the muscle layers, particularly in the neighbourhood of the nerves (intercostal, ilio-hypogastric, ilio-inguinal).

(3) Anæsthetising the peritoneum. This is best done after exposure of the transversalis fascia, or posterior sheath of the rectus, when novocain can be injected beneath it, in contact with the peritoneum.

Novocain injected into the mesentery will usually relieve pain due to manipulation of viscera.

The quantity required is usually between 1 and 2 fluid ounces of the 1 per cent. solution, but more can be used without danger provided that: fresh, unboiled adrenaline solution is added in the strength mentioned; and care is taken that no appreciable quantity is injected directly into a vein.

A native boy of 9 was admitted with a history of colicky pain in the abdomen, beginning with vomiting 12 hours previously. Examination showed a tumour just above the umbilicus and visible small gut peristalsis. There was fæcal vomiting and collapse. After an injection of morphia and local infiltration with 1 per cent. novocain, a right paramedian incision allowed a 12-in. intussusception of the jejunum to be delivered and reduced by manipulation. The intussusception had started at a tumour of the gut wall the size of a walnut; this (a lymphosarcoma) was resected, and an end-to-end anastomosis was done at a subsequent operation under a spinal anæsthetic.

GENERAL OPERATIONS

The following notes indicate the general lines of the procedure used.

Abscess.—Many of the smaller types of abscess, and particularly cold abscesses, can be opened almost painlessly through an incision previously injected intracutaneously with 1 per cent. novocain. Subcutaneous injections should not be used, as the solution will either enter the abscess cavity, where it will be ineffective, or will be forced into the surrounding zone of hyperæmia, where introduction will be painful and possibly dangerous.

Amputations.—The fingers and toes are easily removed after encircling them with a band of hypodermic injection, a little novocain being introduced more deeply over the line of the nerves. The same method serves for removing ingrowing toe-nails and for opening whitlows, but in the latter case care should be taken not to cause venous congestion by injecting too much of the solution, or pain will result.

For amputating limbs, in addition to the encircling subcutaneous injection, the nerves must be blocked by injecting a considerable quantity of novocain into their neighbourhood or, where practicable (as in the upper arm), by exposing them and injecting the trunks under direct vision. This method is extremely valuable in the emergency amputation of crushed limbs.

Inguinal hernia.—Hernia offers one of the easiest and most useful opportunities for local anæsthesia. After subcutaneous or intracuticular injection of the line of incision, the needle is introduced at a point about 2 cm. internal to the anterior superior spine and is carried deep to the fascia of the external oblique, and the ilio-inguinal and ilio-hypogastric nerves are blocked with 4 or 5 c.cm. of anæsthetic. Deep injections can then be made round the internal ring, to anæsthetise the peritoneum and cord, or the neck of the sac and genital branch of the genito-crural nerve can be injected after the inguinal canal has been opened.

Hydrocele and varicocele.—These are easily dealt with by (1) injecting the line of incision as described, and (2) blocking the genital branch of the genito-crural and sympathetic nerves by picking up the cord between the fingers and introducing 3 or 4 c.cm. of solution into it.

Tumours of the lower jaw and tongue.—Local anæsthesia here has the enormous advantage of the collaboration of the patient in spitting up blood which would otherwise find its way into the lungs. A preliminary tracheotomy is unnecessary, and the anæsthetist's intrusions are obviated. For the lower jaw one or both inferior dental nerves are blocked by injection of 3 or 4 c.cm. of novocain into the neighbourhood of the nerves as they lie near the lingula on the inner surface of the mandible, the needle being introduced in line with the opposite canine and following the plane of the biting surface of the teeth until the lingula is felt. A hypodermic encircling injection is then made into the face, enclosing the area of the operation.

Hemi-section of the tongue.—This can conveniently be carried out, if the anterior two-thirds only are involved, by blocking both inferior dental nerves as described above, and also the lingual nerves as they lie on the floor of the mouth.

Madura.—The use of local anæsthesia should be confined to the removal of very small early madura, which can be encircled by a hypodermic injection without risk of penetrating the growth. If the injection penetrates, as it easily may in larger growths, the consequent œdema makes differentiation difficult. The larger growths also need a bloodless field only obtainable with a tourniquet, for which general or spinal anæsthesia is necessary.

Skin grafts.—Thiersch grafts are conveniently cut by encircling the area from which the graft is to be taken with a weal of subcuticular injection of 1 per cent. novocain.

A native man, 50 years of age, entered hospital with a tumour of three months' duration projecting from the external surface of the left mandible. There was an indurated ulcer on the external alveolus opposite the premolars, and the submaxillary lymphatic glands were enlarged but soft. After removal of the teeth, morphia and hyoscine were injected and the left inferior dental nerve blocked inside the mouth with 5 c.cm. of 1 per cent. novocain. A line of subcuticular injection of the same solution was next described round the tumour, and carried forward to the symphysis mentis. Through an incision carried back from the angle of the mouth, and dividing to include the skin adherent to the tumour, the whole mass, together with the body of the mandible from the symphysis to the angle, was removed in one piece. The divided skin and mucosa were sutured. Healing occurred by first intention, and the glands gradually subsided. The growth proved to be an epithelioma invading the bone.

SPINAL ANÆSTHESIA IN GENITO-URINARY OPERATIONS

Spinal anæsthesia is of inestimable value in *suprapubic prostatectomy* on account of (*a*) the excellent relaxation, (*b*) the absence of shock and toxic action on the kidneys, and (*c*) the almost total absence of hæmorrhage due to the fall in blood pressure. If the removal is not done under direct vision and the prostate bed sutured, care must be taken that reactionary hæmorrhage does not follow the rise in blood pressure some hours after operation. In many cases it is advisable to anticipate this by exerting pressure on the prostate bed by means of a hæmostatic bag or gauze plug attached to a catheter in the urethra to which a weight can be suspended.

LOCAL ANÆSTHESIA IN GENITO-URINARY OPERATIONS

Ligature of hæmorrhoids.—Piles can be satisfactorily ligated under local anæsthesia, which gives better relaxation of the sphincter than even deep general anæsthesia; the relaxation appears to last longer with the former method, thus giving freedom from pain after operation. The anus is first encircled by a weal of subcutaneous 1 per cent. novocain. One finger is then placed in the anal canal, and under its direction a needle is passed, at intervals of about 2 cm., deeply into the sphincters and under the anal mucosa, 2 c.cm. being injected at each spot. The needle point should be kept moving so as to avoid injecting into the veins. After a few minutes the sphincter will be found relaxed, and the operation can proceed.

Suprapubic cystotomy.—Either for the removal of calculi, or as a preliminary to prostatectomy, suprapubic cystotomy is easily performed under local anæsthesia provided that novocain can be injected via the urethra. It is particularly useful in the case so often already on the edge of uræmia, in which there has been long-standing prostatic obstruction. Ten to twenty cubic centimetres of 5 per cent. novocain with two drops of adrenaline are first injected into the bladder with an ordinary urethral syringe, the bulbar urethra being massaged to pass the solution upwards. A hypodermic weal is next formed along the line of the suprapubic incision with 1 per cent. novocain, a little being also introduced beneath the rectus sheath. The bladder is then exposed in the usual way, a further injection being made into the thickness of its wall before it is opened. If the peritoneum has to be stripped up, as is sometimes the case in contracted bladders, it should first be infiltrated with novocain.

Fistula in ano.—This is treated as for hæmorrhoids.

LOCAL ANÆSTHESIA IN EYE, NOSE, AND THROAT OPERATIONS

Many operations on eye, nose, and throat are so commonly performed under a local anæsthetic that no comments are needed. The following, however, may be less familiar.

Trichiasis.—The operation of splitting the inverted lid margin and tarsal plate and inserting into the cleft an epithelial graft from the lip can be done under local anæsthesia as follows. The conjunctival sac is anæsthetised by instillation of cocaine drops at half-hourly intervals thrice in the ward, morphia being given with the third. On the table, the lid affected is injected with 2–3 c.cm. of 1 per cent. novocain, a little being also introduced with a fine needle into the conjunctiva of the under side of the lid. The lip which is to provide the graft will also need an injection of 2 or 3 c.cm.

Enucleation of the eye.—This can be done painlessly by injecting 1 or 2 c.cm. of 1 per cent. novocain to the neighbourhood of the otic ganglion, the needle being passed inwards along the outer wall of the orbit for a distance of 2 cm. and then a little towards the nasal side. A little solid cocaine may also be placed in the conjunctival sac and, if there is blepharospasm, the lids should be injected with novocain.

CONCLUSIONS

It is emphasised that no originality is claimed for any of the procedures or technique described, all of which are fully described in text-books of local anæsthesia. Of these, the writer has found Farr's [2] to be the most useful. The intention has been to give a brief account of the type of case found most suitable for spinal and local anæsthesia in a general surgical practice in the tropics.

FAMILIAL HEPATOMEGALY OF UNCERTAIN PATHOLOGY

By E. Bellingham Smith, M.D., F.R.C.P. Lond.
PHYSICIAN, ST. GEORGE'S HOSPITAL, AND SENIOR PHYSICIAN QUEEN'S HOSPITAL FOR CHILDREN
AND
Elizabeth O'Flynn, M.R.C.P. Lond.
PATHOLOGIST, QUEEN'S HOSPITAL FOR CHILDREN, AND ASSISTANT PATHOLOGIST, NATIONAL HOSPITAL, QUEEN-SQUARE

The following report of a case of hepatomegaly in a child embodies certain clinical and pathological data, not previously recorded in this country, and for which we were long unable to find any adequate explanation. A recent search of foreign literature has revealed, however, two cases which have somewhat similar pictures; an abstract of one of these is appended.

Our patient was a boy, aged 6 years, who was admitted into the Queen's Hospital for Children on Feb. 16th, 1931, for cough, breathlessness, and abdominal pain.

History of the Case.—The mother had first noticed some enlargement of the abdomen at the age of 1 year and 3 months and since that date the child had been almost constantly in hospital. Various diagnoses appear to have been made, such as enlarged liver and spleen, cirrhosis of the liver, and, finally, while under the care of one of us at the Queen's Hospital, he was shown at the section for the study of diseases of children of the Royal Society of Medicine in April, 1931, as a case of Gaucher's disease. This last diagnosis was founded on the recovery of tissue pulp, containing large clear cells, from what was thought to be splenic puncture, but which in reality was obtained by puncture of an enormously enlarged left lobe of the liver. The pitted scar following this operation was visible at the post-mortem.

---

[2] Farr, R. E.: Practical Local Anæsthesia, London, 2nd ed., 1930.

Hæmatemesis and epistaxis were recorded as having occurred prior to admission to other hospitals, but these were not noticed during the ten months that the patient spent in the Queen's Hospital. There had never been any jaundice, but cough and breathlessness had been a marked and increasing symptom for two years. More recently the cough had been very severe, and was accompanied by a profuse and fœtid expectoration.

Clinical Notes.—On admission to hospital this child presented a curious facial appearance, and bodily development, which is well shown in the accompanying photograph (Fig. 1). He was undersized—height 3 ft., weight 2 st. 6 lb. The head was abnormally large, the face fat and flabby. The abdomen was enormously distended, while the rest of the trunk and limbs were poorly covered. The muscular development of the lower limbs was particularly poor, and there was marked knock-knee and flat-foot. The skin of face, trunk, and limbs was pigmented a deep brown; the hands and feet were a dark ashy grey colour. This pigmentation steadily increased, so that shortly before death the boy resembled a mulatto. There was a profuse growth *of hair on the head and on the trunk and the back, and* the limbs were covered with a fine downy hair. Mental development was considerably retarded; speech was limited and defective. Jaundice was absent, and stools and urine were normal. There was some clubbing of the fingers, but this could be explained by the presence of an advanced fibrosis and bronchiectasis affecting both lower lobes. The child was subject to violent and paroxysmal attacks of coughing in which large quantities of fœtid sputum were expectorated.

The abdomen was prominent and hard. The liver was greatly enlarged, the liver border reaching to the crest of the ilium on the right side and passing thence obliquely upwards to the left to merge with what was thought to be a large spleen. This apparent splenic enlargement filled the whole of the left hypochondrium, and extended thence downwards and forwards to just below the level of the umbilicus. *Its antero-internal border appeared to present a* typical splenic notch. Dullness was continuous upwards into the left axilla to the level of the nipple. This presumed enlargement of the spleen was shown at autopsy to be a greatly enlarged left lobe of the liver. The surface of the liver was smooth, the edge hard. There was no ascites.

The stools on admission were a little loose and pale, but later showed no abnormal characteristics, and the fat content was normal. Neither kidney was palpable, and the urine was clear, contained no albumin, no sugar, no casts, and was free from bile. The usual physical signs of an advanced fibrosis and bronchiectasis were present in the lungs, and occasional exacerbation of a pneumonic character appeared to take place, so that at the end the major part of the right lung was affected in addition to the left lower lobe.

The heart presented no abnormal features; the blood pressure was 110 systolic. The blood count, which was done on several occasions, gave the following readings respectively on Feb. 22nd and April 24th, 1931:—

R.B.C. ..	3,540,000	R.B.C.	3,970,000
W.B.C. ..	.. 15,733	W.B.C.	.. 20,400
Hb.	.. 77 %	Hb.	.. 51 %
Differential—		Differential—	
Polymorphs	.. 40 %	Polymorphs ..	.. 39 %
Lymphocytes	.. 52 %	Lymphocytes ..	.. 50 %
Hyaline ..	.. 8 %	Large mononuclear	.. 4 %
		Mast cells ..	.. 2 %
Megaloblasts	.. 8 %	Myelocytes ..	.. 5 %
		Two megaloblasts	

The blood-urea was 18 mg. per cent.; blood-sugar, 95 mg. per cent.; blood cholesterol, 220 mg. per cent.; van den Bergh, direct and indirect, was negative; Wassermann, negative; fragility of red cells, normal.

On Dec. 27th, 1931, *the patient, while coughing,* was seized with violent abdominal pain, and collapsed and died.

POST-MORTEM FINDINGS

The *abdomen* contains about 6 oz. of clear yellow fluid. The cavity is almost completely filled by the liver, which descends to the pelvic brim on the right side, and to within two inches of it on the left side. It weighs 2500 g. It is nowhere adherent. The normal division into lobes is preserved. It is smooth, firm, pale buff in colour. Its edges are well-defined. Its consistency is that of hard rubber. On incision, the cut surface is smooth, homogeneous, very dense, and somewhat translucent. On close inspection some very minute pale yellow areas are seen to be distributed evenly throughout. The portal tracts appear collapsed, no dilatation of ducts observed. The gall-bladder looks normal and contains about a drachm of viscid bile. Test for amyloid disease negative. The *spleen* weighs 75 g. Its capsule is shrunken, and the splenic pulp is rather soft and vascular. The cut surface is homogeneous. *Kidneys* are congested and slightly enlarged, suprarenals normal. The pancreas is normal.

Thorax: Heart dilated and fixed by adhesions to the right and left pleura. *Lungs* show fibrosis and bronchiectasis. No normal lung tissue to be seen. An abscess cavity *is present in the lower part of the left upper lobe.* Radiating from the hila are clusters of soft enlarged glands which penetrate the lung tissue for a considerable distance and appear to surround the bronchioles in their finer ramifications. From the hila these can be traced up the lateral aspect of the œsophagus and trachea as far as the thyroid gland. In appearance they resemble hæmolymph glands.

Sections of the liver stained by hæmatoxylin and van Giesen show under low power a structure very unlike the normal. Division into lobes and lobules is ill-defined, especially at the periphery, due to the invasion of the liver parenchyma by fine strands of connective tissue. There is a condensation of connective tissue in the portal areas with consequent compression of the smaller ducts, but no pericellular invasion by connective tissue. There is some cellular reaction in the portal spaces.

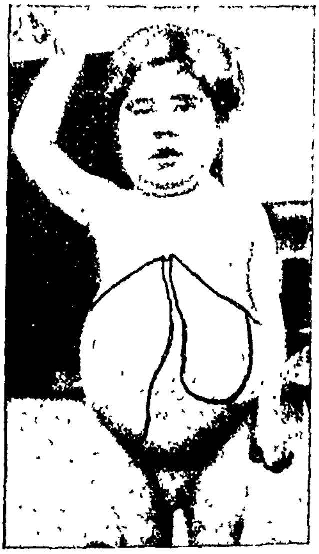
Under the high power (Fig. 2) the most striking features of the sections are: (1) the emptiness of the individual liver cells; (2) their increase in size—sometimes to two or three times the normal; (3) the preservation of the nucleus in most cells; (4) the increase in connective tissue in the region of the portal spaces; (5) the grouping of cells, in groups of 4 to 20, by fine connective tissue strands. Occasionally an area is seen where clusters of liver cells appear to contain a trace of protoplasm staining brown. The nucleus, in many cells, is represented by its nuclear membrane only.

In sections stained by Sharlach R most of the cells appear empty. Sharlach-positive material is present in some of the cells, and a considerable amount of neutral fat in the portal spaces. The substance in the liver cells consists of some material which is neither fat nor lipoid, and is not doubly refractile.

Sections stained by *Bielchowsky's method* failed to demonstrate the presence of a stroma, such as is seen in the cells in Gaucher's disease. This is interesting in view of the clinical diagnosis previously arrived at.

Sections stained for glycogen were negative. This was to be expected, owing to the rapidity with which glycogen disappears from the tissues after death and, unfortunately, alcohol was not used as a fixative.

FIG. 1

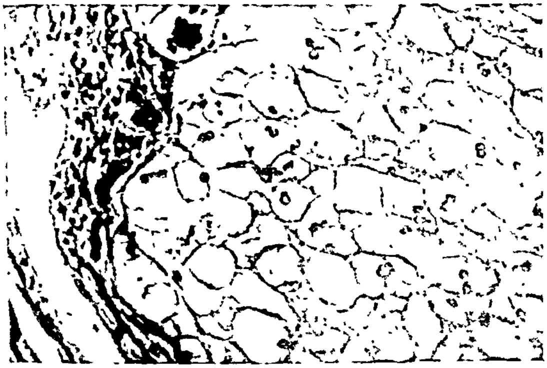


Photograph of child reproduced from Proc. Roy. Soc. Med. (1931, xxiv., 1031), where the case was reported by Dr. W. C. Hartston. At this time, as the marking shows, the swelling on *the left* was regarded as the spleen.

Chemical Examination of the Liver.—The dried material gave on analysis: ether extract, 1·202 per cent. of dry matter. The extract contained: free cholesterol, 0·728 per cent., which is within normal limits, but on the low side; cholesterol esters, 0·060 per cent., which is much below normal; fat and fatty acids, 0·414 per cent.

An inquiry into the family history showed that mother and father were presumably healthy. There were two other children, one an infant, alive, to whom we have been unable to get access, and the second, a girl, who also had a very enlarged liver, and who died of a terminal pneumonia at the age of 1 year and 8 months at Whipps Cross Hospital. The superintendent informs us that she was a thin rickety infant, suffering from diarrhœa and occasional vomiting. At the post-mortem the spleen was found to be only very slightly enlarged, but the liver was enormous, weighing 2 lb. 10 oz. The liver is described as having no typical parenchyma, and being in a state of extreme fatty degeneration. The similarity of this case to that of her brother, our patient, suggests that the condition may be familial in character.

FIG. 2



Microscopic appearance of liver section showing enlarged cells. (× 165.)

SUMMARY

The outstanding and unique features of this case appear to be: (1) the familial character; (2) the pigmentation of the body; (3) the absence of any insufficiency of hepatic function during life; (4) the naked-eye appearances of the liver in respect of size, colour, consistency, and entire absence of any resemblance on section to normal liver; (5) the abnormal histological character of the liver cells themselves.

A search through the literature of familial hepatomegaly reveals the fact that the case is of very great rarity. A similar one was described by E. von Gierke under the title of "Hepato-Nephromegalia glykogenica."[1] A child, aged 8, with considerable enlargement of the liver and a tendency to nose bleeding, who had had rickets, died of laryngitis. Post-mortem examination showed an enormously enlarged liver (2000 g.), and kidneys (245 g.), in addition to acute pulmonary changes. Microscopical examination showed that the cause of the hepatic and renal enlargement was an intense overloading of the parenchymatous cells with glycogen. Extract of the liver contained 1·60 per cent. free sugar and 10·43 per cent. glycogen. The dried substance contained 4·95 per cent. free sugar and 33·70 per cent. combined sugar. Extract of kidney contained 0·71 per cent. free sugar and 6·53 per cent. glycogen. Dried extract 3·91 per cent. free and 36·82 per cent. combined sugar. The most important part of the disease, therefore, was the exaggerated storage of glycogen, probably due to deficiency of the glycogenolytic factor, an error of metabolism, anenzymatosis or hypoenzymatosis. Besides the name given in the title, the name glycogen-storing disease may be used.

Von Gierke says: "Although we were unable to demonstrate glycogen in this case, owing to the fixative used, we are strongly tempted to suggest that the enlargement is due to glycogen storage." Menetrière and Rubens Duval[2] described a case resembling ours in its histological appearance, but in their case the infant was definitely syphilitic. They also suggested that the enlargement of the cells was due to distension with glycogen.

We are indebted to Dr. A. J. Gardner, of St. George's Hospital, *for chemical analysis, and to* Dr. J. G. Greenfield, of the National Hospital, for the microphotograph.

Clinical and Laboratory Notes

THE MODERN OPERATIVE TREATMENT OF DETACHMENT OF THE RETINA

By R. AFFLECK GREEVES, M.B. LOND., F.R.C.S. ENG.

SENIOR OPHTHALMIC SURGEON, MIDDLESEX HOSPITAL; OPHTHALMIC SURGEON, MOORFIELDS HOSPITAL

LESS than five years ago a diagnosis of retinal detachment was almost synonymous with a sentence of hopeless blindness on an eye so affected; it is true that various methods of treatment, operative and otherwise, had been advocated from time to time and that indeed some genuine successes had been obtained, but in practice these successes were found to constitute a sadly disappointing percentage of the number of cases treated. The method of procedure employed in most of the operations was to perforate the sclerotic with the purpose of draining away the subretinal fluid and so to obtain replacement of the retina. The point chosen for this puncture corresponded as far as possible with the centre of the area over which the retina was thought to be most separated from the underlying choroid. Perforation was usually made with the red-hot galvano-cautery, partly because of its hæmostatic effect but chiefly owing to the greater amount of inflammatory reaction produced by the cautery than by a cutting instrument; it was hoped that the retina after its reposition by evacuation of the underlying fluid would become adherent to the choroidal scar and so be anchored in place.

That rents or holes might occur in detached retinæ was a matter of common experience, and indeed some observers had gone so far as to say that retinal ruptures were present in all myopic detachments. To Jules Gonin, however, belongs the credit of having first pointed out in 1929 the significance of these retinal holes, and so to have laid the foundation upon which all modern work on retinal detachment has been based. Gonin showed that holes in the retina could be found clinically in almost all cases of retinal detachment if sufficient time and care were taken in searching for them, and that if the retinal hole were carefully located and the site of the cautery puncture in the sclerotic chosen so as to correspond accurately with the position of the hole, the percentage of successful results was enormously increased. He found that by placing the cautery puncture in this situation an adhesion between the area of retina surrounding the hole and the choroidal scar was obtained, and that in this way the hole in the retina became closed; also, that the success of the operation depended on the closure of the hole in the retina.

Those ophthalmic surgeons who adopted Gonin's operation soon found it to be a great improvement upon the older ones, as shown by the increased proportion of successes, but it soon became evident that this method was not entirely satisfactory. Not only was the exact localisation of the retinal hole a difficult matter, but even when this was successfully accomplished the hole was often too large to be covered by the scar of a single cautery puncture, and the operation had to be repeated perhaps more than once. Also, a single adhesion between retina and choroid over so small an area frequently proved to be insufficient, and for this reason a temporary success was sometimes obtained which was subsequently nullified by the tearing away of the retina from the adhesion, with consequent recurrence of the detachment.

Other methods were therefore devised with a view to producing a more extensive adhesion between retina and choroid. One of these is that practised by G. Guist; he advocates the removal of a number of discs from the sclerotic over an area larger than the retinal hole by means of a trephine, 1½ mm. in diameter, care being taken to leave the choroid coat intact. The choroid so exposed is then touched with a pointed stick of caustic potash through each trephine hole in turn, the caustic being at once neutralised by acetic acid. Finally, the subretinal fluid is evacuated by a single perforation of the choroid through one of the trephine holes. This operation gives fairly good results but has proved to be an extremely tedious and lengthy one, and as far as Moorfields is concerned it has been superseded by the method of S. Larsson, who uses the diathermy current to make the necessary series of choroidal scars over a sufficiently wide area. This method is rapid, easy of application, and like Guist's operation does not entail the careful localisation of the retinal hole. A suitable electrode is held in contact with the sclerotic for a period of about five seconds at each point in turn, the strength of the current having been so adjusted as to cause scarring of the choroid without perforating the sclerotic.

An area of sclerotic large enough to more than cover the extent of the retinal hole is thus treated and when this has been done a single perforation of sclerotic and choroid serves to drain away the subretinal fluid and to bring the retina into place.

I do not propose to give a detailed analysis of the cases treated at Moorfields, but a bald statement of my own results will show how encouraging those obtained by Larsson's method have been.

	Cases operated on.	Complete reposition of retina.
Gonin's operation	16	5
Guist's ,, ...	4	2
Larsson's ,, ...	10	8

I have purposely omitted from each section of this list a few cases in which the chances of success were not favourable from the outset, owing to the fact that no retinal hole was discoverable—several of these were cases of retinal detachment following removal of the lens which had been done some years previously. I have, however, included all those in which a retinal hole was present; some of the successful cases had to be operated upon more than once before complete reposition of the retina was obtained, especially among those treated by Gonin's method.

THE RESTORATION OF CENTRAL VISION

With regard to the question of restoration of central vision after operation, the limit of visual acuity obtained probably depends on two factors: first, whether the area of detachment has involved the macula, and secondly, the length of time during which such a detachment has been present. In one case of detachment of five years' duration (the longest period, as far as my cases are concerned, after which success followed operation) an acuity of 6/60 resulted. In most of my cases central vision has tended to show a gradual improvement for some time after the operation, and some patients have ultimately recovered good visual acuity.

It must, of course, be remembered that these operative measures are of very recent date and that several years must elapse before the subject can be regarded with a proper sense of proportion. In my opinion, however, such cases as have been kept under observation warrant the hope that the results obtained will in the main prove permanent.

SUBPHRENIC ABSCESS AND HEPATIC FRICTION

By Walter Broadbent, M.D. Camb.,
F.R.C.P. Lond.
SENIOR PHYSICIAN TO THE ROYAL SUSSEX COUNTY HOSPITAL, BRIGHTON

A MAN of 52 had a sudden acute attack of pain in the right epigastrium, which spread to the right under the lower ribs. He did not vomit. When seen by a doctor two hours later the pain was acute, the temperature 100° F., and friction was audible *for about 4 inches above the right lower rib margin* in front. A diagnosis of pleurisy was made. The next day the pain was much less, the temperature 102°. The friction had gone, the breath sounds at the right base were diminished. During the week the man became steadily more ill, his tongue dry and brown, and his temperature 99° in the morning and 102° to 103° at night. Dullness had progressed up to above the angle of the right scapula. A needle had been inserted, but no fluid was found.

When I first saw him this dullness was marked, but, on deep inspiration, weak breath sounds and fine crepitations could be heard almost down to the base. In front there was diminished resonance in the right third and fourth spaces, but from the fifth space down to the rib margin resonance was tympanitic. On tapping one coin on another a bell note could be heard from the fifth rib down to an inch above the umbilical level in the right nipple line. This bell note area narrowed up to the ensiform cartilage, but widened towards the axilla. Breath sounds, which were fair in the upper chest, ceased suddenly where the tympanitic area began. The heart was pushed upwards and outwards, the apex being in the fourth space 1½ inches outside the nipple line.

This was evidently a subphrenic gas-containing abscess, and a needle inserted in the anterior axillary line in the eighth space let out foul gas and thin fœtid pus. Later, a portion of rib near the costal margin was removed, and a large abscess opened. A hard irregular ridge could then be felt across the right side of the abdomen about an inch above the umbilical level. Unfortunately the man died and no post-mortem was allowed, but this ridge must have been adherent, omentum and colon forming the lower limit of the abscess. The origin of the trouble was, almost certainly, a perforated duodenal ulcer with a slow leak, not sufficient to cause vomiting. In similar cases the gall-bladder and also the falciform ligament become glued by peritonitis to the duodenum and colon, and the colon to the abdominal wall, a channel being formed with the gall-bladder and falciform ligament on either side and the liver and colon above and below, up which the duodenal contents spread round the margin of the liver on to the surface of the right lobe, and form a subphrenic gas-containing abscess.

The friction, which led to the erroneous diagnosis of pleurisy, was really hepatic friction caused by the diaphragm rubbing on the inflamed upper surface of the liver. Hepatic friction may also be heard in the early stage of a perforated gastric ulcer near the pylorus and in some cases of cholecystitis.

INFLUENZA, ACIDOSIS, OR APPENDICITIS?

By William Goldie, M.B. Aberd.
House Physician, Aberdeen Royal Infirmary

In The Lancet of Jan. 21st (p. 141) Dr. H. L. Marriott reports on 47 cases of influenza. Seven of these cases belong to the alimentary type of the disease, which Marriott thinks might well be mistaken for an acute surgical abdominal condition. The definite tenderness in the right iliac fossa naturally suggests the possibility of acute appendicitis. In the January number of the *Practitioner* Dr. A. H. Douthwaite also draws attention to this difficulty in diagnosis, and says: "Probably in no year have the symptoms been so striking as in 1932, when in the early spring numerous abdomens were opened in the faulty diagnosis of appendicitis." He also states that in the absence of a leucocyte count the appendicular form of influenza may ape acute appendicitis so closely as to render accurate diagnosis impossible.

In the following case the differential diagnosis was rendered still more difficult by a complication which can itself simulate acute appendicitis extremely closely.

The patient, a woman aged 24, was admitted to the Aberdeen Royal Infirmary under the charge of Prof. Stanley Davidson on Jan. 11th in diabetic coma. For the three days prior to admission the patient had suffered from malaise, headache, nausea, and vomiting, followed by severe pain in the lower abdomen and the onset of coma. The family doctor suggested that the factor precipitating the coma was acute appendicitis.

State on examination.—The patient was in coma. Pulse-rate, 96. Temperature, 100° F. Urine and breath loaded with acetone. Blood-sugar, 475 mg. per 100 c.cm. Unconsciousness was not complete, since it was still possible to arouse the patient to some slight degree. All the classical signs of diabetic coma were present. Despite her comatose condition, when the appendicular area was palpated the patient immediately groaned and her reflex defence mechanism produced a boarding of the right rectus muscle and a flexion of the thigh on the hip. In addition the cæcum felt distinctly boggy. The white cell count showed that 28,400 leucocytes per c.mm. of blood were present, most of which were neutrophil polymorphs.

There seemed to be three possible causes of the abdominal manifestations:—

(1) *Gastro-intestinal influenza.*—In favour of this view there was (*a*) the fact that an influenzal epidemic was raging in Aberdeen and that a case of influenza was present in the home of the patient; (*b*) the onset and character of the symptoms were suggestive of influenza. Against the diagnosis of influenza was the finding of a marked leucocytosis. It was possible, however, that the leucopenic blood picture of influenza had been masked by the opposing effect of acidosis, which is known to produce an increased leucocyte count in many cases.

(2) *Acute appendicitis.*—In favour of this diagnosis was the marked and extremely localised tenderness and rigidity over the appendicular area, and the high leucocyte count. Against this diagnosis was the absence of symptoms suggestive of previous attacks of appendicitis, and the fact that the abnormal signs cleared up with the acidosis in a few days. The history of the premonitory symptoms was more characteristic of influenza than of acute appendicitis.

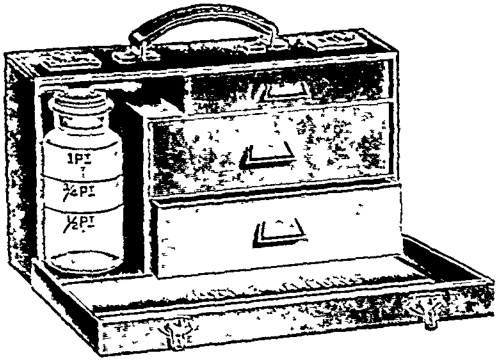
(3) *Acidosis and diabetic coma.*—It is recognised that in severe acidosis abdominal symptoms may be severe and so similar to those of acute appendicitis that laparotomy has not infrequently been performed. Against this diagnosis was the degree of the leucocytosis, the extreme tenderness and definite localisation of the area of rigidity present, and the raised temperature. In conclusion it seemed more probable that a genuine inflammatory condition of the cæcum and appendix was present, but it is impossible to say whether this was appendicitis or a blood-borne inflammation of the bowel as is believed to occur in abdominal influenza.

Surgical measures were not adopted in this case. The usual treatment of diabetic coma was undertaken and the abdominal signs cleared up in a few days.

NEW INVENTIONS

THE PHLEBOTOMIST'S CARRIER

I have devised the handy case illustrated for carrying French's phlebotomy apparatus. The case is stoutly built of fabric and three-ply wood, covered with brown rexine; and the lid when open lies flat, so as to form a tray. The bottle is retained upright by means of a web strap affixed to the back. There are three drawers to carry all accessories. The measurements of the case over all are: 16" by 9" by 4"; and of the drawers the top measures 8¾" by 3" by 1¼", and the middle and lowest 10¼" by 3¼" by 3¼". The carrier is provided with spring locks and key.



Messrs. Allen and Hanburys, Ltd., Bethnal Green, London, E., are the makers.

S. Watson Smith, M.D., Ch.B. Edin.

Glasgow Royal Infirmary: Annual Report.—The recently completed year's working shows that the ordinary income has fallen short of the expenditure by £30,000; in the previous year the deficiency was about £24,000. By using free legacies, however, the accounts have been squared and a small balance carried over to the current year. It is claimed that the reconditioning of the X ray department, now in progress, will make it "in advance of any similar institution in Scotland." Of the 76 probationer nurses who entered for the preliminary State examination all passed but one; in the final there were only three failures out of 66. It is proposed that the bursary of £170 provided by Mrs. Chrystal, of Auchendennan, should this year be given as a travelling scholarship to allow of a trained nurse visiting hospitals in this country, on the continent, or in America. In his speech at the recent annual meeting the Lord Provost urged young women, whatever their position in life, to take a nurse's course "with the object of acquiring a useful training for the ordinary duties of life."

MEDICAL SOCIETIES

ROYAL SOCIETY OF MEDICINE

SECTION OF TROPICAL DISEASES AND PARASITOLOGY

At a meeting of this section, held on Feb. 2nd, the chair was taken by Dr. H. S. Stannus, the president, and a paper on an examination of

Tropical Neurasthenia

was read by Prof. Millais Culpin. He said that the knowledge of neurasthenia was slight, but the conception of it had recently changed. Its distribution even in this country was capricious and often difficult to explain, and its incidence in the tropics was possibly no greater than in some other places. The word had appeared in the eighteenth century, and had been introduced to describe a condition of nerve-wasting, a conception which had harmonised with the materialistic attitude of the time. In what had been termed the "rubbish-heap" of neurasthenia were included anxiety states and obsessional states. When individual cases of "neurasthenia" were clearly described, in accordance with modern psychopathology, the clinical scope of the diagnosis narrowed almost to vanishing point. Anxiety and obsessional states were based on psychological factors and students should be taught to diagnose them. When they were excluded there remained only a temporary state described by Farquhar Buzzard as "autonomous depression," a condition of fatigue, like that after influenza, which did not respond to psychotherapy but recovered spontaneously. It was rare—not more than 5 per cent. of all cases seeking psychological help. The trouble was a reaction of the man as a whole rather than a physical or biochemical change in nervous tissue. Two opposite ætiologies had been set forth by past writers: hard work and stress by some, and dissipation and sin by others.

The phrase "tropical neurasthenia" suggested a direct physical influence of climate, but the dweller in tropical countries was subjected to very numerous depressing and irritating stimuli. He was never at rest, and always on guard, often anxious about personal safety, health, and finance. Innumerable physical causes had been suggested, but it was impossible for anyone who approached the problem from the psychological aspect to argue with those who insisted on a physical basis. Obviously tropical diseases might have an influence on nervous disorders; any debilitating condition might allow a latent psychoneurosis to become manifest, and bowel troubles might be psychologically determined, as in mucous colitis. Any associated physical condition should be treated, apart from the neurasthenia. It was difficult to estimate the incidence of tropical neurasthenia because the condition was disguised under physical diagnoses such as bowel disorders, "D.A.H.," and malaria. Neurotic patients might unwittingly mimic tropical diseases, and people who had had malaria often described as "malarial rigors" subsequent anxiety attacks. A rise of temperature might even occur in hysterical "rigors."

Prof. Culpin recounted his own experiences in Queensland and Shanghai. In a tropical district of the Australian bush there had been scarcely any illness and no nervous troubles. The people had all done heavy manual work and paid little respect to the hot sun. There was a great psychological difference between taking exercise for the sake of exercise and doing hard work for an end in view. Rigidity of occupational conditions everywhere favoured nervous disorder. For this reason the wife was more liable than the husband; she had to work hard in the same hot ill-ventilated kitchen day after day, while he could change his place of work and was in the open air. The great difference between the Queensland area and Shanghai was that the inhabitants of the former regarded it as their permanent home. In Shanghai there had been a good deal of nervous breakdown, but its incidence had been very small among the lower classes who had settled there. The disorder was very rare indeed on the Anglo-Persian oilfields, and this was explained by the careful intuitive psychological selection of candidates. Another factor in preventing nervous breakdown was satisfaction and a sense of security among employees, and another was a medical staff awake to the psychoneurotic temperament, its early symptoms, and the treatment. Medical students ought to be able to answer the question: "What do you think of that man's psychoneurotic state?" as readily as the question: "What do you make of that man's heart?" The stimulus that produced breakdown might be one or several of very many things, and if it were strong enough almost any man might break. Hard work never caused more than a physiological breakdown from which recovery was swift and sure. There was, however, a pathological urge to overwork, based on obsession, which preceded suicide. People had nervous troubles in the tropics just as elsewhere, and there was no justification for assuming any form of neurasthenia peculiar to the tropics. When the trouble arose it should be treated in the same way as a minor psychosis anywhere else.

INVALIDING FOR NERVOUS CAUSES

Dr. H. C. Squires interpreted "tropical neurasthenia" as all those disabilities of Europeans in the tropics, other than the psychoses, which came within the scope of psychological medicine. They caused an immense amount of invaliding, and yet the medical officer received little or no training in their diagnosis and treatment. The most striking feature of such statistics as were available was the high percentage of invaliding for psychological reasons after less than four years' service. The chief ætiological factor was the action of stresses on people of a certain constitution, rather than the effect of abnormal stresses on ordinary people. The emotional factors were more important than the physical agencies such as light, heat, and dust. Those who found acclimatisation difficult usually manifested indications of the neurotic constitution. Sex influenced a man according to his life style. With a man for whom virility was the essential symbol of manhood, tropical conditions might raise unbearable conflict, which might be mitigated by liaisons with native women or by neurosis. Sexual intercourse might be the symbol of masculinity, and the assertion of his power and authority to a man living in a primitive and warlike community.

Dr. Murdo Mackenzie described some cases in which tropical life had precipitated a neurotic state somewhere between the major and minor psychosis. In each of them there was a difficult psychological situation which had not essentially anything to do with the tropics. The only really typical case of neurasthenia he had seen had subsequently manifested tabetic signs! Neurasthenic symptoms might also appear in retarded cases of schizophrenia.

Dr. P. H. MANSON-BAHR said that the London School of Tropical Medicine would soon become a school for the study of neurosis in the tropics. Tropical diseases were playing a very small part in invaliding now: 1 per cent. as opposed to 30 per cent. of psychological disorders. The psychotherapist ought to play a very important part in the examination of candidates. A rugger blue, apparently an ideal empire-builder, might come back in three or four years psychoneurotic. Moreover, the problem arose whether such a case should ever go back. The monotony of tropical life was an ætiological factor worthy of consideration. Patients started with insomnia, and then began to imagine things.

Sir MALCOLM WATSON spoke of 28 years in the Malay Peninsula with a day temperature of 90°, a night humidity of 95–100°, cicadas, bull-frogs, and termites, as well as the social habit of taking alcohol. Malaria had at first been so bad that white women could not live there; 90 per cent. of the men had lived with native women, but this had not affected them in any way. Later, the country had been almost freed from tropical disease, but cases of unfitness for the duties of life had become a problem. There was a certain cure: to send the victim to a hill station regularly for two or three weeks every year. There had been a great increase of neurasthenia during the war when leave was scanty. Eight hours sleep and sweating from active exercise were essential. He agreed that hard work did no harm. Since the war alcoholism and living with native women had much decreased but neurasthenia had increased.

Dr. R. A. O'BRIEN said that neurasthenia was no more a tropical disease than pneumonia, but it caused a grave amount of permanent invaliding. In 1930 the West African service had lost 49 people, 11 for neurasthenia or psychasthenia. In 1931 there had been 13 neurasthenics and 4 alcoholics out of 48 invalided. In the Dutch West Indies the figure for "neuroses" had been between 40 and 59 per cent. of those sent home invalided. A European degenerated physically in the tropics, and probably also mentally. He met more obnoxious stimuli in the tropics than at home and so was far more liable to neurasthenia.

Dr. R. TRAVERS SMITH thought that the astonishing thing was that so few people broke down. Everybody going to the tropics was potentially nervous, and in the tropics they met stimuli likely to break them down. The greatest sufferers were brides, who failed to adapt themselves to married life, cut off from home and friends. Children born in the tropics were over-terrified by their parents of the sexual aggression of the natives. Separation from the mother—the mother-country—had a profound psychological effect. The sun also had profound psychological significance. The heat stimulated sexuality, causing severe conflict. Social conditions promoted alcoholism, which reduced ego-control. Tropical neurasthenia, however, differed in no way from home neurasthenia. Psychoneurosis developed at home might be cured by residence in the tropics.

Dr. DAVID FORSYTH welcomed the spread of psychology into all branches of medicine. He supported Prof. Culpin's views, especially as to the rarity of "true" neurasthenia. Men invalided home were obviously of neurotic constitution, and one motive in selecting foreign service was to escape from the difficulties of life at home. Some had failed to get on at home because of a negative, quarrelsome attitude; others suffered from inferiority and thought life would be easier among an inferior race; while others had suffered from morbid shyness, particularly in the presence of women, and had escaped from this by going abroad. Psychological investigation of candidates would detect these types.

Dr. W. E. COOKE supported Dr. Manson-Bahr's plea for help in assessing the fitness of candidates. Bowel diseases had an enormous effect on the mind; some people "lived in their bowels." The prevalence of helminth diseases and their effect on the mind required a good deal of study before all these conditions were classed as mental.

The PRESIDENT emphasised the necessity of knowing some psychology, and the importance of agreeing with the companies concerned what kind of examination should be made. One of the most calamitous cases he had ever seen had been a rugger blue. None of the "old stagers" had had neurasthenia, though they had often drunk freely. People who had any interest in their bowels were a priori neurasthenic.

Prof. MILLAIS CULPIN replied. He said he did not believe that white men degenerated in the tropics.

SECTION OF LARYNGOLOGY

A MEETING of this section was held on Feb. 3rd, Mr. MUSGRAVE WOODMAN (Birmingham) presiding. Mr. G. GORDON-TAYLOR introduced a discussion on

Malignant Disease of the Oropharynx

He said that the extirpation of primary malignant growths of the oropharynx and fauces practically never now involved the use of the old-fashioned knife, the modes of surgical attack being almost limited to diathermy or one of the various forms of radiation. In this respect the surgery of those parts corresponded with the surgery of the buccal cavity; the knife was only required for the subsequent fashioning of flaps to fill the gap produced by the operation. Though diathermy was at one time disparaged surgeons seemed to be now agreed that diathermy was one of the methods of election for carcinoma of the oropharynx. The endothermy knife was now often used for this purpose. Most surgeons preferred the ordinary knife for removing infected tissues and lymphatic glands in the neck, and he was not convinced that the late results of block dissections were improved by using the endothermy knife, or by the subsequent use of Columbia paste. Where the primary growth was infiltrating, or the lymphatic glands of the neck were involved, the patient was subjected to preliminary dissection of the neck, and the external carotid artery was tied. Mr. Gordon-Taylor had only twice seen severe secondary hæmorrhage following diathermy excision of carcinoma of the tongue; it was easily controlled. He had had one fatal case from severe hæmorrhage following diathermy for malignant disease of the tonsil; in that case the external carotid had not been tied. In the more advanced type of case it might be necessary to gain access to the tumour either by splitting the cheek, or by removing the alveolar or the upper border of the jaw.

When access was insufficient without splitting the cheek, the removal of half the mandible back to the condyle of the jaw gave good access to the base of the tongue in the neighbourhood of the tonsil. In carcinoma of the hypopharynx he tried to preserve the sternomastoid muscle, and in oropharynx cases he was sometimes able to preserve it. Occasionally, by turning the posterior belly of the digastric muscle over the facial artery, putting in a rubber dam and stitching it in place over the tonsils he provided a good landmark for the second operation and lessened the chance of infection. He admired Mr. Wilfred Trotter's operations on the pharynx, but had never managed to secure adequate access to the area around the base of the tongue either with superior lateral pharyngotomy or through transmedian lingual pharyngotomy. He preferred to gain access by removing half the jaw and the canine fossa condyle.

For malignant growths of fauces Mr. Gordon-Taylor carried out diathermy excision, or coagulation, or a combination of these. For larger growths he did the double operation: block dissection of neck, followed by diathermy of the primary growth. For still more extensive growths he did dissection with ligature of the external carotid, obtaining access to the primary growth by removing a portion of the cheek or resection of half the mandible. In the presence of doubtful growths at the base of the tongue it was important to do a biopsy. In the decision whether to deal with a particular growth by ordinary surgery or by radium the sex, the social environment, and the physical conformation of the patient must be considered. A large body of statistics showed that three out of every four tumours had been relatively sterilised by radiation treatment. In carcinoma of the tongue Mr. Gordon-Taylor held that diathermy excision was the best of all treatments.

Mr. **Norman Patterson** said that carcinoma in this locality was comparatively rare; of 500 cases of cancer dealt with by Sir James Paget, 2 were in the tonsil, 9 in the gums and palate, and 30 in the tongue. Only in the early stages of a case could the exact site of origin be determined; a growth originating in the tonsil might later show the main mass in the tongue. In every case a thorough examination should be made of nasopharynx, hypopharynx, and larynx both by mirror and palpation. A growth too small to be visible might be detected by palpation. Sometimes tonsillectomy was valuable as a diagnostic measure. It was a serious error to mistake cancer for syphilis; on the other hand, he had rarely seen syphilis diagnosed as cancer. The average age of patients in his series of fifty cases was 58 (the oldest 80, the youngest 38). Forty-eight were males and two females, and neither of the latter had carcinoma of tonsil or pharyngeal portion of the tongue. Preliminary removal of tissue for microscopical examination was, he thought, rarely needed; but if it should be, the endothermy knife should be used for the purpose. The outlook in these cases had much improved since the introduction of excision of the primary growth by diathermy combined with a bold attack on the cervical lymphatic glands. But his results after the use of radium had been disappointing. In some cases a combination of diathermy, surgery, and radiation was best. Sometimes, owing to the size of the growth, it was necessary to do a bilateral operation on the neck. After removing the tumour, the cavity should be treated with the button electrode.

Treatment of the gland-bearing areas presented a bigger problem than treatment of the tumour itself. Enlarged glands were sometimes found, on removal, to be non-malignant, but a negative report on tissue removed from the neck was not always conclusive, and glandular metastasis might appear years after the primary tumour was removed. For a growth of the oropharynx he always took away the sternomastoid muscle. Unless there was reasonable hope of lasting good from extirpation, it was not desirable to carry out block resection. He ligatured the external carotid at the time of the operation, and when the growth was large it might be well to also ligature the fellow carotid.

Prof. **L. van den Wildenberg** (Antwerp) spoke of the treatment of tumours of the tonsil and at the base of the tongue. The varieties he had met with in this region were lymphosarcoma and epithelioma. He treated the first of these with X rays, the routine dose being 180 kv. at a distance of 40 cm., with a filtration of 1 mm. of copper, using large fields. The tumour disappeared rapidly and it was rare to see local recurrence. On the other hand, distant metastasis was common, and the duration of life depended on the number of secondary deposits and their situation. A good but more expensive method of treatment was by means of moulded wax with contained radium. In these circumstances the dose was 1 millicurie per sq. cm. at a distance of 3–4 cm., with a filtration of 1 mm. of platinum. Both sides were treated, and a dosage of 100 to 150 mg. was spread over about a week. Some of his patients had survived eight years. He considered it advisable to treat neighbouring gland-bearing areas, even if the glands showed no sign of involvement. For epithelioma he used either the routine X ray treatment or the surface application of radium if the growth was such that only palliative results were to be hoped for. He did not advise the use of radium needles here, since it was difficult to keep them in position. He inclined most to telecurietherapy. Usually the growth disappeared locally, but there might be local recurrence. At present he was combining medical with surgical treatment.

DISCUSSION

Mr. **Wilfred Trotter** agreed with Mr. Gordon-Taylor's dictum that in early cases, where the growth was superficial, it was unnecessary to insist on immediate gland resection. When a point had been reached in the treatment of a particularly deadly kind of cancer at which experience showed the patient could be spared some of the suffering involved in dealing with it, that opportunity should be grasped. He disagreed with Mr. Gordon-Taylor's remarks about the median pharyngotomy; he had used it with advantage in cases of comparatively early tumours close to the middle line, for he found it was the only operation for the radical cure of growths fairly far down the pharynx, and it did not cause bleeding.

Mr. **Douglas Harmer** said he had been carefully following radiological methods for 20 years, but various ways of treating cancer should not be pitted one against another, since all had their special uses in appropriate cases. Taking that view, the question was one of selection. Here biopsy was very important, but it should not be done if a clinical diagnosis could be made with certainty, for fear lest it might spread cancer cells. Such dissemination could be effected even by massage, or by considerable handling. With rapidly growing sarcomata, epitheliomata, and transition-cell carcinomata there were grave risks from surgical, and even diathermy treatment, but they responded miraculously to irradiation. With early growths surgery gave good results, and he advised surgeons to stick to their surgery unless they had worked for a long time at radiology. Growths of the oropharynx were too deeply situated for complete disappearance of the growth to be expected from purely superficial irradiation. Present radiation bombs were not large enough to get results at such a distance without serious damage to the skin. The best way was to give some surface X radiation, and supplement it by interstitial application.

Mr. W. S. DICKIE (Middlesbrough) said he regarded the tonsil as, to a large extent, immune from cancer; cases so-called of tonsillar carcinoma originated, he contended, in the anterior pillar of the fauces. These cases were becoming commoner, those of the lip less so. Cancer of the anterior pillar of the fauces did not readily infect the lymphatic glands; it was, he considered, a local disease. He dealt with it by block dissection of part of the neck, division in the midline, resection of the jaw to the canine fossa, and excision of the growth.

Mr. W. L. WATT suggested that in so-called borderline cases (late operable, early non-operable) a full course of deep X ray therapy should be given. He thought it possible that a combination of three methods might give improved results in severe cases.

Dr. DAN MCKENZIE gave the results obtained in 11 cases of removal of cancer in this region by diathermy excision. Six recurred: 2 soon after operation, 2 in a year, 1 in 3 years, 1 in 5 years. Two were now alive after 4 years, 1 after 6 years, 1 died of morbus cordis after 12 years. Removal of the sternomastoid facilitated dissection and removal of glands, and he always tied the external carotid.

Dr. T. B. JOBSON spoke of some cases of carcinoma in this region which he had treated. Most of them were squamous-celled. All but one were operated upon by diathermy, and some had X ray treatment secondarily. The results as a rule were discouraging; many cases were far advanced before the surgeon saw them.

Mr. GORDON-TAYLOR, in reply, agreed about the risks of dissemination through biopsy; if biopsy was necessary it should be done with the endothermy knife.—Mr. NORMAN PATTERSON took the same view.

SECTION OF OTOLOGY

AT the meeting of this section on Feb. 3rd, with Mr. J. F. O'MALLEY, the president, in the chair, the discussion on

Should Acute Mastoiditis be Operated upon Early or Late?

was opened by Dr. DOUGLAS GUTHRIE (Edinburgh). The decision, he said, was not always easy. The question really was how early could one operate, rather than how long could one wait. "Early" he took to mean operation during the first week of the otitis, and "late," operation after the fourth week. "Early" did not mean immediate. In the last decade there had been a growing tendency to operate early, and it had been suggested that in acute suppurative otitis the mastoid process should be opened for drainage, even when the usual signs of mastoiditis were absent. The time had now arrived to determine whether the pendulum had swung too far in favour of early operation. It might be that the risks in operating too early were equal to those of operating too late. The indications for operation were not always definite; cases of acute suppurative otitis were met with in which there was only slight mastoid tenderness, and yet the antrum and numerous air-cells were filled with pus. Hence the clinical symptoms bore no dependable relation to the pathology of the mastoiditis, and so the decision on the case became a matter of personal opinion. Signs of meningeal or labyrinthine implication constituted a definite call to operate, and so did a profuse discharge of pus which reappeared after some had been mopped away. Temperature and pulse-rate were not a constant guide, indeed in many cases the temperature remained normal. A high leucocyte count denoted a severe infection, but few otologists would decide to operate from the blood picture, and very few as a result of X ray examination. The chief sign was the presence of mastoid pain and tenderness or œdema. The two former were significant according to the period which had elapsed since the onset of the otitis. Alexander spoke of a prior and less severe condition which he called "mastoidism," and said operation was not necessary until mastoiditis could be diagnosed.

How long should the otologist wait after the establishment of a free meatal discharge? The longer a case went on, the greater became the importance of the symptoms. Some argued that, as in the case of appendicitis, mastoiditis should be operated upon at sight, but Dr. Guthrie claimed that the two situations were not analogous, and in some cases of mastoiditis a spread of the infection might be favoured by dealing too soon with the local focus. Neumann, as a result of an analysis and study of 1300 cases, stated that the second and third weeks after the onset of symptoms were the best time for operation, and in the cases operated upon in the first week there was a mortality of 8 per cent., and a complication rate of 25 per cent. There were no deaths or complications in the cases operated upon in the second and third weeks.

Cases could be divided, he said, into three classes—the average, the mild, and the severe case. In the first class, early operation could be said to be sound in practice, and the results were good; the safest period for these seemed to be during the second or third week. In the second class there was always the possibility of recovery without operation; early mastoid symptoms did not necessarily demand immediate operation. In the acutely fulminating case operation in the first week was not so safe as some considered; dealing with it at this stage might result in a general septicæmia, and longer delay seemed to be justified by experience.

Mr. C. A. SCOTT RIDOUT (Portsmouth) held that there was a closer analogy than Dr. Guthrie conceded between mastoiditis and acute appendicitis; it could be placed in the same category of urgency as any other form of osteomyelitis. For 15 years his practice when recognising acute mastoiditis had been to at once open and drain. The text-book signs were well known, and in addition he paid particular attention to the toxic appearance of the patient, with an increasing pulse-rate, mastoid tenderness, a swollen and bulging tympanum, either with or without discharge, and sagging of the posterior meatal wall. Sometimes cases presented themselves in which the problem was to determine whether the condition was acute mastoiditis or acute furunculosis with œdema. In 24 years he had operated upon 196 cases, and four patients died, one of these not having been seen until the eleventh day. It was his firm view that lateral sinus thrombosis and meningitis were more likely to ensue if operation was delayed. By early operation and sewing up the greater part of the wound he expected complete healing with preservation of hearing. In only one case had he regretted operating early.

DISCUSSION

Dr. DAN MCKENZIE said his leanings were towards early operation in these cases, but one must be governed by what seemed best for the particular patient. It was suggested by some that in the fulminating case it was advisable to wait a few days before operating, so as to allow of the fixation of the abscess, and thus lessen the risk of general septic dissemination. Referring to the statistics of Neumann, which Dr. Guthrie quoted, he said that whenever one set out to seek justification for any particular policy one was able to find some comfortably supporting statistics. His criticism of these figures of Neumann's was that it was not stated whether the operations were done because a definite complication was present, or done simply in carrying out the principle of early operation. Without this essential information the figures were useless as a guide. There was danger in this region that pus might go inwards to the brain as well as outward. Of his last 100 cases 6 died of meningitis. He advocated early operation and drainage in the fulminating cases.

Dr. H. M. Hendershott (Oregon, U.S.A.) thought that the blood picture gave a valuable indication as to the time to operate—i.e., as to whether or not the blood was putting up a good fight against the disease. If not, operation was called for.

Mr. Eric Watson-Williams said that in cases where the decision had been reached that an operation would be required—for some cases got well without operation—he believed in doing it at once. Even by waiting a week one was unnecessarily exposing a patient to risks. Many fulminating cases of septicæmia were fatal, whatever was done for them. The preservation of the hearing was very important to aim at.

Mr. T. B. Layton agreed that treatment of osteomyelitis afforded the best basic treatment for these cases of mastoiditis. In invasive mastoiditis there was a danger of septicæmia and great risk of spread to the brain. He attributed the greatest importance in diagnosis to the general appearance of the patient. For years Mr. W. M. Mollison had been teaching that deafness was a sign of mastoiditis; and for a long time he did not agree, until a tragic case convinced him that Mr. Mollison was right.

Mr. E. Cowper Tamplin wished more stress were laid on the need for carefully watching the patients. This advice from experts would be valuable to general practitioners, who usually saw cases first.

Sir James Dundas-Grant laid emphasis on the importance of tenderness as a sign to be assessed with other signs and symptoms, especially a sense of throbbing in the area. Cases differed greatly in the guise in which they were presented, and peculiarities of anatomical conformation must not be left out of account.

Mr. W. Stuart-Low professed himself, after 50 years of practice in this field, strongly in favour of early operation for mastoiditis. He agreed as to the importance of a throbbing, and if in such a case pus returned after its aspiration he did not hesitate about operating.

Dr. R. Scott Stevenson said it was a mistake to think every case of mastoiditis must be operated upon, and the statistics of the Mayo Clinic showed that the results had been better since operation had been delayed for a time. Only 28 cases out of 1302 were operated upon in the first week. In 16 of the 28 cases there were early complications.

Mr. W. S. Adams (Birmingham) said his experience with fulminating cases had been disastrous, since of six such cases four died. Of 100 cases of mastoiditis in his experience of 18 months he did no more than paracentesis in 41, and in the remaining 59 he operated on the mastoid. One of them was lost through fulminating otitis, followed on the second day by lateral sinus thrombosis, death taking place on the fourth day.

Mr. L. Graham Brown said he considered there was a period in these cases when one could hope for natural drainage from the mastoid antrum and cells. Even in so-called influenzal epidemics he had seen these cases clear up if operation was delayed. When empyema occurred it was an indication of the need of something further. But how was one to recognise empyema in the mastoid bone? Only by the clinical, and especially the physical, signs. Many cases were seen in which it seemed appropriate to operate, but the disease was limited to the muco-periosteum, and they cleared up without calling for operation.

Mr. J. A. Gibb said there was no need to hurry about operation in the first 24 to 48 hours, but to wait for a week or more was to ask for trouble. Mastoid disease in the child was a different condition from that in the adult.

Mr. Somerville Hastings thought it had not been sufficiently emphasised that mastoid disease was not, per se, lethal. He had seen cases having definite pain and tenderness on pressure recover. The chief question was whether there were liable to be complications; if so, operation must be carried out.

Dr. Guthrie, in reply, said he took the view opposite to that decided upon by Mr. Ridout in order to induce a thorough discussion; yet he largely shared Mr. Ridout's view, though he still held that cases did occur in which it was as well to delay operation for a time, while carefully watching the patient.

Mr. Ridout said he was still an unrepentant advocate of operation within a few hours of mastoiditis being diagnosed. Admittedly if the case was not too acute, a night spent in hospital might be to the good; but delay he did not believe in.

ASSOCIATION OF CLINICAL PATHOLOGISTS

The sixth annual meeting was held on Jan. 28th in the pathological department of St. Bartholomew's Hospital. Prof. E. H. Kettle opened the meeting, and in the absence of the president, Dr. G. W. Goodhart, the chair was afterwards taken by Dr. J. G. Greenfield, vice-president of the association.

Dr. D. Embleton (London) contributed some observations on obesity in men and women. In endeavouring to reduce overweight of individuals Dr. Embleton had found a great difference in the behaviour of the two sexes. A fairly high proportion of overweight males showed sugar in the urine, and on examination of the glucose-tolerance curve gave a rise of the blood-sugar above what is usually regarded as the normal level; in certain cases the curve assumed the plateau form usually regarded as of prediabetic form. The male patients responded well to treatment with a balanced diet fairly rich in carbohydrate and slightly below their metabolic requirements. Sugar and pastry were omitted from the diet, and the carbohydrate taken in the form of fruits, vegetables, and bread. The caloric value might be from 1500 to 2000, according to the work and weight of the patient. Dr. Embleton laid great stress on the importance of absolute prohibition of alcohol in any form. Women, however, seldom gave any abnormality of the glucose-tolerance curve, and in them glycosuria in the absence of frank diabetes was a rarity. It was difficult to bring down the weight of female patients, and their weight tended to become stationary before the standard weight for the height and age had been reached in spite of drastic reduction of the diet. In certain cases the metabolic rate was below normal, and in these thyroid was of assistance.

Dr. Cuthbert Dukes (London) recorded observations on the glucose tolerance in cases of rheumatism and pruritus. In a small proportion of cases of rheumatism he had found abnormalities of carbohydrate metabolism; in one case rheumatic symptoms had developed after prolonged over-indulgence in sweetmeats and had persisted, and here the glucose-tolerance curve approached the plateau type of diabetes. Some benefit had been brought about by regulation of the diet. He did not think it necessary to plot the glucose-tolerance curve in every case of rheumatism; a test dose of glucose followed by examination of the urine would reveal whether further investigation was necessary. In cases of pruritus other than those of diabetic origin, Dr. Dukes found no disturbance of the glucose metabolism.

Dr. A. Renshaw (Manchester), Mr. F. Twyman, and Mr. D. H. Follett (London) demonstrated an apparatus, tentatively named the hemovisor, for the quantitative examination of the blood and of suspensions of precipitates by optical methods. On the same specimen the mean diameter of the red cells was shown by the halometric method of A. Pijper; the enumeration of these cells was brought about by the passage through the suspension of a beam of light which afterwards fell upon a light sensitive cell, the number of red cells per c.cm. being indicated upon a calibrated scale by the beam from a galvanometer. The instrument was also adapted to give a numerical expression to the density of precipitates such as those formed in the Kahn test and of other suspensions such as bacterial emulsions. The apparatus is being constructed by Messrs. Adam Hilger and Co.

Dr. J. G. Greenfield and Dr. Elizabeth O'Flynn (London), investigating pituitary tumours, had been unable to demonstrate any constant abnormality in the glucose-tolerance curve for any particular type of tumour. They suggested that glycosuria in such cases might be brought about in some instances by the antagonistic action of pituitrin on insulin, and in others by a disturbance of renal function inducing failure of reabsorption of the sugar in the glomerular filtrate.

The same workers recorded observations on the leucocyte count after irradiation of the thymus. Contrary to expectations irradiation resulted in no drop in the relative or total lymphocytic count. Dr. Greenfield also showed highly decalcified bones from two cases of toxic adenoma of the thyroid.

Dr. Eric Wordley (Plymouth) demonstrated the most recent method of Kay for the estimation of the blood phosphatase and referred briefly to its importance in clinical medicine. He emphasised the fact that the blood phosphatase is greatly raised in osteitis fibrosa of the generalised type, only moderately so in osteitis deformans, and not at all in osteitis of the focal type.

Dr. D. S. Murray (London), in the absence of Dr. Goodhart, demonstrated an adenoma of the pancreas which had given rise to hypoglycæmia. The patient, a female of middle age, was admitted to the Archway Hospital, Highgate, suffering from recurrent attacks of coma. During these attacks the blood-sugar was found to be very low, on one occasion reaching 0·02 per cent. An adenoma of the pancreas was diagnosed but the patient refused to submit to operation and discharged herself. She was later admitted suffering from broncho-pneumonia, from which she died; an adenoma of islet tissue was found in the pancreas at post-mortem. The tumour was embedded deeply in the pancreas, and surgical removal would have entailed great difficulty.—Dr. W. W. Mackarell (Leicester) described a similar case in which the pedunculated tumour would not have been difficult to remove.

Dr. S. C. Dyke (Wolverhampton) demonstrated a tumour of the parathyroid which had given rise to general osteitis fibrosa. The patient, a girl aged 13, was admitted to the Royal Hospital, Wolverhampton, in 1930, suffering from pain and shortening of the left leg. Radiograms showed rarefaction of the bones of the left hip; the blood calcium was found to be over 17 mg. per cent., and the urinary excretion of calcium increased. A tentative diagnosis of parathyroid tumour was made but operation was not performed until two years later. Calcium balance investigations showed a calcium retention; an adenoma of the parathyroid was removed at operation, whereupon the blood calcium dropped, the calcium balance became positive, and symptoms disappeared.

Dr. Dyke also demonstrated, for Mr. R. L. Dutton (Wolverhampton), an apparatus for the clinical estimation of the cholesterol content of the blood. The method required only 0·25 c.cm. of blood; this was taken up on absorbent paper and extracted with chloroform in a special apparatus; the estimation was made colorimetrically, using the acetic-anhydride-sulphuric acid colour reaction.

Dr. R. Klaber (London) showed an extensive series of microscopical preparations of fungal infections of the skin, with cultures of the different species. He pointed out that the so-called "common ringworm," the microsporon audouini, is not nearly so common as it once was; the "black-dot" ringworm, once rare, is occurring more frequently. Dr. Klaber said that this type of ringworm was difficult to diagnose; infected hairs were best secured by lifting them out with the overlying scurfy skin.

Mr. H. E. Kendrick (London) demonstrated apparatus for hospital use, and also of portable type, for the estimation of the basal metabolic rate, and also various types of apparatus for the chemical examination of the blood.

LONDON ASSOCIATION OF THE MEDICAL WOMEN'S FEDERATION

A meeting of this association was held on Jan. 25th, with Prof. M. Lucas Keene in the chair. Dame Louise McIlroy spoke on

Things that Matter in Midwifery

As to diagnosis in the early stages, she said, Aschheim-Zondek tests, and after the twentieth week X rays, were useful. At the twentieth week the X rays just showed a row of dots which indicated the line of the fœtal vertebral column and a radiogram near term would show whether the head was in the centre, when it would usually give little trouble, over the pelvic cavity, or to one side. X rays might also give valuable information where death of the fœtus was suspected, showing sometimes only a mottled mass in the pelvis which made it quite clear that the fœtus had died some time previously. In these cases, Prof. McIlroy said, it was her practice to leave the patient alone until abortion occurred spontaneously, or until some indication for interference arose.

When examining a pregnant woman it was customary to begin at the fundus, holding the hands in a cup-shaped position; if there was tenderness at the fundus, breech presentation should be suspected, the tenderness being probably due to intermittent pressure of the head on the uterine wall. An occipito-posterior presentation might sometimes be diagnosed by the fact that when the back was on the right the shoulder could not be felt. This fœtal position was suggested also by failure of the head to descend after the thirty-sixth week in a primigravida, in whom the head ought to fix from the thirty-sixth week onwards. Miss J. Partridge had devised a method of estimating the mobility of the pubic arch, the examiner placed a finger under the pubic arch of a standing patient who raised her legs alternately, and estimated the degree of movement of the pelvic arch. Flat pelvis was not often seen; when the promontory of the sacrum could not be felt the diagonal conjugate was immaterial, since the pelvis could not possibly be flat. The fœtal head was the best pelvimeter; Monro-Kerr's method of pushing the head into the pelvis after the thirty-fourth week would show whether there was disproportion. Another method, preferred by patients, was to push the head down into the pelvis with the patient lying on her back, and to observe the ridge formed above the pubis. X rays were not of much value in assessing degree of disproportion, but would show whether the head was central and well flexed, and whether it had entered the pelvis. Placenta prævia should be suspected when a souffle was heard at *one* side of the abdomen on auscultation, except when the placenta was posterior, but this was uncommon.

If disproportion was slight, the practice at the Royal Free Hospital was either to induce labour with drugs, or to let the case go to term. Induction was never performed before the thirty-eighth week. If the head could not be pushed into the pelvis, induction was not performed, but a trial labour was allowed; in many cases normal delivery resulted. If drugs were used for induction and vaginal examinations avoided, Cæsarean section could always be performed if necessary; but if bougies were used, delivery had to be completed by the vaginal route. Most breeches turned themselves if left alone. Version should not be attempted until the thirty-sixth week. If the fœtus turned easily it would probably have turned without assistance; if not force must not be used since the legs were probably extended. To turn a breech which had descended deeply into the pelvis, the patient should be placed in the Trendelenburg position; the examiner should never try to push up the breech from below. A transverse presentation was usually a breech in the act of turning, and was seldom persistent. Where the pelvis was asymmetrical—as a result of hip disease, for example—a trial labour should be allowed; the head might enter the pelvis in the wide diameter, and all would be well; if not, Cæsarean section could be performed. Small fibroids seldom gave rise to trouble at labour, but larger fibroids might degenerate and require enucleation; permission should always be obtained to perform hysterectomy if necessary. It was surprising how many low fibroids would get drawn up out of the way before labour, but if a fibroid was impacted in the pelvis Cæsarean section should be performed at term and the tumour enucleated. Out of a series of 182 cases of Cæsarean section, Dame Louise said, she had only performed the operation once in a case of eclampsia. She treated mild cases of eclampsia with rest, fluids, and a carbohydrate diet; the bowels were kept well open and a mixture containing sodium calcium lactate, sodium bicarbonate, and potassium citrate was given; vitamins in the form of marmite and adexolin were added to the diet. In severe cases colonic lavage was also carried out and rest in bed enforced. In cases of post-partum hæmorrhage, the usual emergency measure was to place a fist in the anterior fornix of the vagina, and to press the uterus down against it by means of the other hand on the abdomen; it was much better to pull the uterus upwards, thus putting the vessels on the stretch, and diminishing the blood-supply. In hospital it was customary to use an intra-uterine injection of warm glycerin. Dame Louise showed a film of normal labour, taken by herself and a colleague.

Exercises Before and After Delivery

Miss M. RANDELL, with the assistance of a member of her staff at St. Thomas's, and one of her students, gave a demonstration of exercises for the pregnant and post-parturient woman, devised by her many years ago in association with Dr. J. S. Fairbairn. In planning the exercises attention had been paid to the circulation—general, abdominal, and pelvic. Other exercises were meant to stimulate lactation and to develop musculature, so that the convalescent patient would not be exhausted by standing and walking.

ROYAL ACADEMY OF MEDICINE IN IRELAND

AT a meeting of the section of pathology on Jan. 6th Dr. J. LAIT showed a specimen of

Double Tumour of the Breast

The patient, a married woman aged 54, with two children, first noticed in June, 1932, a small swelling over the manubrium sterni.

About this time she complained of some pain above the left collar-bone. The swelling increased in size, and she was admitted to hospital in September, 1932. There was a red, tender swelling the size of a walnut fixed to the anterior surface of the sternum. A small firm nodule was noticed in the left breast, and some small firm glands in the left axilla. Radiography of the sternum suggested that there might be an abscess in the bone. An incision was made and a solid tumour was found growing from the sternum. It was decided to remove the breast and clear out the axilla; at the same time as much as possible of the sternal tumour was removed. There was aseptic healing, and X ray treatment was applied to the sternum. The patient returned home in November, and was now well and had no pain, but reported that there was some increase in the thickening over the sternum.

On histological examination, Dr. Lait said, there was found: (1) tuberculosis affecting a gland in the axilla; (2) endothelioma of lymph tissue on the surface of the sternum, in the gland, and in the breast; and (3) early scirrhous cancer of the breast, with the development of one or two secondary foci in the same gland. When the section was cut two appearances were visible, one an obvious scirrhous carcinoma, and the other a rosette arrangement of cells. It was possible for endothelioma to simulate carcinoma very closely. The case was one of early scirrhous cancer of the breast and, in addition, early endothelioma of the breast.

REVIEWS AND NOTICES OF BOOKS

The Principles and Practice of Rectal Surgery

By WILLIAM B. GABRIEL, M.S., F.R.C.S., Surgeon to St. Mark's Hospital and to the Royal Northern Hospital. London: H. K. Lewis and Co., Ltd. 1932. Pp. 248. 20s.

THIS manual of rectal surgery is welcome. It is of just the right size; not too large to be read, and yet not too small to supply an adequate account of its subject. Mr. Gabriel has done well to dispense with those long anatomical descriptions which fill the opening chapter of so many books of this kind. Indeed he is in some places almost too economical of words—as, for example, where he describes the treatment of fistula in two stages (p. 93). The necessity for leaving the sphincteric part of the fistula to a second operation will not be admitted by some older surgeons, and it would be interesting to know on what grounds this explicit recommendation is made. The treatment of fistula is always a lengthy process, and to divide it into two stages with an interval of "a few weeks" is an innovation which will not be lightly accepted by the patient. The account of tuberculous fistula is excellent, though the statement that "If a fistula of this type occurs in an adult between 18 and 30, its tuberculous nature is certain, *especially if the occupation of the patient is that of a clerk*," is too dogmatic in the passage we have italicised.

Nearly every chapter is of interest, and those on the treatment of procidentia in adults and on fissure are notable. The alcohol injection method for prolapse in children is not apparently used by Mr. Gabriel. His operative procedure for fissure will be thought too extensive by some surgeons, especially as, since we are told, the external wound sometimes splits open on exertion a few weeks after it has healed. This is not surprising as, judging by diagrams, a triangle of skin with a base approximately 2 in. wide is removed from behind the anus. The chapter on carcinoma recti reveals the fact that Mr. Gabriel prefers when possible to do a perineal excision, and for higher growths has found perineo-abdominal much superior to abdomino-perineal excision. There is a slip in diction on p. 188 where it is written of the perineal dissection that "great care must be exercised not to extend the dissection anterior to the prostate"; presumably this means that the prostate should not be encroached upon. Mr. Gabriel mentions but does not recommend conservative resection of the rectum; yet there are patients who would prefer the greater risk of recurrence if they could escape a colostomy, and Prof. Grey Turner's results show, as do those of some continental surgeons, that some patients survive for many years.

This is an attractive book, well printed and illustrated. It fills a definite gap in English surgical literature, and we are grateful to the author for having written it.

Functional Disturbances of the Heart

By HARLOW BROOKS, M.D., Attending Physician, Bellevue Hospital, New York. London: J. B. Lippincott Company. 1932. Pp. 288. 21s.

THE practitioner probably sees 20 cases of functional disturbances of the heart to every one case of true heart disease. He will find in this book pronouncements which bear the stamp of wide experience and understanding, especially in connexion with the relation of disturbances of the cardiovascular system to the nervous system and the endocrines. Though they do not endanger life, functional conditions often entail far more mental and physical suffering than do any forms of organic disease, with the exception of angina pectoris; and because of the annoying character of the symptoms they cause constant uneasiness if not alarm. A large section of this book is devoted to a detailed consideration of the condition described as neurocirculatory asthenia. In his account Dr. Brooks draws largely on his war experiences, which has enabled him to understand and assess the importance of this condition to society and to the individual. He shows in a preliminary historical survey that references are to be found to its incidence during the Civil War in America. An illuminating section deals with cardiac neuroses, notably the psychological aspect. Some statements, however, will certainly meet with criticism. For example, Dr. Brooks observes in his opening paragraph on pain in the præcordium that "it is the present tendency of physicians to consider most of these cases of unaccounted precordial pain as tentative instances of angina pectoris"; this is surely too sweeping. The views here expressed on cardiac exhaustion are contrary to those generally held. The book is, however, in accordance with modern teaching in essentials, and can be commended to the practitioner.

Skin Diseases and Nutrition

Including the Dermatoses of Children. By ERICH URBACH, M.D., Dozent in Dermatology and First Assistant to Prof. W. Kerl, University Clinic for Skin and Venereal Diseases, Vienna. Authorised translation by F. R. SCHMIDT, A.B., M.D. Vienna: Wilhelm Maudrich. 1932. Pp. 242. $7.

DIETETICS have always been recognised as a factor in the treatment of skin diseases, but so far there has been little exact knowledge to guide our instructions to the patient or his nurse. Dermatologists will therefore welcome the appearance of this manual. The translator has overcome the difficulty that not only the diets but their constituents differ widely in different countries with great skill. His book is divided into two main parts, of which the first contains a dissertation on the effect of nutrition on the chemical structure of the skin, and on its biological reactions to diet. The diseases due to malnutrition are considered in detail; a section is devoted to the dermatoses due to alimentary infections and intoxications, and others discuss dermatoses caused by disease or dysfunction of the digestive tract, metabolic disturbances, and nutritive idiosyncrasies. In the special part the diet advised in a number of selected skin conditions is considered in detail, and the concluding section deals with food-provoked skin disease in animals. A useful supplement includes a mass of practical information on such subjects as the normal weights of growing infants, the use of food charts for the preparation and calculation of dietaries, and a table of weights and measures.

The subject matter makes somewhat heavy reading for the clinician, and the constant citation from the works of other authorities is rather disturbing. In some cases such extracts seem redundant, in others mutually contradictory. Undoubtedly, however, it is a book which every dermatologist will do well to study, and a copy should be available for the practical guidance of dietitians in the larger clinics and hospitals.

Diseases of the Nose, Throat, and Ear

Third edition. Edited by A. LOGAN TURNER, M.D., LL.D., F.R.C.S.E., Consulting Surgeon, Ear and Throat Department, Royal Infirmary, Edinburgh. Bristol: John Wright and Sons. 1932. Pp. 465. 20*s.*

THIS book was originally produced, in 1924, as the joint work of those engaged in the teaching and practice of the specialty in the Edinburgh Medical School. It was intended as a tribute to the memory of Dr. W. G. Porter, whose manual had passed through three editions before he was killed in 1917. Dr. Logan Turner has had the assistance of Mr. W. T. Gardiner in the section on diseases of the nose, while Dr. Douglas Guthrie has been responsible for that on the pharynx and nasopharynx; Mr. J. D. Lithgow writes on the larynx, Mr. J. S. Fraser on the ear, and Mr. G. Ewart Martin on the chapters on endoscopy and diseases of the œsophagus. The book shows little alteration from the text of the second edition, issued in 1927; 16 new illustrations in the text and seven new plates have been inserted to the advantage of a work which before was notable for the excellence of its pictures. The chief addition is a description of the physiology of the otolith apparatus. The book is only slightly increased in size, is well and clearly written throughout, and the teaching is sound. It remains one of the best text-books on its subject in the English language.

Physical Therapeutic Technic

By the late FRANK BUTLER GRANGER, M.D. Second edition, revised, by WILLIAM D. MCFEE, M.D., Visiting Physician, Department of Physical Therapy, Boston City Hospital. London: W. B. Saunders Co., Ltd. 1932. Pp. 436. 32*s.* 6*d.*

IN preparing the second revised edition of this book Dr. McFee has kept in view the desire of the late Dr. F. B. Granger to instruct the practitioner who wishes to administer physical methods of treatment on occasion without making a specialty of the subject. The general plan of the book remains the same, though a few additions have been made. Among them is a new chapter on physical therapy in diseases of the ear, nose, and throat, contributed by Dr. George R. Rice. Dr. McFee has added some notes on experiments with diathermic currents on animals, which were conducted in order to ascertain the degree of heat which could be produced in different organs.

The part of the book which will provide most interest for readers in this country is the index of diseases, which may satisfactorily be treated by physical methods. In describing treatment for each disease the author has made it his aim to answer the questions, "What, where, how much, how long, and how often?" The forms of treatment most often prescribed are electrotherapy and ultra-violet ray therapy. Massage and hydrotherapy receive scarcely adequate attention. Under the heading hypertrichosis the use of X rays is rightly condemned, and the removal of superfluous hairs by electrolysis is described. A method of treatment by fulguration is also noticed; the skin around each follicle is sparked until it acquires a greyish discoloration, and the hair can then "be forcibly pulled out." If force has to be used in extracting the hair it does not seem likely that this form of treatment can destroy the follicle. The book is beautifully prepared. Several illustrations, notably pictures of apparatus and of patients under treatment, could have been spared, since they give no information of use to the medical reader.

Gynäkologische und Geburtshilfliche Diagnostik

In Tabellenform. By Prof. Dr. HEINZ KÜSTNER, Leipzig. Munich: J. F. Lehmann. 1932. 65 tables. Mk.11.40.

THE author of this small book maintains that a general practitioner's interest in medicine is becoming limited to diagnosis because adequate treatment requires special apparatus and equipment. He has therefore thought fit to compile a series of tables which describe the various diseases and abnormalities met with in gynæcology and obstetrics, and indicate their clinical features and pathology. So far as the book goes the result is satisfactory. The illustrations are exceptionally good, and include some beautiful coloured plates. The tables indicate in column form notes of symptoms, physical signs, pathology, and prognosis, and the whole field is covered. The obvious objection to this scheme is that practitioners get more help from a symptomatological approach rather than from notes on individual diseases.

The work should serve as a useful cram book for final-year students. It is essentially a German counterpart of the lists of causes and diseases which are popular in the medical schools of this country.

The Marketing of Literary Property

By G. HERBERT THRING. With a letter to the author from Mr. G. BERNARD SHAW. London: Constable and Co., Ltd. 1933. Pp. 242. 7*s.* 6*d.*

THE literary property of the medical profession is to-day large, for the specialisation of the calling is multifold, and the impulse to express the personal view is widely felt. The property though imposing in the mass is not necessarily valuable to individual owners, and this is inherent in the circumstances giving rise to much of it; for, speaking generally, it is the special subject that asks regularly and often for a record of developments along particular lines, while the more the subject is special the less will its literature be in common demand. And, unfortunately both for author and publisher, the production of a scientific treatise is as costly as, and usually much more costly than, that of a popular book.

Mr. Thring was for 30 years secretary of the Society of Authors, and no one can be better qualified than he to write a book on literary property, its value, and the methods for its disposal. He has set out here the copyright law of this country and our Dominions, and of the United States, with a chapter on the international position. He has analysed the various forms of contract which prevail in the publishing of books, and has set out under the obvious headings the points which have to be considered in dealing with different categories of literary production. There is no chapter that applies in particular to medical authors, but the explanations clause by clause of certain of the agreements that medical authors may be invited to sign afford valuable information. In a wise and amusing prefatory letter Mr. Shaw desires a wide circulation for the book, and the book deserves it.

THE LANCET

LONDON: SATURDAY, FEBRUARY 11, 1933

THE MIND IN UNEMPLOYMENT

AMONG the evils which unemployment brings in its train none is more alarming than impairment of mental health in the workless population. Something has been done of late in this country to counteract such influences by the provision of training centres, opportunities of recreation and physical exercise, organisation of unremunerative but satisfying work, and other schemes, such as those initiated by the Society of Friends. But there has been little precise information available about the form of ill-health chiefly found among the unemployed, or about the circumstances in which it is most likely to develop. Some studies that are now being carried out on a London group of unemployed suggest that neuroses are seldom found where there has not previously been evidence of a definite disposition to such disorders in response to any social or individual stress. It is not only in the form of well-defined neuroses, however, that the results of enforced idleness manifest themselves. There are numerous less obtrusive deviations from the normal balance of the personality that are the almost inevitable outcome of insecurity, dependence, and lack of satisfying occupation. These deviations may most strikingly be encountered where occupation had previously been constant rather than casual, and there had therefore been greater security; where, moreover, the work had made sufficient demands on the capacity of the worker to afford him grounds for a feeling of worth and adequacy.

In a valuable pamphlet[1] just issued by the National Committee for Mental Hygiene in the United States, Dr. GEORGE PRATT sets out the responses to economic adversity which are most frequently found, and the means by which they may be combated. It is addressed not so much to physicians, who may be called on to deal with definite mental disorder, as to social workers, nurses, and those who administer relief on official or voluntary bodies. They it is who are daily in contact with hitherto normal and on the whole contented people who are now unwillingly obliged to change the habits of their lives, and are deprived of their usual outlets and means of satisfaction. Where there is danger of a gradual deterioration of morale and the development of apathy, despair, self-pity, or resentment among the unemployed, it is necessary that those who attend to their material needs should also take into account those psychological factors which are of the utmost importance for the future. They must recognise that truculence or invalidism may be understandable responses to a changed environment and not merely the expression of a habitual antisocial attitude or of a psychopathic personality. The situation is not dissimilar from that which obtained during the late war, with its prolonged and almost intolerable stresses to which many proved unable to adapt themselves. The present troubles may be less terrifying and less violent than those of war, but they are, for the continuously unemployed, insistent and without abatement or lull; they occur in the setting of daily life and are associated with subtle but wounding conflicts within the family. A morose irritability or a gloomy resentment is often visited upon the immediate relatives though it is primarily directed against the social conditions which have created their insecurity and misery. The psychological play in such a situation is not far to seek; it is described very simply in Dr. PRATT's brochure.

The manner in which the social worker or administrator of material relief can take a part in diminishing these evil effects of unemployment is, as Dr. PRATT points out, more a question of his or her habit of mind and freedom from emotional entanglement than of any active interference. Where interference is required it will generally be in the presence of deviations from health so severe as to require psychiatric attention. But the great mass of depression, suspicion, and resentment which is the fruit of unemployment will yield in some measure to sympathetic (not sentimental) understanding, and sometimes to advice. The part of the general practitioner in providing such mental hygiene is difficult to over-estimate. But equally important, however, are those measures for which the community, rather than individuals, must be responsible, and which provide means of occupation and recreation, thus keeping alive self-respect and preventing a corroding dissatisfaction. It will, in most cases, be imperative that these activities should be begun by outside agencies, rather than by those who will benefit from them, for in the sufferers initiative has often become weak after months or even years of unemployment, and there will have been little or no preparation for the use of a leisure that may be unwelcome and turn to tædium. The spread of schemes for dealing with the mental problems of the unemployed is a hopeful sign in this country.

THE PATHOLOGY OF APPENDICITIS

ACUTE appendicitis is one of the most common and dangerous of the surgical emergencies, and there is a good deal of evidence that mild attacks of inflammation of the appendix occur much more frequently than is generally supposed. Our knowledge of the exact pathology and ætiology of the disease is, however, far from complete, and any serious contribution to their elucidation is to be welcomed. Prof. L. ASCHOFF has long been interested in appendicitis; he wrote a monograph on the subject as long ago as 1908, and his views on the pathology of the disease are now well known.

---

[1] Morale. The Mental Hygiene of Unemployment. By George K. Pratt, M.D. The National Committee for Mental Hygiene, New York. 1933. Pp. 64. $0.25.

In a more recent publication,[1] he brings forward further evidence in their support. He has always held that appendicitis is an enterogenous infection arising on the surface of the mucosa, and in the present work he again denies the possibility that the disease may ever be blood-borne. No doubt this conception of the process is correct in the majority of cases, and Aschoff himself has produced *a wealth of evidence in support of it*; but it may be questioned whether it is justifiable to exclude altogether the possibility of a hæmatogenous infection. Twenty years ago F. J. Poynton and A. Paine [2] demonstrated the production of appendicitis in young rabbits by the intravenous inoculation of streptococci, and it seems unreasonable to rule out entirely the likelihood of a similar process occurring in man. Prof. Aschoff, however, will have none of it, and in the present study concerns himself entirely with the recognition of the organisms responsible for the lesion and their mode of action. In addition to the usual bacteriological methods, Prof. Aschoff has worked largely with direct smears, a valuable technique which has unfortunately been neglected in recent years. A large number of inflamed appendices were examined by him in this way, and control observations were made on normal organs removed at operation or obtained from the post-mortem room.

Briefly, the conclusions he arrived at are as follows. The normal appendix has a flora of its own which is quite distinct from that of the cæcum, and consists chiefly of gram-positive cocci and fine gram-positive rods. In smears taken from the *lesions of acute appendicitis* organisms having a similar morphology and staining reaction predominate, and, a point which Prof. Aschoff regards as highly significant as indicating their pathogenicity, these are the organisms which are most actively phagocytosed by the cells of the exudate. Cultural observations show that about 70 per cent. of acute infections of the appendix are due to one of the intestinal streptococci, pneumococci accounting for another 17 per cent.; and taking all the evidence into consideration it is concluded that acute appendicitis is due to infection of the mucosa with organisms which are normal inhabitants of the viscus. How is this infection brought about? G. Ricker has developed the ingenious theory that appendicitis is primarily due to vascular *disturbances of the organ* brought about by reflex irritation of their nerves, a process akin to the "chill" mechanism of respiratory disorders. In severe cases the vascular disturbance is sufficiently intense to cause necrosis or infarction of the tissue, which then becomes invaded by microbes from the lumen. Aschoff, however, denies that a vascular disturbance is the primary lesion; he believes that such changes are secondary to a bacterial invasion of the surface of the mucosa. By the use of the oxidase reaction he claims that such primary foci can be demonstrated in histological preparations when they might well be missed in material by the ordinary routine methods. And the study of the lymphatic system of the appendix, illustrated by *really beautiful figures*, which is contributed by Dr. H. Seng, bears out his contention that nothing is easier than for an infective process to spread from a small primary focus in the mucosa throughout the whole of the organ.

The actual infection of the mucosa is, Aschoff holds, independent of any trauma; it occurs, for example, distal to and not in the immediate neighbourhood of a stercolith. But it seems to be due to an increase of virulence of the bacteria normally present in the lumen. How this increase of virulence is brought about is quite uncertain, but it depends largely on *stagnation of the contents*. A regular flushing of the appendix with fæcal matter would act beneficially, for it would result in the replacement of the appendix flora by that of the cæcum, but it appears that such a flushing occurs only irregularly and imperfectly, frequently failing to extend to the distal third. Stagnation of fæces in the proximal portion of the tube would, on the other hand, favour retention of the contents of the extremity; and kinks or bends would have a similar effect. Prof. Aschoff presents his thesis with great skill, and supports it with a wealth of facts and illustrations, but it must be confessed that it fails to carry complete conviction. It would not be difficult to adduce contrary arguments of considerable weight; and a good deal more work will be necessary before it can be accepted as proved that the virulence of a normal inhabitant of the alimentary canal can be so raised by a moderate degree of stagnation as *to render it capable of breaking down the natural* defensive mechanism of the mucosa. Nevertheless, Prof. Aschoff has written a most stimulating work which will well repay careful study.

◆

THE MARKETING OF MILK

The medical profession is unanimous in its advocacy of milk as part of the diet, provided it is *clean and free from infection*; but, owing to doubts as to the quality of some of our milk-supplies, it has, on the whole, hitherto thrown its influence against rather than for an increase of milk consumption. This sentence is taken verbatim from page 64 of the report,[1] which appeared on Monday, of the Milk Commission appointed *last April* by the Minister of Agriculture under the Agricultural Marketing Act; and the commissioners, of whom Sir Edward Grigg is chairman, are of opinion that nothing can better serve the *health of the community*—and incidentally the interests of the milk industry—than the removal of these doubts. Contrariwise, a sympathetic understanding, on the part of the medical profession, of the position of the producer and distributor is eminently desirable for the speedy solution of the problem of a pure milk-supply. Perhaps the most formidable obstacle

---

[1] Ministry of Agriculture and Fisheries. Report of the Reorganisation Commission for Milk. Economic Series No. 38. H.M. Stationery Office. Pp. 228. 6*d*. The members of the Commission are Sir Edward Grigg, Prof. A. W. Ashby, Mr. F. N. Blundell, D.L., Mr. A. E. Cutforth, F.C.A., and Major-General Sir Philip Nash, with Mr. J. B. Baber, secretary, and Mr. A. R. Manktelow, assistant secretary.

to its attainment is the plea of the producer that he gets so little money for his milk that he can scarcely make a living out of its production, with the corollary that it is a sheer impossibility for him to do more than he does now in the way of providing healthier stock, more hygienic premises, or greater cleanliness in collection and transmission of milk.

The milk producers point to the discrepancy between the money they get for liquid milk and the price charged to the consumers, and when the perennial milk war is settled each year between producers and distributors, by the formulation of an agreed milk price, the problem has not been solved even for the year. It has only been shelved in favour of the distributor. For it must be borne in mind that the root of the difficulty lies in the fact that there are two prices for milk: one for that sold to the public as liquid milk, the other for that sold for manufacture into milk products, loosely called "surplus" milk. The difference in price between these two kinds of milk is so great that the producer makes every effort to sell his milk for liquid consumption, and not for manufacture; and whether he can do so or not is largely a matter of geographical position. Should his milk lie within the area of supply of a large town he can market as liquid milk all he can produce, whereas if he is far away from such a market most of his milk has to be sold at the price of milk destined for manufacture. This dual usage makes the interests of the distributor dominant in any process of bargaining. The distributors will naturally prefer to draw supplies from their own neighbourhood, but, should local producers combine to get what they consider a fair price, the distributors can then go a little further afield into areas where the prevailing price is the price of milk for manufacture. Just because there is an almost unlimited field of milk production for them to draw upon, and because the farming interests have in the past been unable effectively to combine, the position of the producer has been an unhappy one. How large may be the proportion of manufactured milk appears in a survey issued not long ago by the Hannah Dairy Research Institute. which showed that of the total milk produced in Scotland only 59 per cent. was marketed in liquid form, 17 per cent. was consumed at the source, and the remaining 24 per cent. went to the manufacturers. The commissioners propose to solve the difficulties of this situation by setting up a series of boards under the Agricultural Marketing Act, with two main objects in view: (1) the strengthening of the position of producers by enabling them to negotiate as a solid body with one voice and with adequate information, and by ensuring that negotiated agreements are universally observed; and (2) the coördination of the efforts of all concerned—producers, distributors, and manufacturers—to secure prosperity for the whole milk industry of the country, with adequate safeguards for the interests of the consuming public. The organisation would include three new bodies, (1) a Central Producers' Board, (2) a Central Dairymen's and Manufacturers' Board, each with its own regional organisation, and (3) a Joint Milk Council consisting of members of these two boards, along with three outsiders. The ownership of all milk other than that sold by producer-retailers would be vested in the Producers' Board, but the Joint Council would fix from time to time the price of milk, both for liquid consumption and for manufacture. By means of a system of regional prices, and of devices to reduce inequalities, it is hoped to strike a fair balance between the prices paid for the two kinds of milk.

This is in brief the discharge by the commissioners of their duty to draw up a scheme or schemes for regulating the marketing of milk; but they have gone further in many directions on the liberty given them to make recommendations with respect to the matters investigated. They have for instance examined the consumption of liquid milk in this country, in regard to which statistical data are extremely meagre, and they estimate the present total requirements of the liquid milk market of England and Wales as between 607 and 730 million gallons, with a daily consumption of milk per head of population of between one-third and two-fifths of a pint. This estimate agrees closely with the careful study on p. 342 of this issue by Dr. JESSIE GELLATLY of the consumption of milk in some East Anglian arable farm counties. The commissioners point to some astonishing variations in the per-capita consumption in various English towns: Hull and Cardiff are surprisingly low, Bournemouth and Chichester surprisingly high. There seems however no doubt of the downward trend of liquid milk consumption throughout the country as a whole; partly no doubt as a result of the need for economy in the domestic budget, for the decline in retail milk prices has admittedly not been commensurate with the fall in producers' prices. But there is a further potent factor in the alarm aroused among the public by statements that milk is unsafe unless treated by heat and that when so treated its nutritive value is impaired. Propaganda on the part of the medical profession is regarded as deterring many parents from giving milk to their children to drink. To meet these doubts the commissioners have set before the producers, as one of the chief objects of reorganisation, an improvement in the quality of milk. Some improvement there has been in the last decade, an important factor being the recognition of certain statutory grades of milk, and the commissioners are assured that in some parts of the country at least much of the milk produced is now of Grade A standard, though not sold under that designation. They think it would be convenient now to reduce to one the number of official grades, this "special" grade to be produced under the same conditions as the present Grade A (tuberculin tested). Although not unanimous themselves, the commissioners regard it as the view of medical officers of health that the safety of the milk-supply, at least in large towns, can be ensured only if milk below the tuberculin-tested grade is efficiently pasteurised. But they fear the adverse effect of compulsory pasteurisation on the producer who lies in close proximity to consuming centres, and they state with insistence that pasteurisation can never be a substitute for clean production. When carried out it should be under thermostatic control, and repasteurisation is held to be so undesirable as to be totally prohibited. The continued sale of unbottled milk is deprecated, but we miss in an otherwise compendious report any allusion to the paper carton which might do more than a little to popularise milk as a food.

The commissioners attach importance to a uniform and effective administration of the Milk and Dairies Order, although they make no recommendation how this is to be obtained. Finally they would like to see a whole-time chief veterinary inspector take his place in the official hierarchy of each county and county borough; some counties in which whole-time veterinary departments have been set up have already taken over the work irrespective of whether it comes under the purview of the Ministry of Health or of Agriculture, and they think a whole-time service would in the long run prove cheaper as well as more effective than the present system.

ANNOTATIONS

A B.M.A. COMMITTEE UPON MEDICAL EDUCATION

At a Council meeting of the B.M.A. held on Jan. 25th a special committee on medical education and examination was set up upon the receipt by the Council of an emergency committee's report on the subject. Sir Henry Brackenbury, presenting that report, explained its origin as due to the recent inquiry held at Cambridge and the subsequent discussion of the problems at a joint conference between the representatives of Oxford, Cambridge, and London Universities, and of the English Royal Colleges. At that joint meeting the personnel, observed Sir Henry, was entirely composed of teachers, and the advisability of evidence being given before it by a representative of the B.M.A. was held doubtful as a too indirect method of approach. The decision, however, had been come to by the chairmen of various committees and himself that a special committee of the Association should be set up, and an emergency body had consequently produced the report which he was submitting, and which recommended the institution of a special committee. The reference to the special committee, proposed by the emergency body, was:

> "To consider and report upon (*a*) the conditions that should be required for entrance upon medical studies, (*b*) content of the curriculum, the position of the various subjects therein, and their proper relationship to one another, (c) the nature of examination or other tests which should be satisfied prior to graduation, (*d*) whether, and to what extent, post-graduate education or experience should be required prior to registration as a fully qualified medical practitioner or licence to practise independently as such."

The procedure will be that the special committee will issue an interim report to the Council in June in order that the full document may come before the annual Meeting of Representatives in July in Dublin.

AFTER-EFFECTS OF SPINAL ANALGESIA

There has for long been a vague notion that remote after-effects of a nervous or paralytic kind are not uncommon following spinal anæsthesia. Most anæsthetists have heard tales of this sort, but have been unable to get hold of any definite instances or proved facts. The excellent paper read by Mr. H. K. Ashworth and the discussion which followed it at the section of anæsthetics of the Royal Society of Medicine on Feb. 3rd have done a great deal to clear up the position. The truth seems to be that serious after-effects, in the absence of errors of technique or dosage, do not occur, but that slight, remote after-effects, in the form of headaches and weakness or tingling of the legs, do occur in a very small proportion of cases. Further, it was clearly shown that in a number of cases nervous symptoms appearing for the first time at a date subsequent to an operation under spinal analgesia have been attributed to the injection without sufficient investigation. A thorough examination proves the symptoms to be due to some organic disease quite unrelated to the spinal injection, such as chronic kidney trouble or varicose veins. By following up some 270 patients during a three-year period Mr. Ashworth succeeded in bringing up for examination 30 patients who, according to their answers to his questionnaire, were suffering from remote effects following operation under spinal analgesia. Out of these 30 only seven were held after careful neurological investigation to be right in attributing their symptoms to their operative experience. Two of these patients suffered from one-sided deafness, one of whom has since recovered. Headache has been regarded as the most frequent after-effect of spinal injection, but speakers at the meeting differed widely in their interpretation of the cause of this symptom, and consequently in the treatment recommended for its prevention. Mr. Ashworth regarded headaches as due either to leakage of cerebro-spinal fluid at the site of puncture, or else to an upset of the choroidal plexus function secondary to meningeal traumatic irritation. When the latter was the cause he believed in repuncture for a cure. Several speakers, notably Dr. R. E. Apperly, believed that the Trendelenburg position carefully maintained for hours after operation, and complete stillness of the patient, obviated headache. On the other hand, Mr. E. T. Milligan stated that out-patients who were allowed to walk out of hospital after minor operations performed with low spinal injection often remained free from headache. Mr. Dickson Wright laid stress on the force of suggestion, and on the fact that headaches afflicted chiefly those who were subject to that complaint.

SURGICAL STIMULATION OF BONE GROWTH

A new method of stimulating the growth of bone is described by Dr. Albert B. Ferguson,[1] roentgenologist to the New York Orthopædic Dispensary and Hospital. In his preliminary report he points out that it has often been observed that a bone has recovered some of its length after a fracture with shortening, and that this phenomenon is in accordance with a general principle of bone physiology which deserves more attention than it has received. The principle is that "during the period of epiphyseal growth interruption of the medullary blood-supply to the metaphysis without interruption of the periosteal blood-supply to the end of the shaft produces an increase in the speed of longitudinal growth of the metaphysis affected." Ferguson's paper is designed to show the surgical application of this principle to secure stimulation of growth in suitable cases. In children, after osteotomy of the tibia, the upper end of the fibula was usually found to be short in relation to the tibia, which suggested that interruption of the medullary supply of the tibia had stimulated growth. A study of various cases in which such interruption had occurred was held to confirm these conclusions, and up to last October medullary section had been carried out in 16 cases in which there was shortening of the leg. The operation is a simple one, consisting of drilling into the bone half-way from the epiphyseal line or lines to the middle of the bone, inserting a knife and dividing the medulla transversely, the wound then being closed in the usual way. Whenever medullary section is done on the tibia it is done also on the fibula, the upper end of the femur not being used unless the shortening is great. Ferguson gives the order of preference as (1) lower end of femur, (2) upper end of tibia and fibula, (3) lower end of tibia and fibula, and (4) upper end of femur. A sufficient number of metaphyses are treated to gain the required length, the gain being estimated at ⅛ in. annually for each metaphysis treated up to the age of 14 for girls and 15 for boys. The growth seems to be more rapid in the first year after operation, but Ferguson suggests that the operation can safely be repeated after two to three years, if growth slackens. In no case treated has there been any evidence of disturbance of the bone other than the change in the rate of growth. The children who have undergone this medullary resection are to be followed up through adolescence, to determine the actual gain in length over a period of years for the various bones at various ages.

SUSCEPTIBILITY TO TUBERCULOSIS

The theory set out in the report on Tuberculosis in the African Native[1] that certain of the natives recruited for work in the gold mines exhibit a soil hyperallergic to tuberculosis, which leads them to succumb, when on the mines, to acute fatal tuberculosis, was developed by Prof. Lyle Cummins in a communication to the Tuberculosis Association which we reported last week. This liability to contract acute infection was found to vary directly with the severity of the reactions of the subject to tuberculin tests; "positive plus" natives were more liable than "positive" natives, and the latter more liable than "negative" natives. Before a superstructure is raised on the existence here of hyperallergic soil, it must be remembered that a more obvious explanation is difficult to exclude. When they left their homes for the strange environment of mining service, the "positive plus" natives may have had more or less active tuberculous foci which had eluded even a vigilant clinical examiner. Such a vast change in environment might be expected to activate latent foci in direct proportion to their previous activity; the tuberculin reactions might be regarded as some measure both of the presence and activity of these foci. A condition of hyperallergy to tuberculosis would appear to have been postulated in contradistinction to the idea that resistance to tuberculosis may be acquired from subinfection. But the theory that resistance to tuberculosis is acquired from subinfection is hard to substantiate. Tuberculosis as an infectious disease does not display the clinical features of other acute infectious diseases, such as scarlet fever, influenza, small-pox, and the like, from which the sufferer recovers by establishing antibodies to counteract the toxins of the disease. Attacks of such diseases end in a definite way as these antibodies come to be formed. There is no such clinical course about tuberculosis to give support to the view that useful antibody reactions occur. On the contrary, evidence points to the fall of tuberculosis mortality among Europeans, and indeed among negroes in America, as being a measure of contemporaneous rise in the social standing of the communities affected. Although this outlook upon resistance to tuberculosis differs from that of an allergic soil on the one hand, or the effect of subinfection on the other, as claimed by Prof. Cummins, we note that his practical advice is the same as if it were based on different theoretical grounds—namely, that natives on gold mines must be housed, fed, and cared for on generous lines.

Another discussion reported in last week's LANCET also centred round the susceptibility to tuberculosis attributed to local damage in the tissues of the lung following upon the inhalation of certain toxic dusts. Of these silicosis has hitherto received the most intensive study, but recent work is disclosing that another form of dust, that of asbestos, is even more injurious to the physiological functioning of the lungs, while it is only second to silica in increasing susceptibility to superimposed tuberculous infection, or to the reactivation of tuberculous foci already present. Evidently, although agreement has not yet been reached on minor points, the old idea that the lungs are mechanically abraded by sharp particles of dust has been definitely discarded. The available evidence indicates that the dust particles pass into solution in the lung tissue, upon which they then react according to their chemical composition. Thus, on one hand, lime salts pass away harmlessly, while silica compounds, whether in the form of quartz or asbestos, set up a fibrous reaction which varies in type according to the kind of dust concerned. On the other hand, insoluble particles, such as dust from carborundum (silicon carbide), appear to be almost inert, and to remain in the lungs without provoking any reaction. Thus we arrive at different classifications for dust. E. H. Kettle divides them into active or inert; the former, such as silica and asbestos, produce active lesions in the tissues, and appear to exert a definite influence in assisting the growth of tubercle bacilli. Here we are dealing with susceptibility to tuberculosis based upon either a physical interference with the functioning of the lung tissue, or the presence of a foreign element favourable to the tubercle bacillus, or, possibly, upon both combined. The further the study of the pneumoconioses goes, the more evident it becomes that the effects of each dust must be studied separately, especially in relation to its effect on susceptibility to tuberculosis.

THE HOUR OF BIRTH AND DEATH

In a study of maternal mortality and stillbirths in New York State, J. V. Deporte[1] found that neither live births nor stillbirths were spread evenly over the 24 hours. The maximum number of live births was recorded between 3 and 6 A.M., exceeding by more than 40 per cent. the minimum between noon and 3 P.M. There were relatively fewer births in the three groups between noon and 9 P.M. than at any other time. In an analysis of very much more extensive material (the 350,106 live births registered in Switzerland between 1926 and 1930), Dr. E. Jenny[2] finds a very similar distribution. Whereas nearly 100,000 of these births took place between 3 and 9 A.M., only 75,000 are recorded as taking place between 3 and 9 P.M. As with the New York figures, the maximum is at 3 to 6 A.M., and exceeds the minimum by nearly 40 per cent. It is at these hours that metabolism is at its lowest, and temperature and pulse-rate reach their minimum. On the other hand, the distribution of stillbirths, according to Deporte's somewhat limited figures, is precisely the reverse. Most of the stillbirths, he found, occurred during the day, the maximum number falling between the hours of 9 and 11 A.M., and the minimum between midnight and 2 A.M. Measured as a percentage of total births the stillbirth rate was highest (4·7 per cent.) between 3 and 5 P.M., greater by nearly 60 per cent. than the minimum (3 per cent.) between midnight and 2 A.M. Jenny provides no figures for stillbirths, but he has analysed 12,099 deaths (at all ages) registered in Aarau between 1894 and 1929. The distribution over the 24 hours is much less variable than with the births, though there is a suggestion of two maxima, one at 7 A.M. (as night turns to day), the other at 5 P.M. (as day turns to night). The numbers are too small to be conclusive, and, as Jenny points out, the combination of all ages and all causes of death may make the material heterogeneous and obscure the issue. He suggests that knowledge of the hour of death for individual causes would emphasise the special hours of risk, and be of assistance in treatment of the sick.

THE EPIDEMIOLOGY OF CHANCROID

Dr. Albin Proppe,[1] of the dermatological department of the Berlin-Britz Municipal Hospital, draws attention to the sudden outbreak of chancroid which occurred in Germany in 1928. The whole country was not affected, but increased incidence of the disease was specially noted in Berlin and the Ruhr and Lower Rhine districts, as well as in Bremen, Altona, Königsberg, Gleiwitz, Reichenbach, and Dresden. On the other hand, large areas of Central Germany such as Hanover, Brunswick, Magdeburg, Leipzig, and Chemnitz, as well as Mecklenburg, Breslau, and the whole of South Germany entirely escaped. In the Berlin-Britz Hospital a chancroid wave was first noted in April, 1928, and in August reached its first peak, which was followed by a second in September and October, 1929, and a third in January, 1930. The epidemic then began to subside, though a few rises in the incidence of chancroid were still observed, the highest being in November, 1930. Since February, 1932, however, the disease appears to have almost entirely died out. Proppe alludes to similar epidemics of chancroid which have occurred in recent years in various foreign cities—for example, in Kharkov, Odessa, Prague, and Vienna in 1925–26, Belgrade and Trieste in 1926, Bucharest in 1926–27, Moscow in 1927, Vilna in 1929, and Hungary in 1929–30. Although chancroid is regarded by many authorities as a filth disease, Proppe found that the incidence of lousiness in his chancroid patients was no higher than in those suffering from gonorrhœa, being about 10 per cent. in each group. On the other hand, there was some evidence that in comparison with syphilis or gonorrhœa, chancroid had been contracted from prostitutes in an unusually high proportion. Bruck's observation that women may be carriers of the Unna-Ducrey bacillus without any clinical evidence of chancroid should be regarded with caution, in view of the fact that Pfeiffer's "Streptococcus urethræ" may easily be mistaken for the causal organism of chancroid. Although the cause of the epidemic is not entirely explained thereby, the disease appears to have been introduced into Germany by sailors coming down the Rhine who had been infected in Dutch ports. A similar introduction of the disease from abroad had occurred at St. Etienne in 1926, when out of 109 chancroid patients 64 were foreigners, most of whom were Poles.

ARTIFICIAL MENOPAUSE

MOST gynæcologists prefer not to remove both ovaries when performing hysterectomy for non-malignant conditions before the climacteric. On the other hand, some have advocated extirpation of both ovaries with the uterus, because they believe that the subsequent surgical menopause, though more severe, is shorter and therefore preferable. J. V. Sessums and D. P. Murphy[1] have studied the after-histories of 91 patients subjected to hysterectomy, with conservation of one or both ovaries, before the age of 36. They found that 40 (44 per cent.) of these patients *developed hot flushes before the age of 40; whereas* of 52 patients in whom the uterus and both ovaries had been removed, 42 (81 per cent.) developed hot flushes before that age. The flushes were described as severe by 37 per cent. of the first group, and by 73 per cent. of the second group of patients. The onset of menopausal symptoms was thus earlier in those who had had both ovaries removed. Conclusions about the duration of menopausal symptoms require observation over a very long period; only 25 per cent. of the 82 patients who experienced flushes described them as having ceased. In this series apparently more of the patients with ovaries intact described the flushes as having ceased; yet the "average duration" of the menopause is given as shorter in the group with bilateral oöphorectomy, being 7·2 months on the average in these cases. This conclusion should be regarded with some reserve. The dates of operation are not given, however, though the "total time" of the period of observation extended over 14 years. It is possible that some of the cases have not been under observation for anything like this period. We are informed that surgical menopause following radium treatment may be prolonged; some patients, followed up over a period of as long as 10 or 11 years, still have flushes. It is questionable whether much can be gained by attempts to estimate the duration of menopausal symptoms without differentiating them into mild or severe. Occasional flushes are of little importance, and they may continue over many years. It would be more useful to ascertain the time during which a patient goes on having flushes every day; but not all patients seem to be much troubled by the symptom, even if it occurs frequently. Doubtless the psychological attitude of the patient is a big factor in determining the severity of symptoms following artificial menopause, and this can be greatly influenced by that of her doctor. On the whole, gynæcological opinion seems to favour the retention of some ovarian tissue in a premenopausal hysterectomy.

BRITISH SPAS

A NEW edition has appeared of the handbook of the British Spas Federation,[2] compiled from the reports of the local medical committees for the use of the medical profession. Sir Humphry Rolleston supplies a short introduction, and there is a foreword by the Committee for the Study of Hydrology in Great Britain. The committee call attention to the fact that there is in England little or no provision made in medical education, under graduate or post-graduate, for the study of this form of treatment. For more than ten years they have endeavoured to fill this gap by periodical illustrated lectures and by conducting parties of medical men and students to the spas. This attempt to make the subject better understood by the medical profession has been made financially possible by the British Spas Federation.

[1] Surg., Gyn., and Obst., 1932, lv., 286 and 728.

[2] The Spas of Great Britain: the Official Handbook of the British Spas Federation. Bath: Pitman Press. 1932. Pp. 230.

This handbook contains a variety of information, geological, historical, topographical, and—more important—medical indications. The latter are of chief interest to the practitioner, and might perhaps have taken a more prominent place in the text. The judicious comparison of a group of spas may be of value. The biological properties of waters and muds are now much discussed on the continent. Certain observations are here recorded on the action of the Buxton waters on vegetable growth, and on the bactericidal action of the old sulphur water at Harrogate. It would be interesting to learn whether the waters of Bath, which, coming from a depth of some 5000 feet, shows signs of any biological properties of this nature. From Cheltenham comes a discussion on the general actions of baths; the aeration and whirlpool baths, devised in England during the war, are regarded as stimulant remedies in atonic nervous disorders. No mention is made here or elsewhere of sedative baths in the treatment of cardiovascular and nervous cases. Very little information seems to be available about the composition and mode of action of peats and muds, which are more and more employed in bath establishments in England, especially for rheumatism.

It is regrettable that some British spa authorities still think it necessary to attach foreign names to most of the baths in common use; it would appear to the uninitiated reader that the Scotch douche is the only one which belongs to these islands! The medical committees have presented a varied and interesting collection of information. The resources of civilisation are evidently by no means exhausted at the health resorts, and there is still scope for British energy and enterprise.

PROBABILITIES IN MODERN WARFARE

SINCE the responsibility for the care of casualties in any war falls upon doctors, the medical profession has a special interest, apart from that of the thinking citizen, in the forms which warfare would now take. Last year the Inter-Parliamentary Union published the views of 19 experts belonging to nine different countries on the probable characteristics of the next great war; this book has just been republished in a popular edition [1] and deserves far more attention than it received on its first publication. To say that it is a terrible book might give a wrong impression, since it is only by exercise of imagination that the presentation of the facts, figures, and opinions can be translated into human terms. The impression is left that a future war would not merely be an intensified repetition of the last one, but that it will be of quite a different character. Just as the old wars between barbarian tribes were wars of extermination so, after passing through the stage of professional armies and of the "nation in arms" as exemplified by the late war, the advent of air and chemical warfare has made strategy revert to the primitive idea of extermination; the nation in arms will be the nation under fire—a very different matter. The results of the use of modern air power would be, in effect, to bring a whole country within range; chemical agents would be of immense use against an unprotected civilian population; the destruction of the "nerve centres" of government and industry are almost certain to be the immediate objective. The question remains whether their destruction is possible. "In the course of manœuvres 250 aeroplanes took part in a night attack on London. According to military estimates only 16 of those were discovered by searchlights, and even under the most favourable circumstances it is not certain that even these would have been all shot down." As to the results, Prof. Langerin stated that 100 aeroplanes, each carrying a ton of gas, could cover Paris with a gas cloud 20 metres thick in one hour. Besides gas, thermite bombs weighing only 1 kilogramme each can develop a temperature of 3000° C. and burn through steel, while no extinguishing appliance has yet been invented. With such weapons used under the new strategic conception that "to attack the civilian population is now a basic principle of modern warfare" (Major Endres) a further war might well become mass murder of the civilian population rather than a conflict between the fighting forces.

The possibility of "bacteriological warfare" has been studied by a commission of the League of Nations on Chemical Warfare,[2] and the conclusion is that while there is a possibility of the destruction of crops by parasites distributed by air over a large area there is no immediate likelihood of any use being made of the bacteriological weapon against enemy personnel. Certainly on a priori grounds it is difficult to imagine conditions which could fulfil the four obvious postulates for its use: (1) the effects must be disabling, at any rate, temporarily; (2) it must be communicable in the first instance to the enemy; (3) it must spread rapidly; (4) the side employing it must be protected either by complete isolation or by some form of preventive or curative agent unknown to the enemy.

THE MEDICO-LEGAL SOCIETY

THE Medico-Legal Society has signalised the thirty-first year of its existence by issuing a new journal.[3] In future the transactions of the society will be issued quarterly instead of yearly and will be combined with book reviews and hitherto inaccessible material such as abstracts of foreign literature of medico-legal interest. Dr. Gerald Slot and Mr. Everard Dickson are the honorary editors. Lord Riddell, the president of the society, in a foreword, expresses the hope that the journal will in time provide a complete survey of medico-legal and criminological subjects. The first number promises well. The opening paper by Sir John Collie on medico-legal practice is in light and anecdotal vein, but Dr. F. J. McCann provides more solid fare in his exhaustive survey of impotence in the male and female, a paper which contains much of value to the practitioner as well as to legal and medical specialists in the courts dealing with matrimonial causes. In a retrospect of the history of the society its founder, Mr. Henslowe Wellington, recalls with justifiable pride the many eminent men who have filled its offices, including Lord Justice Atkin, the late Lord Russell, Dr. Stanley Atkinson, and Sir Samuel Evans. He notes that three of the original office-bearers of 1902, Sir William Collins, Sir Walter Schröder, and himself, are still active members.

[3] The Medico-Legal and Criminological Review. Published for the Medico-Legal Society by Baillière, Tindall and Cox, London. Vol. I., Part I, January, 1933.

There are special reasons why the Medico-Legal Society should attract influential and widespread support. The varied duties which are included under the term "medico-legal" are carried out in England with great ability, but under considerable handicaps. There is no centre for teaching, research, collection and storage of specimens, or the performance of laboratory tests, such as can be found in the great cities of almost every other civilised country, including that part of Great Britain which lies north of the Tweed. The society has for long filled at least a part of the gap, in that it provides a meeting-ground where doctors and lawyers can discuss in amity those thorny problems which too often arouse mutual antagonism in the more heated atmosphere of the courts. Doctors and lawyers have everything to gain personally by a better understanding of each others point of view and perhaps the lay public, over whose bodies, live or dead, the forensic battles rage, stand to gain most of all in the shape of sounder and better informed administration of justice. A case in point was quoted by a stipendiary magistrate in the discussion on Dr. McCann's paper, reported in the new journal (p. 53). An application for an affiliation order was made to the court over which he presides against a man of 69. The defendant produced a certificate with which he had been going about armed for some time and which he had been sufficiently business-like to have had brought up to date. It was signed by a surgeon who had removed his prostate gland, and stated that in consequence it was impossible for him to become the father of a child. The case might well have ended there but for the enterprise of the solicitor who represented the child's mother. He enlisted the help of the medical press and before the adjourned hearing had secured evidence that pregnancy had followed intercourse in at least one known case of prostatectomy. The learned magistrate, arguing no doubt that "what man has done man can do," granted the order of affiliation, a course which subsequent events proved to have been just. The story has several morals, not the least of these being the great value of transactions in which such cases are recorded.

OXYGEN AND CARBON DIOXIDE AS RESPIRATORY STIMULANTS

THE increased use of carbon dioxide as a respiratory stimulant has led to further investigation of its mode of action, and recent work suggests that many of the standard explanations of the effects not only of carbon dioxide but also of oxygen-lack will need to be revised. Some experiments reported in a paper[1] from the department of physiology at the Middlesex Hospital by Dr. S. Selladurai and Prof. Samson Wright, throw some light on this complicated problem. A new point of view, they say, was reached in 1927, when J. F. Heymans and C. Heymans showed that chemical changes in the blood might modify respiration reflexly, without necessarily acting directly on the respiratory centre itself. These workers, with their collaborators, concluded that acute anoxæmia stimulates breathing reflexly for the most part by acting on the carotid sinus and (to a lesser extent) on the aortic nerve-endings, and that its direct stimulant action on the respiratory centre is comparatively unimportant. Prof. Wright and Dr. Selladurai have now re-examined the action of oxygen-lack in the cat. Inhalation of various concentrations of oxygen (4 to 16 per cent.) and of nitrogen were studied in decerebrate and in chloralosed animals. With the carotid sinus nerves eliminated and the vagi cut it seems to be proved that lack of oxygen depresses the "isolated" respiratory centre. The increase in breathing which is often obtained in the intact animal appears to be wholly reflex, and depends upon excitatory afferent impulses in the sinus nerves and the vagi which overcome the direct depression of the centre. Examination of this point in greater detail revealed that the reflex stimulation from the sinuses may under certain circumstances be of greater importance than that produced by the vagi. Apparently the integrity of what Prof. Wright has called the "buffer" nerves enables the respiratory centre to withstand for long periods degrees of anoxæmia which are lethal to it when it has been isolated by section of the vagi and denervation of the sinuses. In view of these results, which confirm in the main those reached by the Belgian investigators in their work on dogs, the classical theories in which oxygen-lack is considered a stimulant to the respiratory centre can no longer be regarded as tenable. Experiments on the circulatory effects of the low oxygen mixtures used do not support the idea that fall in blood pressure is playing any important part in the results obtained.

In a second paper[2] similar detailed studies of the mode of action of carbon dioxide have been made, and here again the classical theories, which assume that the influence of this gas on breathing depends entirely on an action on the respiratory centre, will have to be revised. The results obtained are not, however, so clear-cut. In the cat it is found that denervation of the carotid sinuses usually decreases the rate of breathing and the minute-volume of ventilation—whether the vagi have been previously cut or not. It is concluded that the chemical composition of the blood stimulates the nerve-endings in the carotid sinus in the resting animal to discharge tonic excitor impulses to the respiratory centre. The response to carbon dioxide was usually reduced when the sinuses were denervated, and it was concluded that raised carbon dioxide concentrations stimulate the respiration in part reflexly from the carotid sinus. The effects of vagotomy varied somewhat in different experiments, and it is suggested that carbon dioxide may act differently on the various sensory components of the vagus nerve.

EPIDEMIOLOGY OF THE COMMON COLD

INVESTIGATIONS made at the Johns Hopkins University, with the support of the John J. Abel fund for research on the common cold, include a study, by V. A. van Volkenburgh and W. H. Frost,[3] of the prevalence, distribution, and character of the minor respiratory disorders observed over a space of two years (November, 1928, to November, 1930) in 114 Baltimore families comprising a mean weekly population of nearly 500. Notification was made immediately upon the occurrence in any member of the family of any respiratory illness whatever, including those which were apparently trivial, and on report of a case a staff physician promptly visited the home and obtained a record of the illness by interrogation of the patient or (in the case of children) of the mother. Each case was revisited, usually by a nurse, at short intervals until recovery. The result is a body of very full and detailed data with regard to incidence and clinical aspect. Counting all respiratory illnesses reported, the attack-rate during the first year, November, 1928, to November, 1929, was 318 cases per 100 persons observed, while in the second year it was almost the same—namely, 307 per 100—despite the fact that the first year was marked by a fairly severe epidemic of influenza. The incidence, as would be expected, does not fall equally upon each age. It is at its highest in children under 5 years of age, declines progressively to about the age of 15–19, increases somewhat between 20 and 35, and thereafter declines slowly as age increases. Though the populations in some of the age-groups are very small this course agrees with previous figures reported by J. G. Townsend and E. Sydenstricker,[4] who pointed out that the fall in incidence with advancing years is at variance with the rising death-rate from respiratory disease.

[1] Quart. Jour. Exp. Phys., 1932, xxii., 233.

[2] Ibid., p. 285.

[3] Amer. Jour. Hyg., January, 1933, p. 122.

The most striking feature of the seasonal distribution is the high prevalence in the autumn, followed through the winter and spring by a series of epidemics. This confirms the previous evidence of W. H. Frost and Mary Gover,[5] which showed that during the season of higher prevalence the incidence curve exhibits a series of oscillations, each of several weeks' duration which, although irregular in sequence and magnitude, cannot be regarded as mere chance fluctuations. The incidence is not therefore, as might readily be supposed, equally spread over the winter months, but consists of a series of distinct epidemics, irregular in spacing and magnitude. Clinical data are given in detail for 1388 cases, some of the symptoms (e.g., irritability) being, perhaps, too subjective to be of very much value. The average duration of symptoms was 16 days, which, taken in connexion with the mean number of attacks suffered (3·07 per person for the year 1929–30), gives an average of approximately 49 days per person per year during which symptoms were present. In other words, on the average this population suffered from symptoms of minor respiratory disease for nearly one-seventh of the year, a figure which seems unduly high in spite of the fact that 10 per cent. of the cases under 5 years of age were complicated by otitis and 3 per cent. by adenitis. The most frequent symptoms were coryza, cough, and sore-throat, and, naturally, presence of the symptoms does not necessarily denote incapacity for work, though a quarter of the patients were confined to bed and the same proportion had fever. From this evidence van Volkenburgh and Frost conclude that the "common cold" implies more than coryza, and that the systemic reaction is more marked than is generally believed.

BACILLARY DYSENTERY IN CHILDREN

THE importance of bacillary dysentery as a cause of infantile diarrhœa in this country has often been emphasised of late years, and in our issue of Jan. 28th Dr. Eileen Harvey described five cases of sudden death (four of them in children) which she regarded as due to this cause. In each of these there was a ring of lymphoid hyperplasia and œdema around the ileocæcal valve, and *Bacillus dysenteriæ* Sonne was isolated from the stools of the sister of one of the patients who was ill at the same time. Dr. D. Nabarro and Dr. A. G. Signy[1] have reviewed the cases of dysentery seen in the Hospital for Sick Children, Great Ormond-street, from January, 1929, to December, 1932, which number 106 in all. Most of them occurred in small ward outbreaks, and in the older children the condition was usually mild; the cases due to the Sonne organism showed a mortality of 4·5 per cent., and those due to the Flexner type 10·5 per cent. The infection was recognised through the routine examination of the stools of all cases of diarrhœa admitted to, or occurring in, the hospital, both for blood and pus and by culture for dysentery organisms. Cultures were made direct from an emulsion of the fæces on to McConkey plates, and the diagnosis of the type of micro-organism was determined both by direct agglutination with prepared rabbit serum and also by fermentation reactions. Most of the cases also had the blood examined at least once for the presence of agglutinins, the authors considering that a "standard" agglutination with any of the strains of dysentery organisms to a titre of 1/125, or a strong agglutination to a titre of 1/50, was presumptive evidence of a recent dysentery infection. They emphasise the importance of using mixed strains of Sonne in carrying out these tests. Clinically, infection was usually characterised by abdominal pain followed by severe diarrhœa. The typical dysenteric stool contained considerable quantities of blood and mucus, with a minimum of fæcal matter. Tenesmus usually occurred, and malaise at onset, with a variable amount of fever. D'Herelle's bacteriophage was tried in the treatment of a few of the children, but with no special success. The effect of serum therapy also was not striking, though Nabarro and Signy recommend the employment of serum (given in repeated doses of 10 c.cm. intramuscularly) in cases which are obviously acutely toxæmic. General measures to prevent spread in the ward should involve the patients being treated as highly infectious, and no nurse who handles the stools should be allowed to prepare the food of another patient.

REMOVAL OF THE CORPUS LUTEUM OF PREGNANCY

EVIDENCE is accumulating that the corpus luteum is not necessary for the maintenance of pregnancy after the first few weeks. It must be the experience of a fair number of gynæcologists that the corpus luteum, or the ovary which contains it, can be removed and the pregnancy go to term. In spite of this the evidence is very strong that the corpus luteum is essential for the implantation of the fertilised ovum, and there is good reason to believe that its influence is required in the first few weeks; later in pregnancy its control of the attachment of the ovum is perhaps shared by the placenta. R. M. Corbet[2] not long ago described a case in which the ovary containing the corpus luteum of pregnancy was removed 42 days after the first day of the last menstrual period, and the pregnancy nevertheless went to term. The importance of the case depends upon the early date at which the operation was performed. On the other hand, O'Donel Browne[3] reports a case in which both ovaries were removed during the early months of pregnancy and in which the ovum died and abortion and post-partum hæmorrhage followed. Cases are on record in which both ovaries have been removed during pregnancy, in spite of which pregnancy proceeded normally (Carlton Oldfield, Essen Moller). It is well known that follicle-ripening proceeds throughout pregnancy, and that ovulation is inhibited by the corpus luteum. It is possible, if the corpus luteum alone is removed or even if one ovary is excised during pregnancy, that the removal of this inhibitory influence may lead these ripening follicles to rupture so that a second corpus luteum is produced. Some cases can perhaps be explained along these lines, although there is no evidence available to confirm the suggestion. It should be remembered that the corpus luteum develops signs of retrogression relatively early in pregnancy, and it is more than probable that its nidatory influence is restricted to the first few weeks. On the other hand its persistence until the puerperium indicates that it continues to serve some purpose, and it may inhibit not only ovulation but also the uterine contractions caused by the oxytocic hormone of the posterior pituitary. Some experiments on this point were described by Dr. J. M. Robson at a meeting of the Edinburgh Obstetrical Society on Jan. 11th. Working with slips of rabbit uterus in vitro he distinguished three stages of pregnancy: in the first half neither oxytocin nor vasopressin caused any contraction; in the second stage vasopressin caused contraction while oxytocin did not; and in the third, or terminal, part of pregnancy the reaction to oxytocin returned and gradually increased until parturition. Similar experiments were performed on strips of human uterus removed at various stages of pregnancy. None was obtained earlier than three months, but at three to five months it was found that oxytocin had no effect while vasopressin caused contraction. Subsequently the muscle became steadily more sensitive to oxytocin, and the sensitiveness reached its climax (as in the rabbit) at parturition. It is possible, Dr. Robson thinks, that the corpus luteum secretes a specific hormone, the inhibitory hormone, which acts on the uterine muscle, and which is different from the progestational hormone which prepares the endometrium for the ovum. The actions of the corpus luteum, on endometrium and muscle alike, do not occur, he believes, unless sufficient quantities of œstrin are present, and for its action on muscle more œstrin is required than for its action on the endometrium.

DETERIORATION IN THE TROPICS

MOST of the speakers in the discussion reported on p. 302 had lived in the tropics, but most of them are now living in London. The verdict of men on the spot might have been less favourable to a tropical life, and in face of breakdown they might be disposed to lay more emphasis on faults of environment and less on faults of personality. For example, in the December issue of the *Malayan Medical Journal* Mr. Kenneth Black, professor of surgery at Singapore, writes with envious enthusiasm of the benefits of a temperate climate. Times, as he says, may change, and in another 1000 years the belt of optimum climate may have shifted to Egypt and Mesopotamia. Meanwhile, however, Europeans who leave England for the tropics must expect a physical and mental deterioration which occurs independently of the onslaughts of disease, and is observed even in countries, such as Malaya, where the incidence of tropical infections among Europeans is comparatively low. Evidence of such deterioration was collected by Dr. G. H. Garlick, who, in reporting on the Colonial Survey Station making a topographical survey of Johore, stated that the graph showing the area surveyed per white man per month rose steeply at the beginning, as the man became accustomed to his work, maintained a steady level until he had been working for two and a half years, and then showed an equally steady decline until he was relieved at the end of his third year. Mental deterioration cannot be demonstrated so neatly, but it is significant that out of the total number of European government officials sent home on sick leave from the Dutch East Indies, the numbers suffering from neuroses and psychoses during the past 12 years have averaged just over 50 per cent. Prof. Black falls into line with speakers at the Royal Society of Medicine when he wonders how far this high incidence of nervous disorder is due to lack of training for self-control. Missionaries rarely get "nerves," he says, and he goes on to quote a medical authority experienced in examining people from the tropics who said that he never found neuroses in those who were really keen on their work. At the same time he urges that in Malaya three years should be the maximum tour of service for white people if they wish to keep their efficiency, mental equilibrium, and alertness. The editor of the *Malayan Medical Journal* remarks in comment that "the pendulum of lay opinion appears to be swinging from the former unjust extreme of referring to certain tropical countries as deathtraps to the other no less erroneous extreme of now regarding the same parts as health resorts."

THE COLLEGE OF PHYSICIANS

THE Milroy lectures of the Royal College of Physicians of London will be given by Dr. Robert Cruickshank on Feb. 23rd and 28th and March 2nd, the subject being Pneumococcal Infections. The Goulstonian lectures will follow on March 7th, 9th, and 14th, when Dr. Charles Newman will speak on the Physiology of the Gall-bladder and its Functional Abnormalities. Dr. C. R. Box will deliver the Lumleian lectures, on Complications of the Specific Fevers, on March 16th, 21st, and 23rd, and Dr. E. A. Carmichael the Oliver-Sharpey lectures, on the Peripheral Pathway for Sensation, on May 2nd and 4th. Prof. E. Mellanby's Croonian lectures will be given on June 8th, 13th, and 15th, the subject being Nutrition and Disease—the Interaction of Clinical and Experimental Investigations. All these lectures are to be delivered at the College at 5 P.M. on Tuesdays and Thursdays, and members of the medical profession will be admitted on presentation of a card.

WE regret to announce the death on Feb. 6th of Dr. Alfred Eichholz, chief medical inspector of the Board of Education from 1919 to 1930 and a research officer of the Ministry of Health.

INDEX TO "THE LANCET," VOL. II., 1932

THE Index and Title-page to Vol. II., 1932, which was completed with the issue of Dec. 31st, is now ready. A copy will be sent gratis to subscribers on receipt of a post-card addressed to the Manager of THE LANCET, 7, Adam-street, Adelphi, London, W.C.2. Subscribers who have not already indicated their desire to receive Indexes regularly as published should do so now.

UNIVERSITY OF OXFORD.—Dr. G. D. H. Carpenter has been appointed Hope professor of zoology as from the first day of Trinity Term, 1933.

OPEN-AIR COUNTRY HOSPITALS FOR CHILDREN *

By Sir Henry Gauvain, M.D., M.Chir. Camb., F.R.C.S. Eng.

MEDICAL SUPERINTENDENT, THE MORLAND CLINICS, ALTON, AND LORD MAYOR TRELOAR CRIPPLES' HOSPITALS, ALTON AND HAYLING ISLAND

In modern life no feature, perhaps, is more striking than the almost universal acceptance of the value of open air and sunshine. The importance of these agents having been recognised in the treatment and prevention of disease, they are being increasingly utilised by the population at large for the maintenance and improvement of health. It is no matter for surprise, therefore, that special hospitals for the treatment of children suffering from chronic disease should be established in increasing numbers, in suitable districts in the country and at the seaside, where patients may enjoy the benefits of fresh air and of all available sunshine. It must be confessed, however, that the advance in the design of such institutions leaves much to be desired; their inmates rarely find the fresh air they need combined with comfort and shelter, and as rarely are they able to take full advantage of the sunlight. Open-air hospitals are too often draughty and cheerless buildings, damp in wet weather, cold in cold weather, unduly hot in hot weather. Balcony accommodation is often woefully deficient and badly planned. Patients who should be kept immobile have to be wheeled to reach the sunshine through narrow doorways and round awkward corners. Unnecessary discomfort to the patients, useless labour for the nurses, needless damage to furniture and fabric—those are the drawbacks of many existing hospitals.

The Ideal Open-air Ward

The ideal open-air ward should be so constructed that when completely closed it still has perfect ventilation, and when completely opened its ceiling is the sky and its walls the horizon. There must be abundance of open air but freedom from draughts or excessive movement of air; there must be free access to sunlight and yet adequate provision of shade, for in sun treatment darkness is, in my opinion, as essential as light, and excess of sunlight may be even more harmful that its lack. Warmth and comfort should be ensured, for who needs them more than a sick person, and why should a patient be deprived of what reasonable foresight can procure? Wards should be so planned that all the inmates are under constant responsible supervision; every child needs that, and none more than a sick child.

Why should we be unduly concerned with the distance between beds when not only the air in the ward, but the whole air of the countryside is at our disposal? The freest possible access of air is obtained by providing wards with walls which can be folded back at will. In windless weather all the walls may be put aside. If it is not raining a sliding roof makes it possible to open the ward to the heavens and immediately the patient, without being moved, has access to all the sunshine there is. In most wards it is usual to arrange the beds about the walls, leaving the centre of the ward free, and this is convenient too for the open-air ward in which the centre portion, unoccupied by patients, has a fixed roof provided with a ventilating louvre under which the outer portions of the roof may slide. These outer portions are made of wired vita-glass, which transmits ultra-violet radiation when the roof is lowered. The sliding roof is counterbalanced by weights, so that the only effort required in raising it is to overcome friction, and even this can be dispensed with by attaching a small water-tank to the counterweights, when the roof may be raised or lowered by simply turning a tap. Below this sliding roof are canvas blinds which may be raised or lowered to exclude sunlight or moonlight when desired. Curtains can be drawn across the folding-glass walls as required and the ward thus completely darkened. The permanent walls reach just above the level of the beds and in their lower sections are rain-excluding flap ventilators which may be open or closed as needed. Thus, in very inclement weather, when full protection is required, the sliding roofs and the folding walls may be closed, good ventilation still being obtained through the flaps; the air enters the ward at floor level, and passes out through the central louvre.

AN EXAMPLE AT BRAMSHOTT

In such a ward, it will be seen, all weather conditions are provided for. One such erected on my suggestion at King George's Sanatorium for Sailors, Bramshott, some years ago has been in constant use summer and winter, in rain, hail, and snow, and has no balcony accommodation, for no balcony is needed. The patients have complete access to open air and to sunlight without their beds ever being moved. The ward is cooler in summer and warmer in winter than other parts of the institution. Heating is desirable for such wards in this country, if only to exclude damp. At Bramshott it is obtained by the use of anthracite stoves, which are clean, economical, readily adjusted, and only require fueling once daily. The patients, adult and often heavy men, obtain all the light and air they need without labour on the part of the staff, without discomfort to themselves, and without damage to hospital property. It remains, in my opinion, the most perfect open-air ward hitherto erected; but it could be improved by having two sliding roofs, one of asbestos or copper to exclude light and afford additional protection, and the other of wired vita-glass. Such a ward represents the ideal for this climate; it is, however, so revolutionary in conception and so foreign to our notions of a hospital, as to be viewed with suspicion by both architects and governors. Nor does it lend itself readily to architectural display or give the impression of permanent durability. Nevertheless, the experience gained at Bramshott shows the design to be practical and efficient. Many variations to this plan may easily be devised. Thus the fixed wall from bed level to the ground may be dispensed with, the folding walls reaching from ground level to any convenient height and above that, rain-excluding, centrally fixed windows provided. The sliding roof may be duplicated, either the external or internal being of wired vita-glass, the other of asbestos for lightness, or of copper on wood for durability. As an alternative the roof may slide in sections laterally, but the type already described will probably prove the most practical, useful, simple, and economical.

---

* Based on a presidential address to the Section for the Study of Disease in Children of the Royal Society of Medicine.

The idea of these open-air wards evolved from the employment of specially designed balconies with sliding roofs constructed at the Morland Clinics. One such balcony has already been illustrated in The Lancet.[1] They have amply justified their value, are much appreciated by the patients using them, are labour-saving and therefore popular with the staff, and have proved very economical in avoiding damage to hospital walls and furniture, which is inevitable when patients have to be wheeled from ward to balcony. Patients occupy these balconies day and night all the year round, undoubtedly to the advantage of their health. The danger of infection of all kinds is reduced to a minimum, basal metabolism is raised, appetite rapidly increases, recovery is hastened, and without question from every point of view they are advantageous to the patient, who literally lives in the open air but is sheltered from the weather as may be required.

Diagrammatic section of an open-air ward.

The Treloar Hospital

In planning an open-air hospital one has not only to think of the ward, but of the general lay-out and of the accessories indispensable for the work. At the Treloar Hospital, while the open-air ward just described was not adopted in the final plan, the wards approach very closely to that ideal; they combine permanent structure and successful architectural treatment with maximum convenience and efficiency, as well as the maximum of open air and light. The wards are single-storeyed for convenience in dealing with crippled and mostly recumbent children, as well as for safety in case of fire. The lay-out is on clean and straight lines, a great advantage from the engineering side, for bends and curves in pipes encourage furring and increase the power required for distributing the water. Sewerage is simplified. Pipes and cables are conveyed in a large main trench, which is a subway under the cloisters behind the wards, readily accessible in case of breakdown.

The hospital consists of five similar ward units of 60 beds each. Experience has shown us that with the type of case treated one fully trained sister is able to supervise such a unit with the assistance of probationer nurses. The Board of Education has laid down that 30 such patients may be taught by one teacher, and in order to earn most economically the educational grant for a hospital school the ward unit is divided into two similar parts, each half consisting of one large ward of 24 beds with its sanitary annexe, one small ward of four beds, and two cubicles. The small ward and cubicles are desirable for patients who are very ill, or who for some reason have to be nursed apart from the others or under different conditions. The cubicles are very useful for isolation, when a patient develops a complication such as a rash, the nature of which is in doubt, or for septic cases, which it is desirable to keep apart. This small ward with adjacent cubicles has its own sanitary annexe. Nevertheless, there is ready access to the main ward for educational purposes and for convenience in supervision and nursing.

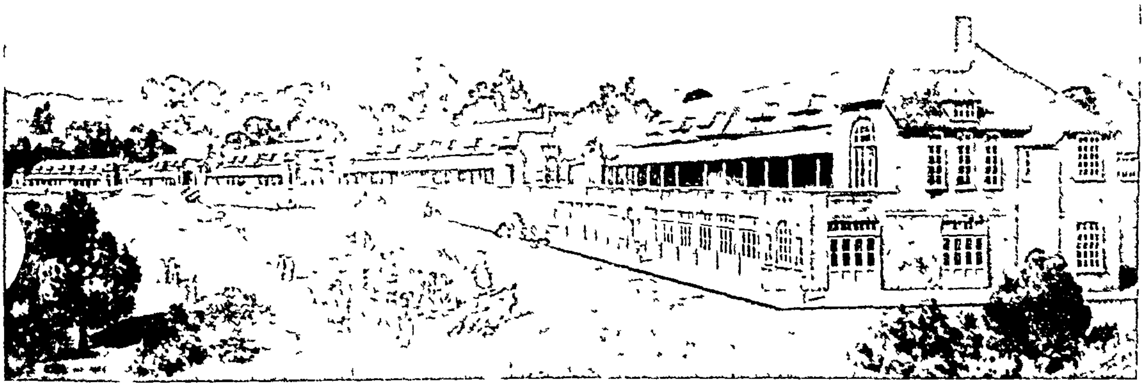
THE WARD UNIT

In the centre of the ward unit is the sister's office, which may be regarded as the pivot of the whole.

---

[1] The Lancet, 1927, i., 755.

FIG. 2



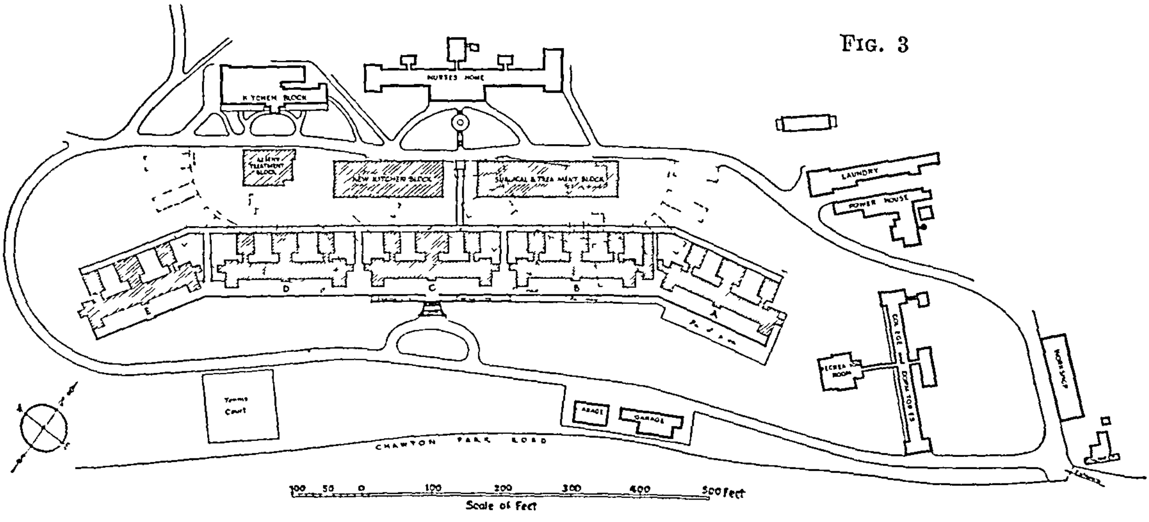
Perspective view of the completed Treloar Cripples' Hospital at Alton.

From this she can see all the patients in each ward and on the terrace outside; she controls the lighting and is in direct telephonic communication with the hospital exchange. For ventilation the wards have folding doors with Esavian fittings on the whole of their southern aspect, as a rule kept open, but capable of being closed in very inclement weather. Above these doors are windows the whole length of the southern part of the ward; these may be opened by gearing, are rainproof, and with the windows on the other side of the ward afford perfect cross-ventilation when the folding doors are closed. The wards being lofty, their inmates have the most abundant supply of gently moving air with the minimum of draught, so that dormitory and ward infections have less chance of developing. For the sake of comfort each ward is provided with an open fireplace with tiled surround. The psychological effect of such a fire, especially on a dreary day, is great. The main heating of the ward is, however, by panels beneath a terrazzo surround, a method which has not yet given rise to any difficulty in application. There is no need for a child in an open-air hospital to suffer from cold, although access to cold air is desirable. By means of the panel heating dampness may be excluded, a matter of great importance to children with joint disease, many of whom are immobilised in bed for lengthy periods.

The walls to a height of 4 feet are covered with terrazzo, while the centre of the floor is composed of teak blocks. The whole side of the ward being open, the beds are pushed on to the balcony with the minimum of labour. At the junction of the ward floor with the terrace outside is a guttered grating to catch any rain which may be blown in, but there is no obstruction to the wheeling of beds—ward floor, terrace, and grating being on the same level. The wards are illuminated by concealed roof lights which may be increased or diminished at will, and are so placed as to cause no glare in the patients' eyes. Differentially heated electric mattresses were at one time provided for the patients but these have been given up. Instead, in cold weather, each patient has hot-water bottles, changed four-hourly, when they are placed in a steam-heated chamber to be warmed up. This procedure is not only labour-saving but prevents waste of hot water. The beds and spinal stands are provided with large wheels and are easily moved.

The terrace in front of the wards is 25 feet in width, and is provided with a vita-glass covered balcony for a width of 10 feet. The proximal half of

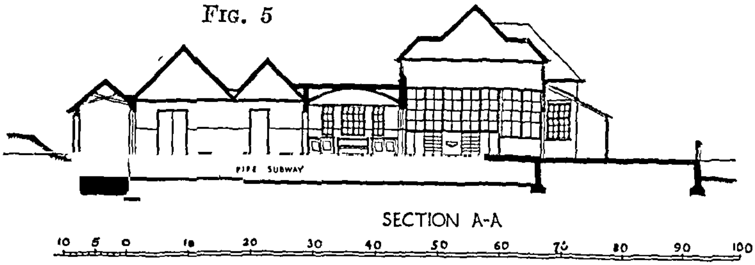
FIG. 3



Lay-out plan of the same. The dotted lines indicate the position of the wards in the original hospital.

the roof of this balcony is fixed to the wall, the distal half being a sliding roof of vita-glass, counterbalanced and so constructed, that by means of simple gearing it may be raised or lowered in sections at will. In fine weather this sliding roof is raised, in wet weather it is lowered; all patients therefore may be in the open air without danger of being disturbed by rain or snow. This terrace, approximately 1000 feet long, is paved with artificial stone blocks tinted green to avoid glare. It is readily accessible for every bed in the wards, and facing south-east, ensures the maximum of sunlight for the patients, combined with the maximum of protection. From the centre of the terrace are steps to the ground and a ramp on each side for the use of ambulant children who are crippled or need crutches.

FIG. 5



Section of the ward block.

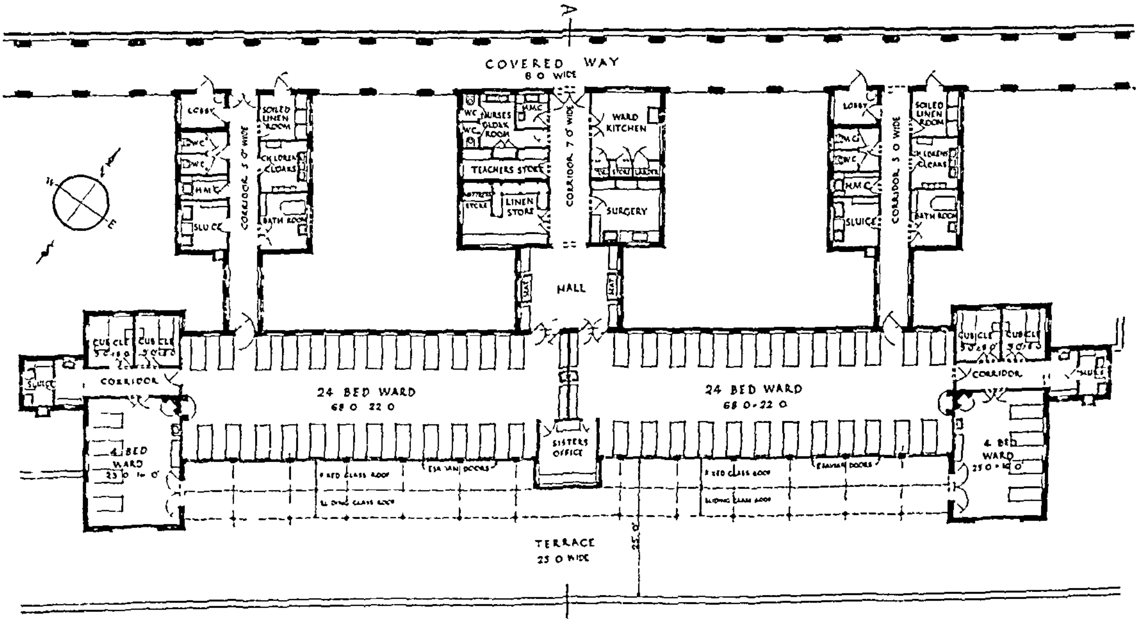
SANITARY ANNEXE

Each ward has its own sanitary annexe, comprising a sluice house, with hot-water rack for keeping bed-pans warm, and an appliance for sterilising them after use. There are separate lavatories, a room for ambulant children to wash in, a room for recumbent children to be washed in, with a special bath and special bath bed. At the north end of each annexe is a room for brushes, brooms, coal, &c., which may be brought from the cloisters behind the hospital without entering the ward at all. On the other side of the corridor is a room for soiled linen, which is collected in bins and removed via the cloisters. In the centre of each ward unit is a passage way from the cloisters leading to the main wards, with ward kitchen, surgery, housemaid's pantry, nurses' cloakroom, room for teacher's stock, and extra mattress, blanket, and linen rooms specially heated. The sister thus has her complete stock conveniently under control. The ward kitchen has, in addition to a hot plate, a small gas-stove and a steamer for sterilising crockery and cutlery after they have been washed. No child ever has any food presented to him on any utensil which has not been sterilised, and the danger of cross-infection is thus minimised. In the surgery there is a steamer for sterilising dressing bowls, &c., used in the wards. Dressings, gowns, and towels are sterilised in the central department. Attached to each patient's bed is a metal locker containing his own toilet requisites, so that danger of intermixing is excluded. Should any infectious disease arise, the patient is transferred at once to the isolation block which, in addition to small wards, has five separate cubicles approached by a passage way behind, but completely separate one from the other. Here observation is made easy by glass walls. The windows open completely and the south half of the roof is comprised of wired vita-glass on the sliding roof principle, so that even though suffering from infectious disease, the patient may enjoy the benefits of sunlight and fresh air without being moved from the cubicle. In inclement weather the windows are closed and the sliding roofs lowered, ventilation being ensured by flap ventilators.

OTHER DEPARTMENTS

Connecting the ward units behind is a long covered passage through which patients may be wheeled or carried under shelter to any department of the

FIG. 4



Ward block for 60 beds: plan.

hospital—actually they will be conveyed by electric trolley. A subway beneath these cloisters carries the heating, electricity, and gas for the ward units. The water for domestic purposes is softened, but hard drinking water is also laid on. In the centre of the hospital on the north side, and in ready access to the cloisters, there will be erected a treatment block, containing a fully equipped operating theatre with anæsthetic, sterilising, and surgeon's rooms, X ray department with fireproof room for storage of films, a studio for photographic work, plaster room with plaster store, massage and remedial exercise room, dressing rooms, dispensary, &c. On the floor above it is proposed to erect a surgical ward where patients may remain before and for a few days after operation. There will also be a special ward for sick staff, a lecture theatre, and a fully equipped laboratory. Owing to the nature of the ground there is a difference of 12 feet in level between east and west ends of the hospital. The extreme east block is therefore constructed in two storeys, the upper being a ward unit as described, and below it a dining-room with servery for ambulant patients, class-rooms, open-air and sheltered play-room, and hobby-room. These rooms will be separated by folding walls, and are so designed that in emergency they may be converted immediately into one large ward or one or more smaller wards, to provide temporary accommodation if at any time one of the regular ward units should need redecorating or repair. Should infectious disease occur in any of the regular wards, this section could be utilised while the unit is being disinfected. In fine weather the ambulant children will be taught on a specially designed terrace outside the class-rooms. Adjacent is a head teacher's room, teacher's common-room, and necessary annexes. Behind, on the same floor, is an exhibition room and the new light department with sister's office, and outside will be an outdoor light department designed for use in all weathers, and so constructed that the patients may have the freest access to cold air during treatment. Near-by are the orthopædic workshop and surgical carpenter's shop and stores. This lower floor may be conveniently reached from the wards and terrace above, either by one of the two ramps, suitable for trolleys or ambulant cripples, or even more readily by a staircase.

A Principle that Might be Extended

It may be reasonably argued that there is a wider issue than the application of these principles to open-air country hospitals for children. Has not the time come when, with an accurate knowledge of the value of open air and sunlight, such principles might be usefully applied to other types of hospitals, to residential institutions of all kinds, including schools and even to private houses? There is no doubt that living under such conditions many hospital patients would be restored to health more speedily, that the pupils in schools would be sturdier, healthier, happier, and less prone to infectious disease than at present, and that the community as a whole would benefit. In any case, it is certain that adequate, readily accessible balcony accommodation, with sliding roofs where possible, should be regarded as essential necessities in all modern hospitals and nursing homes.

I desire to acknowledge my indebtedness to Mr. H. Smart, F.R.I.B.A., the architect of the Lord Mayor Treloar Cripples' Hospital, who has kindly supplied the illustrations to this paper, and whose helpful advice and criticisms I have much appreciated.

THE L.C.C. HOSPITAL SERVICE

THE material collected in that portion of the annual report of the London County Council for 1931, which deals with the hospitals and general medical services under the control of the central public health committee, includes also a discussion on hospital management, an account of the salaries and emoluments of the staff, and a description of the London ambulance service.[1]

PATHOLOGICAL SERVICES

In an introduction, Sir Frederick Menzies refers to the development of pathological services, since experience has confirmed the conclusion that the absence of any organised laboratory system in the poor-law hospitals was not only unsatisfactory but also uneconomical The importance of facilities for personal coöperation between clinicians and pathologists is recognised. To this end the establishment of five group laboratories, with a separate histological laboratory, was decided on. Three of these are already in working order and are supplemented by hospital laboratories for examination of pathological material on the spot in eight hospitals. These hospital laboratories are staffed by women hospital laboratory technicians, specially trained for the purpose at the southern group laboratories; Dr. G. W. Goodhart reports that excellent work is being done by these technicians and that there is reason to believe that they are earning the confidence of medical officers.

Eighteen of the 28 general hospitals under the central public health committee are now provided with some degree of pathological facilities. With the gradual development of this service the necessity for having recourse to the services of external laboratories has progressively diminished.

The marked diminution in the number of patients treated for diphtheria is noted—the number of admissions being 7190, compared with 11,505 in the previous year. The amount of diphtheria antitoxin issued (236 million units) is the smallest annual issue made during the last seven years. Among the special investigations recorded is one on percutaneous immunisation against diphtheria by means of an ointment: the results indicate that with the material at present available this method of immunisation is not likely to be successful.

SPECIAL UNITS

Each hospital, prior to its transfer to the Council, served a definite district of London, and patients and their friends are inclined to resent any departure from the long-established usage of the guardians. One of the reasons for the passing of the Local Government Act, 1929, however, was to pool the hospital resources for the benefit of the metropolis generally, and experiments in re-allocation are being conducted in 11 of the boroughs. Steps were taken towards the establishment of special units in certain hospitals, in order to economise in medical nursing staff with special experience, and in special equipment; moreover the convenience of specialists or consultants is promoted by such concentration, and research work can be more easily undertaken.

The special units are to be as follows:—

Plastic surgery.—A unit established by the late Wandsworth Board of Guardians at St. James

---

[1] L.C.C. Annual Report of the Council, 1931, vol. iv., Part 1. No. 2935. London: P. S. King and Son, Ltd., 1932, pp. 233, 2s. 6d.

Hospital, Balham, to which Sir Harold Gillies was attached as visiting surgeon, was transferred to Hammersmith Hospital in June, 1931, and has since been enlarged. Sir Harold is to serve as (honorary) chief surgeon, Mr. T. Pomfret Kilner, as surgeon, with assistant surgeons, anæsthetists, dentists, and a dental mechanic, a speech trainer, and a photographer-stenographer.

Radium therapy is concentrated at Lambeth Hospital under Dr. G. F. Stebbing; the work increased considerably during the year under review and will be described in another volume of the report.

Rheumatism.—In response to a request from the British Red Cross Society, it was decided to set aside a number of beds, not exceeding ten, for selected cases of subacute and chronic rheumatism under certain specified conditions. The patients thus admitted are subject to assessment of maintenance charges and are under the care of the medical superintendent of the hospital, though the staff of the Red Cross clinic are afforded facilities for research into and investigation of their conditions. The arrangement whereby 12 beds for children suffering from acute rheumatism were reserved at the St. Mary Abbot's Hospital has been terminated.

Thoracic surgery.—It was agreed that the intervention of a chest surgeon may be required for conditions which arise as part, or as complications, of subacute and chronic disease. It was, however, impossible to forecast the amount of surgery required and it was decided, as an initial step, to ensure that the services of a thoracic surgeon (unnamed) would be available for the general hospitals, but pending a year's experience no one hospital is being set apart for this work.

Thyroid diseases.—At the request of the Medical Research Council, who had found the lack of sufficient hospital beds to be seriously hampering research into the causes, manifestations, and treatment of Graves's disease, it was decided to provide a special unit of 10–12 beds at the New End Hospital. Dr. G. Scott Williamson and Dr. Innes H. Pearce are to be specially associated with the unit, to which patients suffering from myxœdema and from parenchymatous goitre and cysts may also be admitted.

Lupus, as a manifestation of tuberculosis, is in general dealt with under the Council's tuberculosis scheme. Adult patients requiring in-patient treatment as well as the application of Finsen light are accommodated at the Bow institution and go to the London Hospital for light treatment.

MENTAL PATIENTS

The gradual reorganisation of the mental units associated with the transferred hospitals has been decided on, since the arrangements for classification and segregation were found to be defective in the main; many of the units were somewhat gloomy and ill-equipped; and only two had mental consultants attached. Large observation blocks have been established at Bow to serve the eastern districts and at Constance-road institution to serve the southern districts. By permission of the Mental Hospitals' Committee, nine medical superintendents or deputy medical superintendents, have been appointed to act as consultants to existing units, which they visit once every week. Psychiatric social workers are attached respectively to St. John's and St. Peter's Hospitals, and their work is being much praised. Out-patient clinics, staffed from the Maudsley Hospital, are established in four hospitals in the north, east, and west of London, while patients from south London are seen in the out-patient department of the Maudsley Hospital. These clinics are used as consulting centres by general hospitals not visited by mental consultants, and also for cases of neurosis, psychoneurosis, and early mental disease in which district medical officers or public assistance committees desire an opinion.

VENEREAL DISEASE

Patients will in future be concentrated in nine units, four for men and five for women, in which some 270 beds will be available; all these units are now fully equipped for diagnosis and treatment. The important task of coördinating the venereal disease work in the municipal hospitals with that carried out at the voluntary hospital clinics will be greatly facilitated by the appointment of Mr. Anwyl Davies as general consultant in venereal disease to the Council's hospitals. It will now be possible for the first time to ensure a uniform standard of treatment and of record-keeping.

PATIENTS' DIETARIES

Nine scales of dietary have been prepared to meet the needs of various categories of patients. Prof. S. J. Cowell and Dr. Donald Paterson have given advice on the nutritional value of the diets prescribed, which are here tabulated. The dietaries are supplemented by fresh fruit, and medical officers have full power to add extra foodstuffs or vary them according to individual requirements.

TRAINEE SCHEME

In the part of the report devoted to special hospitals, one of the most interesting sections is that describing the initiation of training centres for tuberculosis nurses and domestic servants among ex-patients at King George V. Sanatorium and at Pinewood Sanatorium. These institutions were chosen because there is little stair climbing or heavy nursing work to be done, and no children—who might be susceptible to infection—are admitted. Candidates for training must be in a quiescent stage of the disease and serve for a preliminary period of six months or more at half-pay rates, being subsequently appointed on probation to the permanent staff. For purposes of establishment three trainees are regarded as the equivalent of two healthy members of the staff. Since the inauguration of the scheme 29 women have been accepted as trainees, breakdown demanding renewed sanatorium treatment occurring only in four cases. The sickness-rate among the rest is little, if any, greater than that among the healthy staff.

AMBULANCE SERVICE

At the end of 1931 186 ambulances and omnibuses were in service, the staff (excluding ambulance nurses and mechanical staff) numbering 404. The total number of calls in 1931 was 43,746, of which 11,226 were dealt with by the two double stations at Bloomsbury and at the Elephant and Castle. The average time to reach cases in the year was 6·5 minutes, the quickest average time since the inauguration of the service, while the average time elapsing between the receipt of calls and arrival at hospitals was only 13·6 minutes. Such swift transport certainly justifies the provision at hospitals of sufficient casualty officers to ensure that emergency cases receive expert attention without a moment's delay.

HEALTH AND DISEASE IN THE ARMY

THE "epidemic constitution" of 1931 is thought to have favoured influenza and cerebro-spinal fever, and the director-general's annual report[1] shows that there were 88 cases of the latter infection, 39 of them (with 10 deaths) at Aldershot. There was no evidence of case-to-case spread. It is suggested that the disease is essentially a nasopharyngitis, invasion of the blood and meninges occurring as a complication. In one case of meningococcal septicæmia without localising symptoms the fever lasted four months, during which the organism was easily recovered from the blood.

Diphtheria cases were reduced by a third during the year; immunisation is now given without Schick-testing. Enteric fever is less common, and there were only three cases in China. In India 80 per cent. of the cases of enteric are now diagnosed by blood culture; of a total of 183, all but 30 were sporadic and unrelated to other military cases. It is claimed that about 98 per cent. of the troops are protected. One patient at Aldershot had not been inoculated. Malaria was slightly reduced and the number of deaths was halved. Plasmoquine reduces the time under treatment, and Atebrin is said to cure both forms of tertian infection. Quinine prophylaxis was tried in China but was not approved, and mosquito repellents were used by troops in special employment at Hong-Kong in August and September, when one case only developed among 1000 men. Little is said of mosquito-proofing of barracks, probably because it is now accepted. The villages near barracks are being swept into the ambit of antimalarial measures, and a weekly day of empty tanks, in which to destroy larvæ, is specially advocated. Pneumonia is the disease causing most deaths; its small increase is attributed to the prevalence of influenza. Pulmonary tubercle has slightly increased, also amongst soldiers' wives. The liability increases after ten years' service and over the age of 30. The heaviest incidence is generally on the Eastern District (which includes London), and is always less in India than at home, perhaps because of the greater age of men on home service. Conditions of housing and food have been steadily improving in India since the war, but the case-incidence remains much the same, though it has lessened in the last two years. Cases of "pyrexia of uncertain origin" are increased, and it is suggested that unwillingness to accept this diagnosis is "tantamount to assuming that every species of tropical fever has been already sorted out from its fellows and duly labelled." Venereal diseases caused fewer admissions and less loss of service this year. The striking reductions since 1913 at the large stations is well brought out.

The equipment of operating theatres is being steadily improved, making surgical operations easier and safer, and this applies to families' hospitals in which (at home and abroad, but not in India) 1849 confinements took place with only two deaths. X ray equipment is also much better, while massage and electrotherapeutic sections are said to have secured a marked saving of days in hospital.

A committee has decided that a separate suitable uniform must be provided for war and manœuvres "as for other active games," and that the soldier's load should not exceed a third of his weight, otherwise, in action, he throws away some of his important equipment or reaches his objective unfit to fight. It is mentioned that four-footed beasts of burden are better shaped for weight-carrying than is the soldier, yet that they carry proportionately less; the elephant, weighing 3½ tons, carries a seventh of his weight; the camel, weighing half a ton, and the mule weighing 700 lb., carry only a quarter of their weight.

The object of physical training is said to be mental and physical alertness and agility with symmetrical development, and it is noteworthy that whereas in 1930 there were 61 invalids with disordered action of the heart, there were only 19 in 1931. "The fitter the man the slower the pulse" is found on examination to have support, and it is noted that among long-distance runners there are more non-smokers in the first than in the last ten after three miles across country.

Dental repair conserved 3·25 teeth per man this year (3·16 in 1930), and it is rare now for a man to refuse treatment; if he does, he is apt to return and take it later. Recruits are now examined more minutely with better light, so invaliding for ear disease has fallen from 214 to 153, though it is still the chief cause for rejection at entry.

(FROM OUR OWN CORRESPONDENT)

AN ACTION FOR DAMAGES

IT is amazing to what lengths some litigants will go when there is a prospect, however small, of extracting much hard cash out of a surgeon. On March 27th, 1929, according to the *Siècle Médical*, Dr. A. operated on Madame L. Two days earlier she had consulted him, on the advice of her medical attendant, for a small swelling in the right breast. The surgeon having diagnosed, it was alleged by the plaintiff, a benign tumour, recommended its removal by a small operation of no importance. He took the precaution of requesting the husband to be present in the hospital at the time of the operation. During it he came to the conclusion that the tumour was malignant. He then consulted the husband, who charged him to do what he thought was best. Accordingly, he amputated the breast without the patient's consent, and while she was still under the influence of the original anæsthetic. Fourteen months later the patient underwent a second operation, presumably for an extension of the disease, and death supervened in due course. The widower not only refused to pay the surgeon's fee of Fr.1860, 600 of which represented hospital charges and visits by the surgeon at the patient's home, but sued him for Fr.200,000 in damages. The plaintiff supported his claims by arguing that the defendant had not taken all the necessary measures to ascertain the true nature of the tumour before the operation. He should have warned the patient of the possibility of an extensive operation, and have made a histological examination of the tumour. It was pointed out for the defence that the differential diagnosis of benign and malignant tumours is the more difficult because a benign tumour may become malignant. Further, it was argued that the diagnosis in such a case cannot be definitely made without an exploratory incision. By his prompt action, the surgeon had not only reduced the chances of a recurrence of the disease, but had also saved the patient from the terrors of a second operation following on the heels of the first. In the opinion of the medical experts, whose evidence was taken in this case, the patient would have been exposed to a very real danger had the surgeon suspended the operation and let her entirely regain consciousness in order to solicit her opinion as to any further action. The plaintiff was condemned not only to pay the surgeon his bill of Fr.1860, but also Fr.10,000 in compensation for the losses incurred over this action. The surgeon was also authorised to publish extracts of this judgment in one Paris and one provincial journal.

---

[1] The Health of the Army in 1931. Report by Lieut.-General Sir Harold Fawcus, director-general, Army Medical Services. London: H.M. Stationery Office. 1933. Pp. 158. 2s. 6d.

SITES OF CANCER

Prof. Léon Imbert, who is attached to the anti-cancer centre of Marseilles, has published in the *Presse Médicale* for Dec. 28th certain rather striking statistics covering the years 1929–31 and the first six months of 1932. During this period 1091 patients suffering from cancer were examined. As many as 333 suffered from cancer of the uterus, and as there were only 694 women in this material, it will be seen that approximately 50 per cent. of all the cases of cancer in women were of the uterus. With another 26 per cent. for cancer of the breast, malignant disease of these two organs was responsible for three-quarters of all the cancers in women. Big sex differences were observed in the case of malignant disease of the larynx, mouth, and lips. Among 48 patients suffering from cancer of the larynx, there was only one woman, and among 98 patients suffering from cancer of the buccal cavity, including the tongue, there were only five. Prof. Imbert associates this relative susceptibility of the male to cancer in this region with his indulgence in tobacco.

BERLIN

(FROM OUR OWN CORRESPONDENT)

FEE-SPLITTING

THE question of fee-splitting is discussed in an editorial article of the *Ärztliches Vereinsblatt*, the official organ of the Deutsche Aerztevereins-Bund. The editor states that the system, called in France dichotomy, is quite usual in certain countries; in others it occurs but is not generally accepted, whilst in some it is unknown and is regarded as unprofessional—for instance, in England and America. In Germany fee-splitting is still in its infancy, but the editor draws attention to the fact that some time ago certain advertisements appeared in medical journals in which partnerships or (as it was called) coöperation was offered between general practitioners and specialists, especially surgeons. These advertisements have almost entirely disappeared from the journals since their character has been recognised, but nevertheless offers of fee-splitting continue in other forms. The nuisance began during the late war, when many medical men were in the army, and locum tenents, sometimes of a lower professional standard, were appointed who required fee-splitting from the consultants in a manner then unknown in the profession. Since then the difficult financial position of many practitioners—and specialists likewise—has led to a slackening of professional standards; it is of course obvious that the difference between the somewhat small fee of the family attendant and the sum charged by the surgeon who is consulted is sometimes striking, and the editor is of the opinion that an adjustment should be made in favour of the former; but this should be done openly. If dichotomy were to become more common in Germany than it fortunately is now, people may begin to think that their medical attendants propose operations for the purpose of sharing the fee and not in the interest of the patient's health, and that only those consultants who are prepared to split fees are recommended.

BEE-STINGS AND RHEUMATISM

In popular medicine bee-stings have long been considered as a remedy for rheumatism, and as early as 1888 a Viennese practitioner, Dr. Terk, had his rheumatic patients regularly stung by bees. Dr. Wolff and Dr. Pollack have recently succeeded in isolating the toxin from the bees. It is very like saponin dissolved in formic acid, and they call it apicosan. It is free from albuminous substances, so that no danger of anaphylaxis can occur. By intracutaneous injections—subcutaneous injections being less efficacious—a wheal with a reddened halo like a bee-sting appears. First, 0·2 c.cm. is injected, and the amount is gradually increased to 1·0 by the 13th day. There are three strengths of apicosan on sale, of 1, 3, and 9 units, a unit being equal to the toxin discharged by one bee-sting. As part of the local reaction, general symptoms with increased pains and swelling of the joints sometimes appear. The cure is effective for about five weeks. No undesirable effects have hitherto been observed. The remedy has been applied in chronic and deforming arthritis, and in Bechterew's disease. The pains became less and the mobility increased in cases where other remedies had proved unsuccessful.

IDIOSYNCRASY TO COLD

Dr. Bernstein, of the dermatological clinic of the Düsseldorf Medical Academy, discusses the shock which is experienced by persons with an excessive sensitiveness to cold. The idiosyncrasy may appear in the form of urticaria, hæmoglobinuria, or asthma. Sometimes general anaphylactic symptoms, such as decrease of blood pressure and leucopenia develop. In very sensitive persons fainting fits with unconsciousness occur. Sometimes slight cold is sufficient to produce such symptoms. The sudden death of good swimmers shortly after they have entered cold water is due to an idiosyncrasy of this nature. As a test a piece of ice should be placed on the skin, when a local wheal is soon produced in a sensitive person.

THE SERVICES

ROYAL NAVAL MEDICAL SERVICE

Surg. Comdr. P. B. Egan is placed on retd. list with rank of Surg. Capt.

The following appointments are notified: Surg. Lt.-Comdr. R. W. Mussen to *President*.

Surg. Lt. E. J. Mockler to *Queen Elizabeth* (transfer of flag).

ROYAL ARMY MEDICAL CORPS

The undermentioned Lts. to be Capts.: R. L. Whittaker, J. G. Black, D. A. O. Wilson, T. R. J. P. Kerwick, A. N. B. Odbert, C. A. Levy (prov.), and S. W. K. Arundell.

ARMY DENTAL CORPS

G. M. Sinclair to be Lt. (on prob.).

TERRITORIAL ARMY

Lt.-Col. S. F. Linton, having attained the age limit, retires and retains his rank, with permission to wear the prescribed uniform.

Capt. D. O. Macdonald, from T.A. Res. of Off., to be Capt.

Lts. N. Harkness, F. H. Hollingshead, and R. E. Rees to be Capts.

INDIAN MEDICAL SERVICE

The undermentioned appts. are made: To be Capts. (on prob.): W. J. Moody and A. E. Kingston.

To be Lts. (on prob.): J. D. Murdoch, G. B. Thomas, A. T. Andreasen, J. M. Sclater, D. R. Tweedie, C. F. Garfit, J. W. Richmond, G. S. N. Hughes, and A. D. Barber.

Lt.-Col. J. F. Boyd retires.

THE DOCTOR'S DAY

"Come, tell me how you live," I cried,
"And what it is you do!"

XIV.—THE SHIP SURGEON

No doubt those of you who have travelled as passengers in a big liner at sea have observed in the dining room the ship's surgeon, resplendent in blue uniform, gilt buttons, and red and gold stripes on his sleeves or shoulders, presiding at one of the tables and apparently being vastly amusing to or being amused by the bevy of fair ladies on either side of him. Perhaps you may have noticed him, too, standing at the head of the gangway as the ship is anchoring in some port, awaiting the arrival alongside the ship of the port quarantine officials. Perhaps also you may have seen him going round the ship at 10.30 in the morning, poking his head into various dark holes and corners, or seen him at 10.30 at night sitting in one of those same corners in confidential chat with a passenger. All these sights may have made you think what a pleasant life it must be to be a ship's doctor; how jolly and interesting it must be to meet fresh people every week or two and to see most of the world at no expense; what a care-free existence he appears to have and how easily he earns his pay. Probably, being on a holiday and not wanting to hear anything of medical matters for the time being, you have not troubled to make his acquaintance. So you have left the ship at the end of the voyage with, perhaps, a feeling of envy for one who appears to have a very easy professional life. The ship surgeon has his working hours, however, just the same as any medical man ashore has. How does the surgeon of a big passenger liner spend his days?

THE MORNING

My work of yesterday may be taken as a fair sample. My cabin steward called me at 7.20. Then came a good soak in a hot salt water bath, followed by breakfast at 8 o'clock and a walk on the boat deck for 40 minutes or so. At 9 I went down to the ship's dispensary.

The dispensary is a good-sized room; its walls are lined with racks, drawers, and cupboards in which are stowed our very comprehensive stock of drugs, dressings, and instruments, and it contains also an operating table, a dental chair, steam and electric sterilisers, and a writing desk. Here I met the dispenser and the hospital nurse, and here I was kept busy till about 9.40 seeing various members of the crew on the attending list—three pantrymen with cut fingers, two engine-room hands with small scalds, a couple of stewards with sore-throats and a cough, a bell-boy who wants a tooth out, and a quarter-master who wants his pension papers signed. One of the stewards who has a temperature is put into the hospital. Then the third-class passengers come in with various small complaints—a mother whose baby is vomiting its milk, two girls who require a laxative, a woman who, following the excitement and fatigue of packing and joining the ship, has missed her period and is rather anxious about it, and a man who wants me to visit his wife who is laid up in their cabin. It is all rather like the out-patient department of any hospital ashore.

Then comes the "round of the wards." In the ship I am in there are four hospital cabins, all pleasant rooms, two of them being fitted with real beds for passengers and the other two with iron bunks for members of the crew; 15 beds in all. The dispensary and adjoining hospital cabins are situated along one side of the ship a little aft of amidships, for most ship designers have learnt (at long last) not to put the sick quarters at the very after end of the ship right over the propellers. I have an isolation hospital as well, on a raised deck all by itself. This has 5 cabins and 22 beds. So my total hospital accommodation amounts to 9 cabins and 37 beds—more than many a good-sized town hospital has. Sometimes they are all wanted, as when one gets an influenza epidemic abroad, but yesterday I had only 7 beds occupied.

The cases in the hospital were nothing very exciting clinically. In one ward I had a cabin steward with "housemaid's knee" from over-much kneeling at scrubbing and not using the padded mats supplied for the purpose; a deck sailor with a sore-throat and a temperature, and a waiter who had upset a pot of tea over his foot and got scalded. In the female passenger ward was an oldish woman with chronic rheumatism. With a slightly rolling ship the struggle up and down the somewhat steep stairs between her cabin and the dining room is rather risky for her. So I have put her into the hospital mostly for her convenience and safety. In the isolation hospital are a measles child and her mother, and also a mental patient being returned to his own country.

With these cases I am kept busy till 10.20. Ten minutes later, with the purser, the chief and second stewards, an engineer officer, an electrician, and the ship's bugler, I attend the captain on his usual daily majestic tour of inspection of the ship. This procession wastes half an hour of my time. At 11 A.M. the nurse joins me and we visit the sick woman in the third-class. It is a case of sea-sickness, for which I prescribe atropine and hyoscyamine. Then we go and see two ladies laid up in their cabins in the first-class. One is liverish, while the other has that tiresome complaint to treat, insomnia. Then comes an emergency call to the dispensary where the nurse and I find a third-class passenger boy who has fallen and cut his head rather badly. This requires five stitches, and also entails the filling in, on my part, of a somewhat lengthy document called an "injury form." This document ultimately reaches the shipping company's lawyers, providing them with the main facts of the case should there be a claim for compensation.

Between 11.30 and 12.15 is my time for seeing first- and second-class passengers in my consulting-room. This is a roomy and nicely furnished apartment adjoining and communicating with my own private cabin. On an average two or three patients turn up there, but yesterday there were five. One lady came to see if I could supply her with two strips of calico for lengthening the sleeves of her husband's dress shirt! Calico supplied. At 12.30 the nurse arrives to say that she believes there is another case of measles in the third-class. A visit there confirms her diagnosis, and the case is ordered to the isolation hospital. A few minutes after 1 o'clock I go down to my table in the dining-room. There I have as table mates a professor of music, an archæologist, a manufacturer of wallpaper, a well-known author, a house-heating engineer, and an American school teacher on a year's leave from her school and on her first trip abroad. She is insatiable in her thirst for information.

Between the lot of them what questions I have to answer! "Do seals travel alone?" "What is the average weight of a seagull?" The wallpaper manufacturer, remembering his very first sea voyage, inquires "What was the name of the chief engineer of the *Persia* in 1908?" The teacher, anxious about getting a draft cashed, asks "How many years has the First National Bank of Boston had a branch office in London?" and also "What is the weather in England going to be like when we get there?" Although to answer all the questions that are put to me would tax the knowledge of the combined contributors to the "Encyclopædia Britannica," it is all good fun and we are all "as thick as thieves."

THE AFTERNOON

At 2.30 I attend at the dispensary again to vaccinate some members of the crew—a matter I had postponed during the hot weather and more busy portion of the voyage. From 3 to 4 o'clock I found myself unoccupied clinically. I fill in that time bringing up to date my medical journal, a somewhat ponderous volume, containing names and brief details of all cases treated on the voyage and destined ultimately for my medical superintendent's information. Also during that time I receive a visit from the secretary of the passengers' entertainment committee asking if I can supply him with a selection of odorous drugs for a smelling competition. From 4 to 4.30 is my afternoon passenger consulting time. Yesterday this was enlivened by a visit from a little old lady who pathetically asked me to aid her in searching the ship for her lost lover! They had quarrelled some 40 years ago, and she has been searching the world for him ever since. Harmless and apparently sane except on this one point. At 4.30 I attend again at the dispensary to see any members of the crew. Here one old "salt" comes along to say that he is beginning to feel the colder weather and fears a return of his old malaria. His doctor at home has advised him to take a couple of bottles of beer a day for this, and could I order . . . ? However, nothing doing. At 4.45 the third-class passengers attend again, one this time with alleged "potoman" poisoning, and after that I make the afternoon round of the wards. Perhaps after that the nurse and I visit a passenger cabin or two, but generally from 5.30 to 6.30 I am free.

Then a quarter of an hour is occupied scrambling into my mess uniform—an Eton jacket affair—before welcoming to my private cabin sundry passenger acquaintances and entertaining them for half an hour or so, for the good of the Company, with a seductive cocktail or a little dark sherry. Then comes the function of the day—dinner—where our efforts to amuse and interest one another are exasperatingly spoilt by a blaring orchestra playing jazz. After dinner I have another short session in my passenger consulting-room, and at 9 the nurse and I pay our final visit to any sick people who may require to be seen in their cabins or in the hospital.

THE END OF THE DAY

Such is the daily routine, a day pretty well occupied in any case, and always liable to be made extra busy by such emergencies as a passenger "running amok" with delirium tremens and requiring restraint and a guard; the appearance of a small-pox case and the vaccination of all contacts; or an acute appendicitis which is a more anxious and troublesome affair afloat than ashore.

Anything can, and occasionally does, happen aboard ship—murder, attempted or actual suicide, childbirth, concealment of birth, any form of insanity, diabetic coma, uræmia, retention of urine, sleepy sickness, typhus, and, in the tropics, plague, dysentery, malaria, and all the rest of the tropical medley—and the ship surgeon must be prepared to deal, with a reasonable amount of competence, with any of them.

Finally, last night, at about 9.40, the wireless operator handed me a message from the captain of a passing cargo boat asking me for advice how to deal with an awkward emergency. I handed in my somewhat lengthy reply at about 10.30 and "called it a day." At 10.50 P.M., when tidying up my consulting-room desk prior to climbing into my narrow bunk, I came across a memorandum from the Company's head office: "The management expects the surgeon to assist the purser's staff in arranging for and in supervising the amusement of the passengers." At all events, I did supply the smells for the smelling competition to-day!

PANEL AND CONTRACT PRACTICE

Investigation by Reference

A CASE recently referred by the clerk of the London insurance committee to the medical benefit subcommittee, and dealt with under Clause 7 (3), is of general interest. In September, 1932, an insured person obtained treatment from the practitioner as a private patient, the fees paid amounting to £1 3*s.* 6*d.* A claim for a refund was put in, and the doctor was asked for his observations under Clause 7 (3). The practitioner, after being furnished at his request with a copy of the clause, described it as autocratic, and concluded his letter to the committee with the following sentence: "The remuneration received for the treatment of panel patients does not encourage me to give any more than very ordinary treatment." For writing this to the clerk of the committee—not for publishing it in a newspaper or stating it to his patients—this medical benefit subcommittee decided that his conduct to insured persons required investigation. They have no power to carry out such an investigation themselves, but can refer a matter for investigation to the medical service subcommittee. The effect of this procedure on the practitioner concerned is serious, for it implies publicity as well as worry, the medical service subcommittee having to report the case to the full committee. This factor is never considered by the lay members of these committees who pass these resolutions for "investigation by reference," as it is called. The trouble is that any person can write any sort of lie about a doctor to the clerk of the committee; he need not be a relative of the patient, he need not have been a witness of the action complained of, the patient need not even have sanctioned his interference. But once the accusation is brought to the notice of one of these committees—mostly composed of laymen—they order an investigation by reference, and then, no matter what the doctor has to say, the medical service subcommittee nearly always insists on a hearing to complete the investigation.

The regulation which sanctions this procedure requires amending. At present a practitioner is entitled to charge an insured person if he fails on demand to produce his medical card whilst stating he is an insured person; but the practitioner must give an official receipt on Form R 52, which enables the insured person to be repaid if he is really entitled to medical benefit. The insurance committee then repay the insured person out of the money that they would normally pay that doctor, but the patient becomes one of that doctor's panel patients. Frequently, however, insured persons, intentionally or otherwise, omit to say they are insured at all, and they then receive an account in the ordinary way—a private bill—from the doctor. If, within one month from the payment of fees or the receipt of bill, they write to the committee to say they are insured persons, the committee may (not must) order the doctor to refund the money. But the doctor is credited with the number of units which would be allowed to him had the patient been treated as a temporary *resident*—i.e., usually 6 units for the quarter instead of 1, which works out to a payment of something like 12*s.* or 13*s.* per case. The practitioner is asked for his observations before Clause 7 (3) is put into operation, and it was in his reply that the doctor in the case reported above made the remarks quoted. It would seem that reference by investigation should not be rashly ordered, and that more discretion should be given to the medical service subcommittee which receives these references to decide them without a hearing, if they so choose. Moreover, they should have discretion when the reporting of such a case to the full committee is concerned. A doctor who wins his case against charges brought against him should surely have some monetary compensation for worry and loss of time, apart from the subsistence allowance which is the only thing he can now claim.

It seems preposterous that a practitioner should be put to the trouble involved in defending his reputation before a medical service subcommittee because he criticises to the clerk of the committee the working of a clause of the regulations with which he was unfamiliar. There was no evidence that this doctor had ever treated a panel patient differently from a private patient.

Fees for Anæsthetics

The panel conference held last October decided that it was proper for any panel committee to determine whether a practitioner in its area administering anæsthetics for a colleague should be specially remunerated or not. The regulations at present require a fee to be paid out of the practitioners' fund for such special service, provided the panel committee is satisfied that the claim is reasonable. In some areas practitioners have agreed never to put in such claims; in some the panel committee discourages them. In other areas there has been an increase in their number, in London to such an extent that the panel committee induced the insurance committee to agree to pay only a nominal fee of a shilling each—just to comply with regulations until the matter could be taken up with the Ministry. This shilling fee has never been agreed to by the Ministry and has therefore never been in force. The Insurance Acts Committee recently sent a deputation to the Ministry, when it was understood that the resolutions of the conference were not being received there with favour. It was felt that the public might think something was being taken from them that they now had, and it would be a difficult position for the Minister to explain in Parliament. London was specially asked to reconsider its resolution, and the matter will come again before the panel service subcommittee.

Continuity of Medical Benefit

The Insurance Acts Committee also gave consideration to the future of insured persons who go out of benefit as a result of being unemployed. There may be hundreds of thousands who thus come officially under the care of the public assistance medical service, but who through habit, or lack of knowledge that they are no longer eligible for insurance medical benefit, will still consult their usual medical adviser. Insurance doctors would then have many patients to attend for whom they were receiving no capitation fee, and they would be placed in a difficult position if they refused treatment on that account. If the Ministry of Health were to make the public assistance medical service open to all practitioners such unemployed patients could still have the doctor of their choice, who would then be paid by the public assistance committee and not out of health insurance funds.

Medical Certification Statistics in Scotland

The Department of Health for Scotland have devised a telling method of bringing out discrepancies in medical certification. Statistical tables of certification have been prepared for the two years 1930–31 and 1931–32, which include: a classified list of counties and burghs, giving for each insurance area the total numbers insured, the total number of first certificates issued, the incapacities begun and ended during the year, the total duration of incapacities, the average duration in days, the days of illness per 1000 on the lists, and the first certificates issued per 1000 on the lists. This elaborate set of facts is set forth in groups for industrial counties; other counties, including the Highlands and Islands; and the burghs. A further table shows the total number of insured persons referred to the regional medical officer; the percentage of these who were declared not incapable; and how many did not appear at the examination arranged for. In a covering circular Miss Muriel Ritson, comptroller of insurance, says that in nearly every area certain practitioners have issued certificates to a considerably larger proportion of their patients, and/or have continued to certify incapacity over longer periods, than have their colleagues. In many of these cases, she adds, the certification of the practitioner concerned presented the same features in both years under review. Moreover, a considerable number of cases referred to the regional medical officers come from the same practices, and in a high proportion of the references the practitioner's certification is not confirmed.

For Scotland as a whole the number certified by the regional medical officers as not incapable of work was more than 40 per cent. of the persons referred. The average duration of the certified illnesses in 1931–32 was 25·83 days, a slight reduction on 1930–31. This does not include chronic illnesses whose duration extends beyond the period under review. But this reduction masks the fact that the increase of certification and consequently in benefit expenditure began in Scotland early in 1932. There is a much heavier increase in the third quarter of 1932 compared with the same quarter in 1931.

The covering circular suggests that instead of full certification, more use should be made of the space provided on the certificate for "remarks"—e.g., on the probable duration of incapacity or the necessity for further examinations. The circular is directed to each practitioner, who can now learn the average certification in his area and discover whether he is above or below that average. At the same time, committees are requested to study the tables and to make a detailed investigation when the percentage of certification in any one practice seems unduly high.

Apart from the immediate administrative purpose, the tables now issued are a good index of the effectiveness of the panel system.

In the remote Highlands and Islands, for example, the average duration of illness is 31·9, and the first certificates per 1000 on the list are 121: in the Lowland counties the corresponding figures are 23·8 and 176: in the large cities they are 27·0 and 197; in the medium burghs 26·1 and 196; in the small burghs 27·0 and 188. The percentage of doctor's total list referred is: for the counties, 2·33; for the burghs, 2·98; for Scotland as a whole, 2·71. The numbers declared by the regional medical officers not incapable were for the counties 19·4 per cent., but 23·7 per cent. failed to appear. There is thus a total of 43·1 per cent. declared not incapable. The corresponding figures for the burghs are 20·3, 21·5, and 41·8. The fact that such a large percentage of referred persons should fail to appear at the clinic either because they had in the meanwhile been certified by the doctor or had themselves expected rejection and did not appear is disconcertingly large.

The circular directs special attention to the National Health Insurance Act, 1932, involving reduction in money benefits and cessation of medical benefit. It also contains details as to the rates of sickness among women. The rise in expenditure in Scotland in the year 1932, up to Sept. 30th, the latest returns available, has apparently no parallel in England and Wales. It is stated that the department have been unable to ascribe to any medical cause the rise in expenditure in Scotland which threatens to counteract the satisfactory results of the year 1931.

PUBLIC HEALTH SERVICES

Immunisation against Diphtheria

In a book reviewed in these columns a few months ago Dr. J. Graham Forbes[1] gave a very full account of the epidemiology of diphtheria and made a survey, which was almost world-wide, of the progress of preventive inoculation up to the end of 1930. He has now[2] ascertained the further trend of diphtheria prevalence and prevention in many countries and has been able to include information as recent, in some instances, as last July.

From 1928 to 1930 diphtheria was pandemic in Europe. Its prevalence reached a peak in the latter year in most European countries, including the British Isles, and in 1931, except in parts of central and eastern Europe, the incidence and mortality fell markedly. In Australia, on the contrary, a phase of low incidence and mortality of some years' duration was ended in 1931–32 by increased prevalence. Neither the years of low incidence in Australia nor the sudden fall in prevalence in Europe can be credited to immunisation but to the ordinary periodicity of the disease. In Australia, until recently, very little immunisation has been done, though the confidence which was shaken by the Bundaberg disaster has now been largely restored. In Europe the decline has occurred in countries where prophylaxis has not been carried out upon any significant scale as well as in those, notably France, where the numbers immunised have been very large.

Over the greater part of the United States of America incidence and mortality have shown a continuous fall during the past five years. Forbes points out that in New York City and State particularly, diphtheria preventive work has been carried out upon an ever-increasing scale and under the most favourable conditions for the last 14 or 15 years, with the result, in his opinion, that prevalence has been definitely checked amongst a number of communities ranging in size from New York, with its 7 millions, downwards. Coincident with the increase of preventive inoculation during 1929–32 there has been a decline in prevalence "amounting to 25 per cent. in one year and 50 per cent. in the last two years. Compared with the 1911 record the fall is 84 per cent." The progressive increase of prophylaxis in Canada has produced comparable results in many of its important cities. In America and Canada these achievements have been made possible by organised and skilful propaganda.

THE PRE-SCHOOL CHILD

In France, although the educated classes have demanded immunisation, the opinion has been expressed by E. Lesné that unless compulsion is introduced, as it has already been for recruits proceeding to stations where the disease is prevalent, the necessary proportion of immunisations of the under-five group essential to affect prevalence will not be secured. In America and Canada this importance of immunising children of pre-school age has been fully recognised, and E. S. Godfrey, director of the New York State Health Service, has shown, for a number of cities, that even if 60 or 70 per cent. of the school population were protected there was no sensible decline in the attack rates until a "critical point or safety threshold" had been reached and maintained amongst the pre-school age-group. When the immunisation of "approximately one-third or more of those under 5 was superimposed on the numbers of school age already protected" a definite decline in the current prevalence of the disease became noticeable. It may be added that among children in this age-group reactions to the prophylactic antigen are minimal in incidence and severity.

Formol-toxoid, the anatoxin of Ramon, has either already superseded or is rapidly superseding the original toxin-antitoxin mixtures (T.A.T.). Toxoid is not only non-toxic but a more efficient immunising agent, especially if two or three weeks separate each of the three injections. Toxoid must be injected; inunctions of Loewenstein's toxoid ointment are definitely much inferior. Ramon is inclined to minimise the importance of reactions, but in this country at least reactions must so far as possible be avoided. Even among the pre-school group, protein-sensitive children, although uncommon, are to be found; in the higher age-groups they become increasingly numerous. Although a preliminary Schick test is always desirable it is not always feasible in clinic work, and even if it is done it is usually possible to take only one reading, a week later, by which time any pseudo-reactions, which indicate sensitiveness, have disappeared. Fortunately, sensitiveness to toxoid can be determined by the Maloney intradermal test,[3] the technique of which has lately been described again in Memo. 170/Med. of the Ministry of Health.

Using toxoid of the same potency as anatoxin, J. G. Fitzgerald and his associates[4] observed 16 per cent. of local reactions in 30,000 children and 10 per cent. of marked reactions between the ages of 5 and 14. In these cases they reduced the prophylactic doses of toxoid or omitted immunisation altogether. R. A. O'Brien and H. J. Parish,[5] using a potent unconcentrated toxoid, found that it was probably not more likely to cause reactions than a preparation like anatoxin which had a strength only one-half to one-third as great. Employing the Canadian toxoid test they were able rapidly to immunise a series of children without troublesome reactions, the non-reactors receiving this potent toxoid in full 1 c.cm. doses and the reactors toxoid-antitoxin floccules (T.A.F.), a preparation whose antigenic value is at least as high as that of anatoxin, but which rarely causes reactions even in adults.

Reactions, when they occur, although unpleasant, are harmless in the healthy. Ramon and Débre have stated (passim) that many thousands of injections of anatoxin have been made in tuberculous children at the Berck Hospital without untoward results. This is, of course, perfectly true, but, according to other observers, exceptions occur. In a recent paper E. Aubertin and P. Boudou[6] quote M. and G. Mozer as having observed activation of a focus in three children at Berck suffering from quiescent surgical tubercle, and Cruchet, Nové-Josserand, amongst others, as having reported similar activation in cases of pulmonary tuberculosis. The immunisation of tuberculous children, if these observations are well founded, is clearly not free from risk and should be avoided.

PROGRESS IN GREAT BRITAIN

In this country immunisation lags, except in a few bright spots like Edinburgh and Birmingham and its neighbouring towns, and some boroughs of Greater London—notably, Heston and Isleworth. The numbers so far immunised in several of our largest centres of population compare unfavourably with those which many an obscure town of central and eastern Europe can show, and can be expected to have no effect whatever upon prevalence. Forbes estimates that in Great Britain up to the end of 1930 a total of about 200,000 persons had been protected or were known to be Schick-negative, the proportion in Scotland being over three times greater than in England and Wales. In London, including Greater London, 43–44,000 were then known to be protected. In New York City the health commissioner, Dr. Shirley W. Wynne, recently reported that 166,000 children were immunised in 1932 alone. He is still concerned about the large number of young children who remain at risk, and appeals for a further extension of the work, particularly by private doctors. The Ministry of Health memorandum, already cited, in drawing attention to the advantages of immunisation, states that about 60,000 cases of diphtheria, with an average of approximately 3000 deaths, are notified annually in England and Wales.

Compulsion is out of the question in this country, and except for sporadic efforts by individual medical officers of health, frequently those of relatively small districts, propaganda is non-existent. Yet nothing is more certain than that well-devised and well-presented reasoned propaganda would meet, as it always has met wherever tried, with a ready response. The public is not really reactionary and stupid about the welfare of its children; but merely, in this matter of the prevention of diphtheria, almost completely uninstructed.

Influenza

In the week ending last Saturday (Feb. 4th) the number of deaths from influenza in the 118 great towns of England and Wales was 1911, compared with 681, 1041, 1589, and 1934 in the previous four weeks. In London the number was 368, compared with 93, 242, 338, and 370. The course of the epidemic in the several geographical regions of England and Wales is shown in Table I., taken from the Registrar-General's Weekly Return for the week ended Jan. 28th, from which it will be seen how sharp was the rise in death-rate in the eastern area of England and in Wales, regions which had remained immune for two or three weeks after the others were affected. The south-western area still has the best record.

TABLE I

—	118 great towns.	South-eastern area.	Greater London.	Northern area.	Midland area.	Eastern area.	South-western area.	Wales and Monmouthshire.
1932 Dec. 17th	0·22	0·17	0·17	0 26	0·27	0·21	—	0·15

„ 28th	4 91	4·06	4·08	5 66	5·08	5 98	2·60	7·15

Figures for some of the principal towns of England and Wales will be found under the heading of Infectious Disease during the week ended Jan. 28th. In Scotland in the week ending last Saturday the decline was interrupted, and the 16 principal towns reported 98 deaths compared with 111, 88, and 84 in the previous three weeks. Small increases were noted in Glasgow, Edinburgh, and Dundee, where the totals were 19, 18, and 31 respectively.

TABLE II

—	Ages 0–25		25–45		45–65		65 +		Total deaths

Table II., which sets out the age-distribution of deaths from influenza during the past seven weeks, shows that the proportion of deaths in the younger age-groups is still falling.

INFECTIOUS DISEASE

IN ENGLAND AND WALES DURING THE WEEK ENDED JAN. 28TH, 1933

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 14 (last week 16); scarlet fever, 1667 (last week 1965); diphtheria, 781; enteric fever, 12; acute pneumonia (primary or influenzal), 4821 (last three weeks 2816, 3456, and 3781); puerperal fever, 36; puerperal pyrexia, 156; cerebro-spinal fever, 66 (last two weeks 47 and 61); acute poliomyelitis, 12; encephalitis lethargica, 9; dysentery, 12; ophthalmia neonatorum, 61. No case of cholera, plague, or typhus fever was notified during the week.

The number of cases in the Infectious Hospitals of the London County Council on Jan. 31st–Feb. 1st was as follows:—Small-pox, 44 under treatment, 5 under observation (last week 40 and 4 respectively); scarlet fever, 1615; diphtheria, 1625; enteric fever, 7; measles, 263; whooping-cough, 637; puerperal fever, 24 (plus 8 babies); encephalitis lethargica, 229; poliomyelitis, 3; "other diseases," 347. At St. Margaret's Hospital there were 10 babies (plus 6 mothers) with ophthalmia neonatorum.

Deaths.—In 118 great towns, including London, there was no death from small-pox, 2 (0) from enteric fever, 19 (0) from measles, 10 (5) from scarlet fever, 68 (13) from whooping-cough, 55 (14) from diphtheria, 55 (13) from diarrhœa and enteritis under 2 years, and 1934 (370) from influenza. The figures in parentheses are those for London itself.

The towns which reported the largest number of deaths from influenza were as follows, last week's figures being given in parentheses: Manchester 100 (106), Sheffield 85 (49), Stoke-on-Trent 72 (58), Bristol 65 (59), Leeds 56 (49), Liverpool 49 (52), Bolton 43 (29), Leicester 37 (16), Nottingham 37 (26), Cardiff 36 (3), Swansea 28 (6), Hull 27 (13), Birmingham 24 (38), Oldham 22 (12), St. Helens 22 (19), Stockport 22 (15), Rochdale 21 (12), Warrington 21 (7), Salford 20 (18), Wigan 20 (6), Middlesbrough 15 (21), Portsmouth 12 (25), Sunderland 11 (15). In Greater London the areas chiefly affected were: West Ham 24 (28), Croydon 22 (11), Leyton 14 (10), Ealing 13 (15), Tottenham 11 (13), Walthamstow 10 (11).

The deaths from enteric fever were reported from Acton and Stockport. Four fatal cases of measles were reported from Hull. Deaths from whooping-cough were widely distributed, each 4 being reported from West Ham, Leeds, St. Helens, and Salford; each 3 from Manchester and Sheffield. Diphtheria accounted for 6 deaths at Manchester, each 4 at East Ham and Leeds.

The number of stillbirths notified during the week was 266 (corresponding to a rate of 43 per 1000 total births), including 37 in London.

CORRESPONDENCE

THE ADMISSION OF WOMEN TO THE G.M.C.

To the Editor of THE LANCET

SIR,—The increased representation of general practitioners on the General Medical Council has encouraged us to make articulate a suggestion which has been whispered for a long time. Why should there not be a woman member of the Council?

The number of women on the Medical Register now reaches the respectable figure of 5391 out of a total of 55,932. This number would not justify a claim to separate representation, and such a proposal would in any case be contrary to the whole policy of the profession and is not what we have in mind. The proceedings of the Council show that the great majority of the matters which come before it concern practitioners and patients of both sexes. The experience of public bodies has proved beyond the necessity for argument the advantage of having women to share in the grave responsibility of forming decisions on such questions. The fact that the General Medical Council is the final authority on many issues makes it all the more important that the membership should be as representative as possible.

The time is approaching when candidates will be chosen by local associations, and we should be glad to think that this point of view would be borne in mind by those making the selection. The excellent public work already done by those women selected to serve as officers, representatives on committees, &c., would suggest that it should not be impossible to find a woman candidate worthy of the honour and acceptable to the whole profession.

We are, Sir, yours faithfully,
JANE WALKER,
LETITIA FAIRFIELD.

Harley-street, W., Feb. 6th, 1933.

MIGRAINE AND THE "BRIDGED-IN" SELLA TURCICA

To the Editor of THE LANCET

SIR,—In their interesting account of Migraine in your issues of Jan. 21st and 28th, Dr. Macdonald Critchley and Dr. F. R. Ferguson are good enough to refer at some length to a paper that I contributed recently to your columns,[1] in which I described a type of menstrual headache that seemed to me to be sufficiently characteristic to permit of its differentiation from ordinary migraine. The important practical result of my work was that many of my cases were relieved of their distressing symptoms by the administration of an active ovarian follicular hormone such as theelin, and I am glad to know that Drs. Critchley and Ferguson can endorse the therapeutic value of such treatment, although they dislike the explanation that I suggested of the cause of the headache, and prefer to continue to regard it as a "migraine variant"—a term which makes up in elasticity what it lacks in precision.

In a large proportion of my cases I found that certain abnormalities in the sella turcica could be demonstrated radiologically, and on this account and for various other reasons I formed the opinion that menstrual headache might be due to increased local tension in the pituitary fossa. The most frequent radiological abnormality was calcification of the interclinoid ligaments, but I was careful to say explicitly that I did not believe that the calcification could by itself cause any compression of the pituitary. Drs. Critchley and Ferguson "feel fairly certain" of this, and I only mention the point because I think the relevant paragraph of their paper may leave the cursory reader with the mistaken impression that I do in fact hold this view. My hypothesis was (and still is) that the local tension in the sella turcica is due to an overdevelopment of the diaphragma sellæ and that the interclinoid calcification may be taken as an index of its existence.

In disputing the probability of this hypothesis Drs. Critchley and Ferguson disregard many of the points that I put forward in its favour and that seem to me important; they are content to rely on the fact that they have collected several cases of "bridged-in sellæ" from patients who have never suffered from migraine. In my paper I described two cases of this type in women who never had headaches until gynæcological operations were performed which involved gross interference with the ovaries. It is clear, therefore, that even in women, interclinoid calcification may be symptomless, but the fact remains that my radiological colleague Dr. C. G. Teall has not yet found a case in a woman who did not complain of menstrual headache. In men I have to admit that it may be more frequently found, and I now have notes of two cases without headache.

Of the three cases mentioned by Drs. Critchley and Ferguson in this connexion, two are men and the third a woman with "migraine epilepsy." It is perhaps unfair to criticise prints from radiograms of this region of the skull unless they have been specially produced, but, although I accept the two male cases as instances of bridging, the picture of the third case (Fig. 4) seems, both to Dr. Teall and to me, to be that of a perfectly normal sella turcica. With his considerable experience of this matter, Dr. Teall tells me that he cannot be certain of "bridging" without radiograms taken in the antero-posterior plane, and it would be interesting to know if Drs. Critchley and Ferguson have had this additional investigation carried out.

Finally, Drs. Critchley and Ferguson mention the case of a woman "who has an almost completely 'shut-in sella' and yet gives a history of typical migraine attacks in addition to the menstrual headache." This case seems to them to argue in favour of their view that the *intermittent headache I described* was a migraine variant. The force of the argument escapes me. The perusal of Dr. Critchley's and Dr. Ferguson's paper, it is true, left me in some doubt as to what I might properly regard as typical migraine, but if a woman has it and in addition has a shut-in sella, I see no reason why she should not have a menstrual headache as well. What I should like to know is whether or not her menstrual headache is relieved by treatment with the ovarian hormone, for if it is, and the "typical migraine" remains, it might be argued that this case clearly differentiated the two conditions.

---

I am, Sir, yours faithfully,

A. P. Thomson.

Edgbaston, Birmingham, Feb. 4th, 1933.

EARLY DIAGNOSIS OF MALIGNANT DISEASE

To the Editor of The Lancet

Sir,—In an annotation on this subject last week you said that "except by accident, for example during the routine microscopical investigation of a uterus or a breast removed for another reason, it is probable that really early lesions are never detected." I venture to point out that the commonest form of malignant disease of the uterus is carcinoma of the cervix, and that in the majority of cases this starts on the outside and can be suspected in its early stages upon a simple inspection of the cervix. Further on you state that periodic examination must include examination per vaginam and per rectum. Of course such examination would include these; they take exactly five minutes to carry out by means of a vaginal speculum and an illuminated proctoscope.

Everybody agrees that early diagnosis of malignant disease is difficult and must be left to the specialist, but to exclude any abnormality of the organ where accessible cancers occur is simple and should be an everyday duty of the general practitioner. I entirely agree with Dr. Maurice Shaw that such examinations do free people from the subconscious, and sometimes conscious, bogy of cancer. If it is the opinion of some people that propaganda in favour of such examinations may create fear, the least the medical profession can do is to make it known that they are willing to carry out such a procedure without the patients feeling that they are being laughed at. It is quite time the medical profession did something positive towards getting rid of cancerphobia, instead of taking up the negative and hopeless attitude that is at present so common.

I am, Sir, yours faithfully,

Malcolm Donaldson.

Harley-street, W., Feb. 7th, 1933.

THE INDUSTRIAL DOCTOR

To the Editor of The Lancet

Sir,—I am particularly interested in No. XIII. of your series "The Doctor's Day" as I have had a certain amount of experience as an industrial doctor—H.E. and mustard gas, not food—and am a humble member of the Council of Industrial Medicine. But I wish your author had stressed the lack of special training in industrial medicine in this country. I am not going to preach on my hobby, but I cannot help wishing that people, especially industrials of all classes, would look into the matter and recognise that the present system is not adequate to give the best service, and that even though the certifying factory surgeon may fill in forms very well, only a few of his kind have the time to give all their energies to this most interesting medico-legal-psychological specialty. Even a certifying surgeon ought to have the opportunity of taking a course in what he is to be regarded as specially knowing. Universities in our great urban centres should easily be able to give a first part of theory and a second part of paid practical work to one who wants to take up industrial medicine, while a diploma in this subject would help in deciding appointments as certifying surgeon, factory doctor, or medical referee.

Another matter which needs further discussion is one which your author leaves out entirely—viz., the relation of the factory doctor to the panel doctors of his workers. It seems from his description of his day that he is doing a lot of the work which is paid for to the panel doctor. Personally I do not like the factory doctor to *be* the panel doctor of the workers in his works, as this smacks of compulsion in choice of doctor. Moreover it is better, as I see it, to keep oneself clear, save for medical, surgical, and first-aid, and such work as the factory nurses can do—rest and a dose of salts or aspirin, for instance—from encroachment on the work of a panel doctor. He would better remain the industrial expert to whom the panel doctor should apply before certifying incapacity, so that his facts may be the more accurate, and so that he may get the special knowledge of the industrial lesion possessed by a properly trained industrial doctor but hardly to be expected in a busy general practitioner. And why should he do the other fellow's work and not draw his pay also?

I am, Sir, yours faithfully,

H. G. P. Castellain.

Moseley, Birmingham, Feb. 7th, 1933.

PULMONARY ASBESTOSIS

To the Editor of The Lancet

Sir,—In your report of the proceedings of the Tuberculosis Association last week I am reported to have said that "an interesting feature of the disease was the extreme length of time that elapsed as a rule between the exposure to the dust and death." I actually referred to the length of time, as a general rule, between the exposure to the dust and the onset of symptoms, which as I pointed out may even commence several years after the patient has left the factory. I also pointed out that pulmonary asbestosis was a more serious disease than silicosis, proving fatal on an average after about 13–15 years' employment as compared with 32–42 years in silicosis (figures from report of Inspector of Factories and Workshops 1931).

I am, Sir, yours faithfully,

Harley-street, W., Feb. 5th, 1933. Philip Ellman.

Mr. A. Mortimer, secretary of the Wholesale Drug Trade Association, writes that the members of his association welcome the removal of ambiguity in thyroid dosage by the new definition in the British Pharmacopœia, 1932 (see The Lancet, Jan 28th, p. 208, and Feb. 4th, p. 277).

A Remedy for Influenza.—Dr. Laver informs us by cable from Kalgoorlie, Western Australia, that he finds the following treatment specific for influenzal pneumonia: sodium salicylate grs. 2, glycerin ʒi, and (? tincture of) strophanthus ♏½—hourly from morning till midnight; hot drinks between doses to help diaphoresis; and mustard on the chest.

Solar, Terrestrial and Cosmic Radiations.—An international association has been formed for the purpose of study of this subject. The headquarters have been established at Nice, because the clear atmosphere there is particularly suited to such observations as the society hopes to undertake. Meetings will, however, be held each year in different towns, and a report is soon to be issued summarising the results which have already been obtained. Further particulars may be had from the president of the Société Médicale, 24, rue Verdi, Nice.

OBITUARY

SIR FREDERIC HALLETT

IT is not given to every man to live to see his own name perpetuated by those he has served, in the award of an annual prize bearing his name, which was the privilege of Sir Frederic Hallett, who died, in his seventy-third year, at his home, Point Close, Long Wittenham, Berkshire, on Feb. 5th, 1933.

Born in May, 1860, Frederic Greville Hallett was the fourth son of the late James Alfred Hallett, J.P., of Putney. He was educated at Westminster, privately, and abroad, and at the age of 17 he became a junior clerk at the Royal College of Surgeons of England, thus beginning an association with the Royal Colleges which was to endure for 50 years.

In 1882 he was appointed assistant secretary of the College and at once became deeply immersed in the formation and constitution of the "Examining Board in England by the Royal College of Physicians of London and the Royal College of Surgeons of England"—known as the English Conjoint Board—of which he became the first secretary in 1886, a post which he held until his retirement in December, 1927. He continued the management of the administrative side of the examinations of the Royal College of Surgeons—for the Fellowship and for the Licence in Dental Surgery—being given the title of Director of Examinations of the College of Surgeons in January, 1914. In these two posts Hallett's genius for administration and organisation found its true outlet, for the entire system under which the examinations of the English Colleges are conducted—a system which has won the admiration of educational authorities all over the world, and in not a few instances has served as a pattern—was his creation. When at the invitation of the Carnegie Foundation in 1912 he visited America to explain the working of the system, the success of his visit cemented the sympathy and understanding between the medical educational authorities in both countries, and the establishment of the National Board of Medical Examiners of the United States, with its procedure similar to that of the Royal Colleges, was largely due to Hallett's inspiration, sympathy, and guidance. The system proved, for the first time, that it was possible to conduct a purely external examination of large numbers of candidates in such a way that not only could justice, expedition, and accuracy be obtained, but also that the result of a candidate's examination could be given to him on the same day as he completed his examination. It is safe to say that, until some better means of selection than the examination system can be evolved, nothing fairer than the "conjoint system" is likely to be created. Under Hallett's inspiration it permits the retention of a human element, and there must be many practitioners to-day who owe not a little to the ever-ready sympathy and advice, in failure or success, of Hallett, while "Hallett's pink papers for pilled people" are still handed to certain unlucky ones. His work for the Royal Colleges in connexion with the building of the first Examination Hall on the Embankment and again with the building of the present Hall in Queen-square, Bloomsbury, was recognised by an honorarium of £500 from the Royal Colleges in 1909. The removal was made not without reluctance, and it was due to Hallett that its advantages were soon demonstrated.

SIR FREDERIC HALLETT

[Photograph by Russell

In 1902 the Royal Colleges established the Imperial Cancer Research Fund, of which Hallett became the first secretary, in addition to his other duties. He retained this position until last year when he resigned on account of his health, and the executive committee of the fund in the last annual report express their deep appreciation "of the way he has guided the policy of the fund during its 30 years of existence, and of his far-sighted ability in drafting its constitution." In recognition of these services Hallett was elected a vice-president of the Fund and awarded a pension.

On the outbreak of war Hallett took over, as additional duties, the responsible work of secretary to the Committee of Reference—a statutory committee appointed to arrange for the calling up and demobilisation of the medical staffs of the London hospitals—besides acting as secretary to the joint delegates of the Committee of Reference and of the Central Medical War Committee, and to various subcommittees of the delegates. It will, thus, be believed that during the war period he would have little spare time, but he found it and used it in helping the boy scouts as the Commissioner for the Hammersmith district, and in serving as a special constable in the Headquarters Division from 1914–17. In 1920 his war work was recognised by the award of the O.B.E., and on his retirement, in December, 1927, after 50 years of devoted service to medical education in general and to the Royal Colleges in particular, Hallett received the honour of knighthood. In 1928 the Council of the Royal College of Surgeons desired to make him a personal gift to commemorate his outstanding work for the College during half a century, and, in deference to his own wish, instituted the Hallett prize which is awarded twice yearly at each primary examination for the Fellowship to the candidate who most distinguishes himself in the examination in anatomy and physiology.

Such is the brief record of one whose zeal and devotion to duty were an inspiration. But outside the official duties, which occupied so much of his life, Hallett was a man of many parts. He was an active J.P. for the county of Berkshire. He was a devoted churchman throughout his life; his energies, some 30 years ago, in the parishes of St. Albans, Fulham, and later at St. John's, Holland-road, are still remembered with gratitude, while during his later years his advice in the deliberations of the church in the diocese of Oxford was widely sought and valued. He was an active Mason, having been initiated in the Old Westminster's Lodge in 1891, becoming Worshipful Master in 1902–03 and serving as treasurer of the lodge from 1906–20. He was promoted to London rank in 1912, and when he finally resigned in 1929 he was elected an honorary member of his lodge.

And always the thing nearest to his heart was his home. In 1884 he married Margaret Elizabeth Lane, the daughter of James Lane, F.R.C.S., and niece of Samuel Lane, whose name is so intimately associated with the foundation of St. Mary's Hospital Medical School. Many years ago he gave up playing golf and billiards—at both of which he could well hold his own—because they kept him away from his home, and he found his main recreations in fishing and boating, for the river runs at the end of his beautiful garden. His well-known hobby was the art of illuminating, and many are the addresses and rolls of honour which testify to his artistic skill and ability, notably the beautiful book of the Roll of Honour in the House of the British Medical Association, and the illustrations to the Legacy Book of the Society for Relief of Widows and Orphans of Medical Men. Specimens of these were reproduced in our pages recently (THE LANCET, 1932, i., 63), and while the absence of colour modifies their beauty, the grace of line and the dexterity of penmanship are very evident.

Throughout his life, sharing all his work and interests, he had the help and support of his wife, who during the last painful months of his fatal illness had scarcely left him. That illness, which struck him down in July, 1931, was borne with the fortitude and courage which sprang from a profound faith and he was bravely cheered by the loving care of Lady Hallett. She survives him, with a son and a daughter, the wife of Mr. H. H. Rew, who succeeded her father in his post at the Royal Colleges.

VICTOR EDGAR SORAPURE, M.B., F.R.C.S. Edin.

THE death of Dr. V. E. Sorapure occurred, after a long resistance to a tuberculous infection manifesting many painful symptoms, in a nursing home in Bournemouth on Jan. 29th, at the age of 58.

Dr. Sorapure received his medical education at the Universities of Edinburgh and St. Andrews and the medical schools of Dundee and Liverpool. He was destined by his parents for a business career in the West Indies, but had set his heart on becoming a doctor and, largely owing to his own enterprise, he achieved his desire to be trained in England. He graduated as M.B., Ch.B. Edin., in 1899, and later took the F.R.C.S. Edin. and became a resident medical officer at the Liverpool Hospital for Women. He then returned to the West Indies, practised successfully there, and later in the United States. He was for a time professor of pathology and clinical medicine in the Fordham University, was assistant physician to the Polyclinic Hospital, and medical adviser to the Life Extension Institute. He made some interesting communications to the American medical press on locomotor-ataxy and allied subjects, and was carrying on a large practice in New York when, at the outbreak of war, he returned to England with a wife and three young children to serve as a temporary officer in the R.A.M.C. He was stationed for a time in France, but was finally attached to the Hampstead Hospital, where he worked under Sir James Mackenzie. With Mackenzie he made a close study of certain of the problems associated with altered blood pressures, as exemplified in communications to this paper, but his main literary work is seen in his considerable contributions to the Oxford Index of Therapeutics, which appeared in 1921 under his editorship, as a compendium of general medicine, with a direct appeal to the family doctor.

The task of editing a collection of essays of varying value Sorapure discharged with zeal and ability, and at the same time he obtained a large practice in London, having given up the idea of returning to New York. His industry was striking, and a personal friend and medical colleague writes of him that "very soon he could scarcely cope with the work which came his way. He never scamped a case; he never thought of himself or of his health and never took a holiday nor a week-end off. Until he was over 56 he saw patients, Sundays and weekdays alike, from 8 A.M. till after midnight. Once he told me that at that age he was working as long hours and doing as heavy work as when he was 30. He became known to a wide circle of practitioners as well as patients as 'having a flair for diagnosis.' Some two years ago the strain thus indicated began to tell; thereafter, until the end, life was for him a prolonged battle against ill-health. Patients and colleagues who worked with him will not easily forget Sorapure's patience and unselfish personality."

JOHN STEPHENSON, C.I.E., F.R.S.

LIEUT.-COLONEL, I.M.S. (RETD.)

BY the death of Colonel Stephenson in London on Feb. 2nd the Indian Medical Service loses one of its most distinguished scientific members. Born at Padiham, Lancs, in 1871, he was educated at Burnley Grammar School and Owen's College, where he took many prizes and obtained honours at the M.B. examinations of both Manchester and London University. He had previously taken the London B.Sc. and went on later to take the D.Sc., as well as the F.R.C.S. Eng. After holding resident posts at the Manchester Royal Infirmary, he entered the Indian Medical Service in July, 1895, at the head of his batch, and had a varied career in India, including active service on the north-west frontier of India in 1897 with medal and clasp, and in Egypt during the war, when he was mentioned in despatches. From 1900 to 1906 he held various civil appointments, on plague duty and in civil surgeonships, but his most important work began in 1906 when he was appointed to the chair of biology in the Lahore Government College, and six years later to that of zoology. At the same time he was made principal of the college, and in 1918 reached the very unusual position for a medical officer of vice-chancellor of the Punjab University—a remarkable tribute to his personality and ability. He was a good linguist, and published the text with translation and commentary of the Hadiqatu-l-Haqiqat. His heart, however, was in his work as a zoologist, and he became an acknowledged authority on the oligochætes and was elected F.R.S. in 1930. He was also editor of the Fauna of British India series. After retiring from the service he was lecturer in zoology from 1920–29 in the University of Edinburgh, and continued to the end of his life a number of valuable studies at the South Kensington Natural History Museum. Colonel Stephenson was a modest and unassuming man, popular with his co-workers and students. The fact that he never enjoyed robust health makes more remarkable the amount of work which he accomplished.

PROF. WILLIAM PHILLIPS GRAVES

WE announced last week the death of Prof. William Phillips Graves, an outstanding figure in gynæcology, whose reputation extended internationally far beyond Harvard, which he adorned, and Boston where he practised. We have received from Prof. Blair Bell the following testimony to the man and his work :—

"William Phillips Graves achieved greatness in his special subject—gynæcology—not only because of his natural ability, but also because he was a man of great character. Since they have not been published, it will not be inappropriate to reproduce, as a text for the few words of appreciation that follow, the short eulogy spoken to him when he was admitted an Honorary Fellow of the British College of Obstetricians and Gynæcologists in December last.

> 'In this world of haste and hurry—conditions not unknown in your own country—you stand out in our branch of medicine as a man of quiet contemplation, wise discretion, and sober judgment. Your influence on the progress of gynæcology has been profound, not only in the United States of America, but wheresoever there exists a parcel post for the transport of your classical works. You are an artist, too, and the beautiful illustrations drawn by your own hand, which adorn your books and papers, are the admiration of all. You bring artistry to your craft. You are, besides, a thinker; and beneath a deep reserve lie golden thoughts. In honouring you, we honour obstetrics and gynæcology.'

"In the United States of America, Dr. Graves—for that is how all medical practitioners there, whether professors, surgeons, or physicians, are addressed—was regarded as *the* sound, conservative, yet progressive gynæcologist, and as a man of great experience and wide learning. I received the impression on both the occasions I was in America that he occupied the same position in gynæcology as that which the late Whitridge Williams held in obstetrics—both were trusted; and their opinions were held in unqualified respect.

"I remember so well expressing in one of the communications I made there—I think to the A.M.A. —my views on the biological value of the ovaries, and the importance of conservative surgery in respect of them. I was told beforehand that Graves would criticise my views, that he, as many of my colleagues in this country and elsewhere, held no brief for the importance of the ovarian function. Graves did not speak; but he came to me afterwards and said: 'I intended to oppose your views, but you made some points that I have not heard before; I have not changed my views yet; I must consider the matter afresh.' When he was in Manchester years later, when I read another paper on the subject, he told me he had been converted. I merely quote this story to show the open-mindedness of the man, and the cautious and fair way in which he formed his judgments.

"It is quite unnecessary for me to speak in detail of his wonderful text-book, his recent work 'Female Sex Hormonology,' or of his numerous papers. They are all marked by the same desire for truth, and by the same lucid thought and expression. His artistic ability is shown in the beautiful illustrations which he made for his medical publications. He also drew for his own pleasure, and for that of his friends, and was not only a draughtsman, but had also very sensitive and artistic feelings. Again let me give an illustration. He had recently purchased a country estate, and in describing this to me he said: 'There is a very old ash-tree by the lawn, but it is dead, the branches are bare. A friend asked me why I did not cut it down. I told him to come and see it in the moonlight.' I had long known that he admired our trees more in their winter bareness, when the outlines of their limbs are clear-cut against the sky or in the moonlight, than when they are in their summer dresses. That shows the kind of man he was in his innermost self.

"He was a deep reader of fine literature, which he was ever ready to discuss, and a great practical surgeon and accomplished teacher. Many of us have lost a close personal friend—a man who was a great gentleman, a sportsman, and a learned and inspiring colleague."

MEDICAL NEWS

Royal Colleges of Physicians of London and Surgeons of England.

At the final examination of the Conjoint Board held from Jan. 2nd–26th the following candidates were approved in the subjects indicated, but are not yet eligible for diplomas :—

Medicine.—D. R. Ashton, St. Bart.'s; A. D. Aveling, Camb. and London; J. E. M. Ayoub, Oxf. and St. Thomas's; L. J. Beynon, St. George's; I. N. Blusger, St. Bart.'s; W. A. Bowdler, St. Thomas's; C. G. Bree, Univ. Coll.; A. Brown, King's Coll.; Hilda M. Brown, Royal Free; S. G. Browne, King's Coll.; T. J. K. Brownlees, St. Bart.'s; J. H. J. Crosse, Camb. and St. Bart.'s; W. J. B. de Gruchy, Camb. and St. Thomas's; A. E. De Sa, Bombay; R. G. Fear, St. Bart.'s; M. K. Gadgil, Bombay and West London; J. Gordon, Middlesex; H. T. J. Hynes, St. Bart.'s; A. H. [illegible] B. F. Jackson, St. Bart.'s; J. F. Jarvis [illegible] King's Coll.; S. H. Kessler, Long Isl [illegible] Hilda I. Lanceley, King's Coll.; S. Lee, [illegible] Mason, Middlesex; Ellen Mayer, King' [illegible] Bombay and St. Bart.'s; S. D. J. Nand, Manchester; L. G. Nicholas, Cardiff; R. M. M. C. Orpwood and W. M. Oxley, St. Bart.'s; H. E. S. Pearson, St. Thomas's; G. D. Pirrie, Camb. and King's Coll.; M. L. Platt, Middlesex; M. Richmond, London; M. A. Rugg-Gunn, Camb. and St. George's; I. M. Shulman and R. T. Simcox, St. Bart.'s; E. J. Smith, King's Coll.; P. G. Stainton, Guy's; B. A. Thomas and W. H. D. Trubshaw, St. Bart.'s; G. N. Wardle, St. George's; C. E. M. Ware, St. Bart.'s; H. Waterman, Leeds; Elma Wolmarans and T. M. Wynter, Royal Free.

Midwifery.—Winifred L. Acraman, Cardiff; S. B. Adams, Bristol; S. R. Ali, Bombay and King's Coll.; J. E. O. Amegatcher, Camb. and St. Thomas's; D. A. Andersen, Univ. Coll.; J. B. Andosca, King's Coll.; T. R. Aubrey, Oxf. and Bristol; F. H. Barber, Birmingham; H. J. Barrie, Oxf. and London; A. J. Board, Bristol; J. Boyle, St. Mary's; C. F. R. Briggs, Univ. Coll.; G. O. A. Briggs, Camb. and St. Bart.'s; Hilda M. Brown, Royal Free; P. S. Buckley, Oxf. and London; K. L. Buxton, Camb. and St. Thomas's; H. R. Cara, Liverpool; F. F. Cartwright, King's Coll.; A. S. Cheong, St. Mary's; E. L. Cohen, Camb. and St. Bart.'s; F. H. Coleman, Camb. and London; Dorothy C. J. Cookson, Royal Free; F. E. Corea, St. Bart.'s; C. F. Critchley, St. Thomas's; T. M. Cuthbert, D. L. L. Davies, and E. E. Dodson, St. Bart.'s; Ruth C. Easterling, King's Coll.; L. R. L. Edwards, Guy's; P. J. England, Cardiff; S. M. Evans, Camb. and St. Thomas's; C. Fletcher, St. Bart.'s; P. A. Flood, Camb. and St. Thomas's; G. L. Foss, Camb. and Bristol; T. Foulds, Manchester; H. Goldfarb, Univ. Coll.; C. L. Greening, Durham; E. M. Griffin, Camb. and London; I. H. Griffiths, Cardiff and Middlesex; A. A. Hakeem, Bombay and Manchester; H. W. Hall, Univ. Coll.; Ida M. Hamp, Royal Free; J. H. T. Harrington, Oxf. and St. Mary's; T. N. Hart, Manchester; K. J. Harvey, St. Bart.'s; Pearl M. Heirshberg, Royal Free; G. A. H. Herbert, London; K. Hooper, Guy's; R. H. K. Hope, Univ. Coll.; C. Houghton-Brown, St. George's; A. V. House, Bristol; D. A. Hovenden, St. Thomas's; J. A. C. Hunter, Guy's; R. H. Isaac, St. Bart.'s; A. H. Ismail and G. H. James, Birmingham; J. W. James and Margaret H. James, Univ. Coll.; R. G. James, King's Coll.; D. A. Jennings, Oxf. and St. Thomas's; H. G. John, Cardiff and Univ. Coll.; E. H. Johnson, Leeds; G. P. Jones, Cardiff; N. K. Kai, Univ. Coll.; C. W. C. Karran, Camb. and St. Thomas's; Alice M. Kenny, Royal Free; S. H. Kessler, King's Coll.; E. W. Kinsey, Cardiff and London; Freda H. Knight, Manchester; Mildred G. Latham, Royal Free; C. A. Lewis, Camb. and King's Coll.; Gwladys R. Llewelyn, Bristol; [illegible] T. F. McNickle, Otago; J. N. [illegible] ddlesex; A. B. Marshall, West- [illegible] nd C. R. Mayou, Birmingham; [illegible]; R. H. Moodie, Bristol; W. B. O'Dowd, Birmingham; D. G. Oehlers, London; A. G. Palin, St. Thomas's; H. S. Pasmore, Univ. Coll.; H. E. S. Pearson, St. Thomas's; V. G. Peckar, Univ. Coll.; R. C. Percival, London; G. Phipps, St. Thomas's; J. W. Piper, Guy's; F. W. M. Plant, Birmingham; E. J. Pryn, Guy's; B. V. S. Rao, Mysore and London; V. B. Reckitt, Guy's; M. Richmond, London; Marjorie C. A. Robson, Camb. and Birmingham; Christine M. Rooke, Univ. Coll.; J. Rosenbaum, St. Bart.'s; M. A. Rugg-Gunn, Camb. and St. George's; M. F. P. Ryan, King's Coll.; C. A. J. Sampson, St. Thomas's; G. H. Saunders, Middlesex; G. E. Scott, Oxf. and St. Thomas's; S. K. Sen, Camb. and St. Bart.'s; G. H. Shaw, St. Thomas's; P. P. Sheth, Bombay and Middlesex; I. M. Shulman, St. Bart.'s; M. Shun-Shin, Univ. Coll.; R. T. Simcox, St. Bart.'s; T. O. C. Smith, Univ. Coll.; L. J. Stoll, Guy's; R. J. C. Sutton, St. Bart.'s; G. L. B. Thurston, Guy's; H. B. Tipler, Camb. and London; F. W. Treadwell, Birmingham; J. R. Vaid, St. Bart.'s; J. L. Whatley and C. S. Whitehouse, Birmingham; V. H. Wilson, Camb. and St. George's; C. R. Wright, Liverpool; and C. H. Yeoh, Oxf. and St. Thomas's.

University of London

Two lectures on the history of medicine will be given in the large lecture theatre of University College medical school, University-street, W.C., at 4.15 P.M. on Wednesdays, Feb. 15th and 22nd, by Dr. J. S. Prendergast (vice Prof. Charles Singer). In his first lecture he will deal with Greek Medicine and in his second with Renaissance Medicine.

University of London Medical Graduates Society

This society was entertained by the Society of Apothecaries of London on Feb. 2nd. The Master (Dr. Cecil Wall) received the members and gave a short address on the history of the society, with special reference to their development as a licensing body for the practice of medicine. Lady Barrett returned thanks. Particulars of membership of the society may be had from the hon. secretaries at 11, Chandos-street, London, W.1.

Royal Sanitary Institute

A sessional meeting of this institute will be held on Friday, Feb. 24th, in the Town Hall, Warrington, at 6.30 P.M., when Dr. John Gifford, deputy medical superintendent of the Winwick Mental Hospital, will speak on Sterilisation of the Mentally Defective. The local secretary is Dr. G. W. N. Joseph, of the health department, Warrington.

Chadwick Lectures

On Tuesday, Feb. 21st, at 5.15 P.M., in the lecture-hall of the Royal Society of Tropical Medicine and Hygiene, 26, Portland-place, London, W., Dr. Matthew B. Ray will deliver a lecture on the Hippocratic Tradition, which will be illustrated with lantern slides. Further particulars of the Chadwick public lectures may be obtained from the secretary, Mrs. Aubrey Richardson, at 204, Abbey House, Westminster, London, S.W. 1.

British Red Cross Society

The British Red Cross Society and Order of St. John Hospital Library has organised three lectures which will be given at the London School of Economics, Houghton-street, Aldwych, London, W.C. On Wednesday, Feb. 22nd, Mr. C. E. A. Bedwell, house governor of King's College Hospital, will speak on the Hospital; on March 1st Mr. Lamb, of the central library, Sheffield, on the Library; and on March 8th Mrs. M. E. Roberts, organising secretary of the society, on the Librarian. All the lectures are at 5.30 P.M.

Hospital Almoners' Association

The annual dinner of this association was held on Saturday last, Feb. 4th, when Miss C. Morris took the chair and presided over the largest annual festivity the association has seen. The toast of Prosperity to the Hospital Almoners was proposed by Sir Frederick Menzies, who in an interesting address outlined the situation of the hospitals now under the control of the London County Council, which since the provisions of the Public Health Act of 1929 has become the largest hospital authority in the world. Sir Frederick, indicating what this must mean in the extension of the work of almoners, recognised that work as now constituting an integral part of hospital administration. Miss M. Edminson, in reply, commented wittily on the public uncertainty as to what is meant by an almoner, and testified to the increasing recognition by all hospitals of the service of the almoners' department. Miss E. Lewis proposed the toast of the guests, with fervour in spite of, as she said, feeling "cowhearted"—an adjective picked up from a timid woman whom she was visiting in the course of her hospital duties. Prof. W. H. Maxwell Telling replied. The function was held in the Hans Crescent Hotel, and was a very successful one.

practised. We have received from Prof. Blair Bell the following testimony to the man and his work:—

"William Phillips Graves achieved greatness in his special subject—gynæcology—not only because of his natural ability, but also because he was a man of great character. Since they have not been published, it will not be inappropriate to reproduce, as a text for the few words of appreciation that follow, the short eulogy spoken to him when he was admitted an Honorary Fellow of the British College of Obstetricians and Gynæcologists in December last.

> 'In this world of haste and hurry—conditions not unknown in your own country—you stand out in our branch of medicine as a man of quiet contemplation, wise discretion, and sober judgment. Your influence on the progress of gynæcology has been profound, not only in the United States of America, but wheresoever there exists a parcel post for the transport of your classical works. You are an artist, too, and the beautiful illustrations drawn by your own hand, which adorn your books and papers, are the admiration of all. You bring artistry to your craft. You are, besides, a thinker; and beneath a deep reserve lie golden thoughts. In honouring you, we honour obstetrics and gynæcology.'

"In the United States of America, Dr. Graves—for that is how all medical practitioners there, whether professors, surgeons, or physicians, are addressed—was regarded as *the* sound, conservative, yet progressive gynæcologist, and as a man of great experience and wide learning. I received the impression on both the occasions I was in America that he occupied the same position in gynæcology as that which the late Whitridge Williams held in obstetrics—both were trusted; and their opinions were held in unqualified respect.

"I remember so well expressing in one of the communications I made there—I think to the A.M.A.—my views on the biological value of the ovaries, and the importance of conservative surgery in respect of them. I was told beforehand that Graves would criticise my views, that he, as many of my colleagues in this country and elsewhere, held no brief for the importance of the ovarian function. Graves did not speak; but he came to me afterwards and said: 'I intended to oppose your views, but you made some points that I have not heard before; I have not changed my views yet; I must consider the matter afresh.' When he was in Manchester years later, when I read another paper on the subject, he told me he had been converted. I merely quote this story to show the open-mindedness of the man, and the cautious and fair way in which he formed his judgments.

"It is quite unnecessary for me to speak in detail of his wonderful text-book, his recent work 'Female Sex Hormonology,' or of his numerous papers. They are all marked by the same desire for truth, and by the same lucid thought and expression. His artistic ability is shown in the beautiful illustrations which he made for his medical publications. He also drew for his own pleasure, and for that of his friends, and was not only a draughtsman, but had also very sensitive and artistic feelings. Again let me give an illustration. He had recently purchased a country estate, and in describing this to me he said: 'There is a very old ash-tree by the lawn, but it is dead, the branches are bare. A friend asked me why I did not cut it down. I told him to come and see it in the moonlight.' I had long known that he admired our trees more in their winter bareness, when the outlines of their limbs are clear-cut against the sky or in the moonlight, than when they are in their summer dresses. That shows the kind of man he was in his innermost self.

"He was a deep reader of fine literature, which he was ever ready to discuss, and a great practical surgeon and accomplished teacher. Many of us have lost a close personal friend—a man who was a great gentleman, a sportsman, and a learned and inspiring colleague."

MEDICAL NEWS

Royal Colleges of Physicians of London and Surgeons of England.

At the final examination of the Conjoint Board held from Jan. 2nd–26th the following candidates were approved in the subjects indicated, but are not yet eligible for diplomas:—

Medicine.—D. R. Ashton, St. Bart.'s; A. D. Aveling, Camb. and London; J. E. M. Ayoub, Oxf. and St. Thomas's; L. J. Beynon, St. George's; I. N. Blusger, St. Bart.'s; W. A. Bowdler, St. Thomas's; C. G. Bree, Univ. Coll.; A. Brown, King's Coll.; Hilda M. Brown, Royal Free; S. G. Browne, King's Coll.; T. J. K. Brownlees, St. Bart.'s; J. H. J. Crosse, Camb. and St. Bart.'s; W. J. B. de Gruchy, Camb. and St. Thomas's; A. E. De Sa, Bombay; R. G. Fear, St. Bart.'s; M. K. Gadgil, Bombay and West London; J Gordon, Middlesex; H. T. J. Hynes, St. Bart.'s; A. H. Ismail, Birmingham; B. F. Jackson, St. Bart.'s; J. F. Jarvis and F. W. H. Kent, King's Coll.; S. H. Kessler, Long Island and King's Coll.; Hilda I. Lanceley, King's Coll.; S. Lee, Westminster; A. G. C. Mason, Middlesex; Ellen Mayer, King's Coll; C. R. Naidu, Bombay and St. Bart.'s; S. D. J. Nand, Manchester; L. G. Nicholas, Cardiff; R. M. M. C. Orpwood and W. M. Oxley, St. Bart.'s; H. E. S. Pearson, St. Thomas's; G. D. Pirrie, Camb. and King's Coll.; M. L. Platt, Middlesex, M. Richmond, London; M. A. Rugg-Gunn, Camb. and St. George's; I. M. Shulman and R. T. Simcox, St. Bart.'s; E. J. Smith, King's Coll.; P. G. Stainton, Guy's; B. A. Thomas and W. H. D. Trubshaw, St. Bart.'s; G. N. Wardle, St. George's; C. E. M. Ware, St. Bart.'s; H. Waterman, *Leeds*; *Elma Wolmarans* and T. M. Wynter, Royal Free.

Midwifery.—Winifred L. Acraman, Cardiff; S. B. Adams, Bristol; S. R. Ali, Bombay and King's Coll.; J. E. O. Amegatcher, Camb. and St. Thomas's; D. A. Andersen, Univ. Coll.; J. B. Andosca, King's Coll.; T. R. Aubrey, Oxf. and Bristol; F. H. Barber, Birmingham; H. J. Barrie, Oxf. and London; A. J. *Board*, Bristol; J. Boyle, St. Mary's; C. F. R. Briggs, Univ. Coll.; G. O. A. Briggs, Camb. and St. Bart.'s; Hilda M. Brown, Royal Free; P. S. Buckley, Oxf. and London; K. L. Buxton, Camb. and St. Thomas's; H. R. Cara, Liverpool; F. F. Cartwright, King's Coll.; A. S. Cheong, St. Mary's; E. L. Cohen, Camb. and St. Bart.'s; F. H. Coleman, Camb. and London; Dorothy C. J. Cookson, Royal Free; F. E. Corea, St. Bart.'s; C. F. Critchley, St. Thomas's; T. M. Cuthbert, D. L. L. Davies, and E. E. Dodson, St. Bart.'s; Ruth C. Easterling, King's Coll.; L. R. L. Edwards, Guy's; P. J. *England, Cardiff*; *S. M. Evans, Camb. and St. Thomas's*; C. Fletcher, St. Bart.'s; P. A. Flood, Camb. and St. Thomas's; G. L. Foss, Camb. and Bristol; T. Foulds, Manchester; H. Goldfarb, Univ. Coll.; C. L. Greening, Durham; E. M. Griffin, Camb. and London; I. H. Griffiths, Cardiff and Middlesex; A. A. Hakeem, Bombay and Manchester; H. W. Hall, Univ. Coll.; Ida M. Hamp, Royal Free; J. H. T. Harrington, Oxf. and St. Mary's; T. N. Hart, Manchester; K. J. Harvey, St. Bart.'s; Pearl M. Heirshberg, Royal Free; G. A. H. Herbert, London; K. Hooper, Guy's; R. H. K. Hope, Univ. Coll.; C. Houghton-Brown, St. George's; A. V. House, Bristol; D. A. Hovenden, St. Thomas's; J. A. C. Hunter, Guy's; R. H. Isaac, St. Bart.'s; A. H. Ismail and G. H. James, Birmingham; J. W. James and Margaret H. James, Univ. Coll.; R. G. James, King's Coll.; D. A. Jennings, Oxf. and St. Thomas's; H. G. John, Cardiff and Univ. Coll.; E. H. Johnson, Leeds; G. P. Jones, Cardiff; N. K. Kal, Univ. Coll.; C. W. C. Karran, Camb. and St. Thomas's; Alice M. devising methods of prevention of such respiratory diseases as influenza. Hitherto, in this and other countries the direct verification of the influenza virus has proved impracticable because the effect of the organism, for it cannot be proved experimentally in the absence of any susceptible species of animal. No general method of immunisation is accordingly at present available.

Viscountess Astor: Would it not be wiser not to talk so much about it? (Laughter and Cheers.) Does the Minister not think that it does more harm to talk about it, and would it not be as well to bear in mind that Job said: The thing which I greatly feared is come upon me? (Laughter).

No further answer was given.

Slum Clearance

Mr. Emmott asked the Minister of Health whether the Government's programme for slum clearance was limited to 12,000 houses a year.—Sir E. Hilton Young replied: No, Sir. No limitation of the sort is imposed in the Government's programme for the clearance of slums. It is intended by the concentration of assistance from State subsidies on slum clearance, and by encouraging the more effective administration of the Act of 1930 by the responsible local authorities, to raise the rate of clearance as much as possible, without any arbitrary limitation. The figure of 12,000 houses a year was referred to by me as the estimated number for which, in the light of experience of the working of the Act, it is reasonable to make provision in the estimates for the coming year, which will be the first year of intensified effort to accelerate the rate of clearance. It is expected that after the first year the rate will be increased.

Medical Diary

SOCIETIES

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

MONDAY, Feb. 13th.—4.30 P.M., UNITED SERVICES. Paper. Major-General J. W. West: The Story of a Small Campaign: the Burma Rebellion of 1931.

TUESDAY.—5 P.M., THERAPEUTICS AND PHARMACOLOGY. Discussion: Iodine Compounds in Thyroid Disease. Openers: Prof. C. R. Harington (the Historical Aspect); Dr. H. Gardiner-Hill (the Clinical Aspect). Other speakers will take part. 8.30 P.M., PSYCHIATRY. Paper. Prof. Millais Culpin: The Occupational Neuroses (including Miners' Nystagmus). Members of the Section of Ophthalmology are specially invited to attend the Meeting.

THURSDAY.—5 P.M., DERMATOLOGY. (Cases at 4 P.M.) 7.45 P.M., NEUROLOGY. A Clinical Meeting will be held at the National Hospital, Queen-square, W.C. 1.

FRIDAY.—5.30 P.M., PHYSICAL MEDICINE. Demonstration. Dr. J. B. Mennell: Manipulative Methods. Members of the Section of Orthopædics are specially invited to attend the Meeting. 8.15 P.M., OBSTETRICS AND GYNÆCOLOGY. Paper. Dr. Elizabeth Hurdon and Dr. Helen Chambers: [illegible] Carcinoma of the Body of the Uter[illegible] logical Specimens. Dr. M. A. [illegible] Endometritis. 2. Sarcoma [illegible] 3. Unruptured Interstitial Tubal Pregnancy. 8.30 P.M., RADIOLOGY. Short reports of cases will be given.

MEDICAL SOCIETY OF LONDON, 11, Chandos-street, Cavendish-square, W.

MONDAY, Feb. 13th.—8.30 P.M., Discussion on the Treatment of Peptic Ulcers by Duodenal Feeding, to be introduced by Dr. Ernest Young and Dr. G. R. M. Cordiner.

ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE, Manson House, 26, Portland-place, W.

THURSDAY, Feb. 16th.—8.15 P.M., Prof. J. Gordon Thomson: The Problem of Immunity in Malaria (lantern) preceded by a Demonstration at 7.45 P.M.

PADDINGTON MEDICAL SOCIETY.

TUESDAY, Feb. 14th.—9 P.M. (at Great Western Royal Hotel, Paddington), Dr. E. K. Le Fleming, Dr. A. F. Heald, and Mr. Ernest Ware: Problems of Medical Representation.

SOCIETY OF MEDICAL OFFICERS OF HEALTH.

FRIDAY, Feb. 17th.—5 P.M. (at 1, Upper Montague-street, Russell-square, W.C.), Diphtheria Immunisation—Its Possibilities and Difficulties. Speakers: Dr. E. H. T. Nash, Dr. J. G. Forbes, Dr. Guy Bousfield, and Dr. R. M. F. Picken.

NORTH LONDON MEDICAL AND CHIRURGICAL SOCIETY.

WEDNESDAY, Feb. 15th.—4.30 P.M. (at St. Mary Islington Hospital), Clinical Demonstration by Dr. W. R. M. Turtle.

BIOCHEMICAL SOCIETY.

FRIDAY, Feb. 17th.—4.30 P.M. (at the Lister Institute, Chelsea Bridge-road, London, S.W.), Communications.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

ROYAL COLLEGE OF SURGEONS, Lincoln's Inn-fields, W.C.

MONDAY, Feb. 13th.—5 P.M., Mr. P. N. B. Odgers: The Anatomy of the Lumbar and Lumbo-sacral Diarthroidal Joints in Man. (Arris and Gale lecture.)

WEDNESDAY.—5 P.M., Prof. R. J. S. McDowall: Experimental Shock, with special reference to Anæsthesia. (Arris and Gale lecture.)

FRIDAY.—5 P.M., Mr. R. W. Raven: Diverticula of the Pharynx and Œsophagus. (Arris and Gale lecture.)

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, W.

MONDAY, Feb. 13th, to SATURDAY, Feb. 18th.—MEDICAL SOCIETY OF LONDON, 11, Chandos-street, Cavendish-square, W. Practical Problems in Medicine and Surgery. Lecture by Dr. H. C. Cameron on Stammering and Bed-wetting in the School-child, Tues., at 4 P.M. (Members and Associates of the Fellowship only.)—ROYAL FREE HOSPITAL, Gray's Inn-road, W.C. Antenatal Demonstration by Dame Louise McIlroy, Frid., at 5 P.M.—ST. JOHN'S HOSPITAL, Leicester-square, W.C. Post-graduate course in Dermatology. Clinical instruction daily at 2 and 6 P.M. Lectures at 5 P.M. on Tues. and Thurs.—CHELSEA HOSPITAL FOR WOMEN, Arthur-street, S.W. Post-graduate course in Gynæcology. Lectures and operations daily. (Courses open only to Members and Associates of the Fellowship of Medicine.)

WEST LONDON HOSPITAL POST-GRADUATE COLLEGE, Hammersmith, W.

DAILY.—2 P.M., Operations, Medical and Surgical Out-patients.

MONDAY, Feb. 13th.—10 A.M., Medical Wards, Skin Dept., Surgical Wards. 2 P.M., Eye and Gynæcological Out-patients. 4.15 P.M., Lecture. Dr. Grainger Stewart: Compression Paraplegia.

TUESDAY.—10 A.M., Medical Wards, Surgical Demonstration. 2 P.M., Throat Out-patients. 4.15 P.M., Lecture. Mr. Addison: Urinary Conditions in Children.

WEDNESDAY.—10 A.M., Medical Wards, Children's Medical Out-patients. 2 P.M., Eye Out-patients. 4.45 P.M., Venereal Diseases Demonstration.

THURSDAY.—10 A.M., Neurological Out-patients. Demonstration of Fractures. 2 P.M., Eye and Genito-urinary Out-patients. 4.15 P.M., Lecture. Mr. Edgeley Curnock: Diseases of the Teeth.

FRIDAY.—10 A.M., Skin Out-patients. 12 noon, Lecture on Treatment. 2 P.M., Throat Out-patients. 4.15 P.M., Lecture. Dr. Reginald Ironside: Anæsthesia.

SATURDAY.—10 A.M., Medical and Surgical Wards, Children's Medical Out-patients. The Lectures at 4.15 P.M. are open to all Medical Practitioners without fee.

NATIONAL HOSPITAL, Queen-square, W.C.

MONDAY, Feb. 13th, to FRIDAY, Feb. 17th.—2 P.M. and 3.30 P.M., Demonstrations in Out-patients' Department.

UNIVERSITY COLLEGE, Gower-street, W.C.

MONDAY, Feb. 13th.—5 P.M., Mr. H. R. Ing, D.Phil.: Chemical Structure and Pharmacological Action. (First of six free lectures.)

ST. MARK'S HOSPITAL, City-road, E.C.

THURSDAY, Feb. 16th.—4 P.M., Dr. B. Alexander: Colitis.

CENTRAL LONDON THROAT, NOSE, AND EAR HOSPITAL, Gray's Inn-road, W.C.

MONDAY, Feb. 13th, and following days.—10.30 P.M., Course in methods of examination and diagnosis.

ST. PETER'S HOSPITAL FOR STONE, Henrietta-street, W.C.

WEDNESDAY, Feb. 15th.—3 P.M., Mr. A. H. Harkness: Treatment of Acute Gonorrhœa.

LONDON JEWISH HOSPITAL, Stepney Green, E.

THURSDAY, Feb. 16th.—4 P.M., Mr. S. I. Levy: Enlarged Prostate and its Treatment. Lecture-demonstration.

PRINCESS ELIZABETH OF YORK HOSPITAL FOR CHILDREN, Shadwell, E.

WEDNESDAY, Feb. 15th.—3.30 P.M., Mr. H. P. Winsbury-White and Dr. O. H. Gotch: Medical and Surgical Aspects of Enuresis in Childhood. Lecture-demonstration.

KING'S COLLEGE HOSPITAL MEDICAL SCHOOL, Denmark-hill, S.E.

THURSDAY, Feb. 16th.—9 P.M., Mr. John Hunter: Goitre.

LONDON SCHOOL OF DERMATOLOGY, St. John's Hospital, 49, Leicester-square, W.C.

TUESDAY, Feb. 14th.—5 P.M., Dr. M. Sydney Thomson: Lupus Erythematosus.

THURSDAY.—3 P.M., Dr. I. Muende: Pathology Demonstration.

ROYAL NORTHERN HOSPITAL, Holloway-road, N.

TUESDAY, Feb. 14th.—3.15 P.M., Dr. P. O. Ellison and Dr. S. McKenzie: Pathological Investigations.

ST. MARY'S HOSPITALS, Manchester.

FRIDAY, Feb. 17th.—4.15 P.M. (at the Whitworth-street West Hospital), Mr. Morley: Some Endocrine Disturbances of Childhood.

ROYAL INSTITUTE OF PUBLIC HEALTH, Queen-square.

WEDNESDAY, Feb. 15th.—4.30 P.M., Miss M. W. Edminson: The Rheumatism Clinic and its Relation to the Social Services.

SOUTH-WEST LONDON POST-GRADUATE ASSOCIATION.

WEDNESDAY, Feb. 15th.—4 P.M., Mr. V. Z. Cope: Demonstration of Surgical Cases.

GLASGOW POST-GRADUATE LECTURES.

TUESDAY, Feb. 14th.—3.30 P.M. (in the Faculty Hall, St. Vincent-street), Dr. A. J. Ballantyne: Interpretation of Ophthalmoscopic Findings.

WEDNESDAY.—4.15 P.M. (at the Royal Infirmary), Mr. J. Patrick: Gynæcological Cases.

British Medical Association

The Sir Charles Hastings lecture will be given on Tuesday, Feb. 21st, at 8 P.M. in the Great Hall of the Association's house, Tavistock-square, London, W.C., when Sir Henry Gauvain will speak on *Sun, Air, and Sea-bathing in Health and Disease.* Lord Dawson will take the chair.

British Institute of Philosophy

Prof. L. P. Jacks, editor of the *Hibbert Journal*, will deliver an address on the *Social Sciences and Philosophy* at University College, Gower-street, London, W.C., at 8.15 P.M., on Tuesday, Feb. 14th. Tickets can be obtained from the director of studies, University Hall, 14 Gordon-square, W.C. 1.

Royal Dental Hospital

Arrangements have been made at this hospital to hold various post-graduate courses on the use of anæsthetics. On Monday, Tuesday, Wednesday, and Friday afternoons from March 6th to the 18th, and again from April 24th to May 6th, two hours of practical instruction will be given daily; and from March 20th to 31st an intensive course consisting of demonstrations in the in-patient department (at Charing Cross Hospital), and daily practical instruction and lectures in the out-patient department (Leicester-square). Further particulars may be had from the dean at the hospital, Leicester-square, London, W.C. 2.

National Hospital, Queen-square

A post-graduate course is now being held at this hospital and will continue until March. Every weekday, except Saturday, there are out-patient clinics at 2 P.M., and lectures and clinical demonstrations at 3.30 P.M. At noon on Wednesdays and Fridays there are demonstrations on the pathology of the nervous system by Dr. J. G. Greenfield, and on Thursdays on the anatomy and physiology of the nervous system by Dr. Macdonald Critchley and Dr. Denny Brown. Mr. L. J. Paton and Mr. T. H. Just are giving demonstrations on neurological ophthalmology and otology at 4.30 P.M. on Mondays and Thursdays. Further particulars may be had from the secretary of the hospital, Queen-square, London, W.C.1.

Harveian Society of London

On Thursday, March 9th, Mr. William Wright, university professor of anatomy at the London Hospital medical college, will deliver the Harveian lecture, on the Anatomy and Physiology of the Central Nervous System; on April 13th Mr. R. Watson Jones, Mr. E. P. Brockman, and Mr. Bryan Burns will open a discussion on Böhler's Influence on the Treatment of Fractures; and on May 11th there will be a discussion on Modern Methods of Treatment of Acute Specific Fevers, introduced by Dr. R. A. O'Brien and Dr. William Gunn. All these meetings will be in the Paddington Town Hall at 8.30 P.M. The Buckston Browne dinner will be held on June 8th at the Star and Garter Home, Richmond, Surrey, and there will be a reception at Down House, Downe, Kent, on July 20th, at 3.15 P.M., when Sir Buckston Browne will give an address on Charles Darwin.

National Council for Mental Hygiene

A series of lecture-discussions on Mental Hygiene in Everyday Life will be delivered in the lecture-room of the Medical Society of London, 11, Chandos-street, Cavendish-square, London, W., on Wednesdays at 5.30 P.M. Dr. J. A. Hadfield will speak on Anxiety (March 1st); Dr. E. A. Bennett on Confidence (8th); Dr. George Somerville on Superstition (15th); Dr. John Rickman on Ambition (22nd); Mr. C. W. Kimmins, D.Sc., on Adaptability (29th); and Dr. E. A. Hamilton-Pearson on Discipline (April 5th). Tickets may be obtained from the secretary of the Council, 78, Chandos House, Palmer-street, London, S.W., or at the lecture.

Joint Tuberculosis Council

After a meeting of the Council on Jan. 21st the members were entertained to lunch at the Hotel Russell by Dr. Lissant Cox, the chairman. The guests included Dr. A. B. Howitt, M.P., secretary of the Parliamentary Medical Committee, Sir Henry Jackson, M.P., Dr. W. J. O'Donovan, M.P., Mr. G. S. Elliston, M.P., Dr. Charles Porter, and Mr. Lewis Elliston. Dr. Lissant Cox proposed the health of the Guests and Dr. Howitt replied, praising the coördinating work of the Council. Dr. O'Donovan proposed the health of the Council, and Dr. Ernest Ward, in his reply, stressed the disgrace to our profession of the continued mortality and crippledom caused by tuberculosis of bovine origin. He advocated the boiling of milk before use in each individual household. Mr. G. S. Elliston then proposed thanks to Dr. Lissant Cox as host, and praised the work of the chairman and the hon. secretary, Dr. Ward. The vote was seconded by Dr. Jane Walker, and Dr. Lissant Cox replied.

Pharmaceutical Society of Great Britain

At a meeting of this society, to be held at 17, Bloomsbury-square, London, W.C., at 8.30 P.M. on Tuesday, Feb. 14th, Dr. J. A. Gunn, professor of pharmacology in the University of Oxford, will give a lecture on the Search for New Remedies.

Paddington Medical Society

The next meeting of this society will be held on Tuesday, Feb. 14th, at the Great Western Hotel, Paddington, at 9 P.M., when a discussion will take place on Problems of Medical Representation. Dr. E. K. Le Fleming, a direct representative on the General Medical Council, Dr. A. F. Heald, organising and assistant medical secretary of the London panel committee, and Mr. Ernest Ware, president of the Society of Members of the Royal College of Surgeons, will be the openers. Visitors are invited.

Fellowship of Medicine and Post-Graduate Medical Association

Dr. H. C. Cameron will lecture on Stammering and Bed wetting in the School-child in the series on practical problems in medicine and surgery at 4 P.M. at 11, Chandos-street, Cavendish-square, London, W., on Tuesday, Feb. 14th. Three courses will begin on Feb. 20th: an evening course of clinical and pathological demonstrations at the National Temperance Hospital on Mondays and Fridays, which will be limited to 16; a fortnight's course in medicine, surgery, and the specialties at the Prince of Wales's Hospital, Tottenham; and a practical pathology class at the Hospital for Consumption, Brompton, on two days a week from 11.30 A.M. to 1 P.M., which will be limited to six. Other forthcoming courses include a course in medicine, surgery, and gynæcology at the Royal Waterloo Hospital, March 6th to 25th; a course in orthopædics at the Royal National Orthopædic Hospital, March 6th to 18th; and an evening course in rheumatism at the British Red Cross Clinic on Tuesdays and Thursdays from March 7th to 23rd.

Royal Institute of Public Health

In July of last year the Royal Institute of Public Health moved into its new building in Queen-square, London, and on Feb. 7th a reception was held, at which Lady Leverhulme acted as hostess, in order that friends of the institute might have the opportunity of admiring the new premises. These have been built in an unpretentious and dignified style, and consist of four stories and a basement. The board room and administrative offices are on the ground floor. On the first floor is the chemistry department, where samples of several foodstuffs sent up for analysis were on view. A laboratory is set aside for the use of students in training for the diploma in public health, and is large enough to accommodate some 20 students at a time. The institute coöperates with official bodies in dealing with the problems of pure water- and milk-supplies, and epidemic diseases such as diphtheria and typhoid, and undertakes the bacteriological examination of water, sewage, food, and other materials such as the dyes used for fur. The laboratories are recognised as a place for research in connexion with the Beit Memorial Fellowships, and the institute encourages medical practitioners and others to make use of its facilities for original research, whether in preventive medicine, bacteriology, epidemiology and immunology, the analysis of foodstuffs, or other allied subjects.

PARLIAMENT

NOTES ON CURRENT TOPICS

Reassembly of Parliament

BOTH Houses of Parliament reassembled after the Christmas recess on Tuesday, Feb. 7th.

HOUSE OF COMMONS

TUESDAY, FEB. 7TH

Influenza Research

Sir WILLIAM DAVISON asked the Minister of Health whether any organised research was being conducted by or at the instance of his Department with a view to ascertaining the primary cause of influenza, and methods for its prevention, in view of the serious effects on the health and industry of the nation caused by recurring epidemics of that disease.—Sir E. HILTON YOUNG (Minister of Health) replied: Investigation into the virus diseases, of which influenza is believed to be one, is continually in progress at the National Institute for Medical Research. A special inquiry subsidised by my Department is also being made into the bacteria of the nose and throat with a view to

ADDRESSES AND ORIGINAL ARTICLES

THE PROGNOSIS AND TREATMENT OF LOBAR PNEUMONIA*

By John A. Ryle, M.D., F.R.C.P. Lond.
PHYSICIAN TO GUY'S HOSPITAL

There are circumstances which compel a new review of the old and familiar diseases. As a rule we find that their clinical portraiture leaves little room for improvement. From time to time, however, research adds novelty or precision to our ideas of cause or points the way to a new therapy. Among the acute diseases lobar pneumonia maintains a high incidence through the generations, and there is no present sign that preventive medicine will make it rare as typhoid fever has been made rare. It remains an important cause of anxiety and mortality in every practice. Of its ætiology, its clinical features and course, and its immediate and remote dangers there is a general appreciation. Many views on therapeutic detail have been voiced and many supposedly specific remedies have been vaunted, but the general principles of management are firmly established. Fraenkel's discovery of the causal pneumococcus in 1884 gave the disease its status as an acute specific fever, but led to no revolution in treatment. More recent work has resulted in the recognition of three main types of pneumococcus and of a fourth heterogeneous group of organisms all capable of causing lobar consolidation of the lung. It has been shown in what proportion these different types are responsible for the disease and how they vary in their individual virulence. The latest outcome of these discoveries is the preparation of protective sera, and notably of Felton's concentrated serum, which is shown to have a certain degree of potency in combating infection with pneumococcus Types I. and II.

While serum therapy in pneumonia may still be said to be on trial enough has been published to set us thinking and to provide those of us who practise with some difficult problems in judgment. These may be briefly stated as follows. We need to know how far it is now incumbent upon us to consider the employment of serum in lobar pneumonia as a routine, or if this is not warranted, how we should select the cases to be so treated. Recognising that the method calls for experience and considerable technical skill we also need to know whether cases can be adequately handled in the home and, if not, whether they ought to be moved to hospital in face of the belief that, given good conditions, the avoidance of such a transfer generally provides a better prospect of recovery.

It is a main purpose of this communication to seek an answer to these questions. My personal experience of serum therapy in pneumonia is negligible, but I have long been interested in the natural history of the disease, and it was my good fortune to be a participant in the discussion on serum treatment at the summer meeting of the British Medical Association. I have also had the pleasure of meeting several of the leading British and American investigators and of serving on committees which are closely concerned with the problem.

There have been discoveries in the scientific treatment of disease in recent years which have been promptly accepted and universally applied, so apparent and remarkable were their achievements. Of such are insulin in diabetes and liver treatment in pernicious anæmia. The antipneumococcal sera, also due to careful scientific studies, are, however, in a different category and for various reasons have produced no such dramatic change in practice. They demand special care and experience for their administration; their preparation is costly; they show a limited specificity; it is very difficult to assess the several causes of symptoms and mortality in the disease which they are intended to benefit; and, finally, this disease has already a high natural recovery-rate. We are not entitled to conclude from this that sera will find no established place in our therapeutic armoury. Rather should we seek to determine the scope and limits of their utility.

Now we cannot discuss the merits of a new remedy unless we have a just appreciation of the natural morbidity and mortality of the disease which it is purported to relieve or cure. For this reason I must ask attention first of all to the difficult matter of prognosis in pneumonia—that is to say, of pneumonia when left to nature and the nurse. Thereafter, having briefly reviewed the contributions of non-specific therapy and the methods and results of serum therapy, I shall attempt an estimate of the extent to which we should be prepared to modify practice on the basis of the newer knowledge.

Mortality and Prognosis

As has been implied, we cannot claim that we are able to reduce the mortality or alter the morbidity of a disease until we know what its mortality and morbidity are. When, as in the case of pneumonia, these vary in some degree from year to year, very considerably from country to country, and markedly so in respect of age-incidence, social environment, individual constitutional factors, and the type of invading organism, our difficulties become very complex. Both the prevalence and mortality of pneumonia in the United States, where the bulk of the work on serum therapy has been done, are more serious than in this country and to some extent our conclusions must be drawn anew.

At present we have hospital figures in England and Scotland which show that the mortality of lobar pneumonia lies somewhere between 10 and 20 per cent. Dr. R. J. Waterfield (personal communication), investigating the figures at Guy's Hospital over a nine-year period ending in 1930 found a total mortality of 16 per cent. between the ages of 13 and 75 years. One-third of the deaths occurred over the age of 50. There were no deaths between the ages of 15 and 20. We have no exact figures as to the mortality of patients treated in their homes, and I imagine that many more patients in this country are treated in their homes than in hospital. As the graver cases and the poorer cases tend to find their way to hospital and as the act of removal is often undertaken rather late in the disease and is not always beneficial to the patient, it would be reasonable to expect a lower mortality among patients treated at home. A death-rate in the neighbourhood of 10 per cent. is suggested by general practitioners of wide experience. The mortality from lobar pneumonia among the troops at Aldershot during the war was shown by Abrahams [1] to be as low as 10·5 per cent. Here the patients were mostly picked men of military age, and it is probable that they were moved to hospital in the earliest stage of the disease. At a base hospital in France obliquely and the lower end brought to the surface; the pharynx was divided above the growth and the œsophagus below it, the cut end of the œsophagus being ligatured. The wound was closed except for the lower inch, and convalescence was uneventful; later, the lower inch of the opening was sewn up and the incision extended upwards. An attempt was made to cover the wound by a small celluloid cup connected with the gastrostomy opening by a tube, but the arrangement did not work well. Later the pharyngeal opening was closed, and a new one made immediately below the hyoid bone. Through this, the short end of a rubber empyema tube was passed, kept in position by tapes encircling the neck, and tied to the holes in the flanges of the tube; the long end was connected with the gastrostomy tube. This apparatus was a success, and was subsequently replaced by a curved rubber tube with a flange, connected by rubber tubing with another tube with a flange which fits the gastrostomy opening. The patient married less than a year after the first operation, and now, 23 years afterwards, is in good health and leads an active life.

---

* An address given to the West Herts and Watford Medical Society on Feb. 15th.

CLEAN FOOD FACTORIES

About 400 people attended a meeting held in London on Jan. 20th, jointly by the Royal Sanitary Institute and the food group of the Society of Chemical Industry, to discuss Factory Cleanliness in the Food Industry. Mr. E. B. Hughes, of Messrs. Lyons, laid it down that food factories should be planned as such from the outset, to facilitate handling of food, and to secure cleanliness by non-absorbent surfaces and good lighting. To avoid infestation there should be no harbourage for insects or other pests. Antiseptics to be used sparingly, though they were essential. Washing was very important. He instanced the cleaning of rotary curved knives used in cutting up meat; these, when dismounted, are first washed and wiped, then washed again with soft soap and hypochlorite solution, and finally wiped dry with a clean cloth. Inspectors and visitors are useful in the factory, though apt to be an annoyance to a young manager. Dr. Thomas Carnwath spoke of the way in which cleanliness reduced the dangers of keeping foods. Lieut.-Colonel G. Leighton emphasised the need for cleanliness not only of the works but of the workers. Sir Weldon Dalrymple-Champneys considered it most important that the methods of cleanliness should be understood by the workers so they could at once readjust their methods when an interruption of the factory routine had suddenly occurred. Dr. Naylor Barlow, medical officer of health for Wallasey, said it was intolerable that a food factory should be fitted into an old five-storey building with dark corners and soft wood floors, and asked for a limit on the relabelling of food preparations by retailers.

On the following day a party was taken over the laboratories of Messrs. Lyons in the Hammersmith-road, London.

Appointments

Brailsford, James F., M.D., Ch.B. Birm., has been appointed Radiological Demonstrator in Living Anatomy in the University of Birmingham.

Mower White, Ann, L.R.C.P. Lond., M.R.C.S. First Assistant, Children's Department, University College Hospital.

Trafford, H., L.R.C.P. Lond., M.R.C.S., Certifying Surgeon under the Factory and Workshop Acts for Warlingham, Surrey.

Vacancies

For further information refer to the advertisement columns

All Saints' Hospital, Austral-street, West-square, St. George's-road, S.E.—Res. H.S. At rate of £100.

Birkenhead General Hospital.—Hon. Orthopædic Surgeon. Res. Sen. H.S. At rate of £150. Also Second H.S., H.P., and Cas. O. Each at rate of £100.

Blackburn Royal Infirmary.—4th H.S. £150.

Bootle General Hospital.—H.P., Two H.S.'s, and Cas. O. All at rate of £150.

Bristol General Hospital.—Hon. Physician.

Burnley, Victoria Hospital.—H.P. At rate of £150.

Cambridge, Papworth Village Settlement.—3rd Asst. M.O. £300 Also H.P. At rate of £150.

Cardiff City Mental Hospital, Whitchurch.—Sen. Asst. M.O. £570.

Carlisle, Cumberland Infirmary.—H.S. At rate of £175. Also H.P., 2nd H.S., and H.S. to Spec. Depts. Each at rate of £155.

Carmarthen, Joint Counties Mental Hospital.—Med. Supt. £800.

Chester, East Lancashire Tuberculosis Colony, Gt. Barrow.—Asst. M.O. At rate of £275.

City of London Maternity Hospital, City-road, E.C.—Asst. Res. M.O. At rate of £80.

Derby County Mental Hospital, Mickleover.—Deputy Med. Supt. £600.

Dudley, Guest Hospital.—Asst. H.S. £170.

East Ham Memorial Hospital, Shrewsbury-road, E.—Hon. Surg. to Ear, Nose, and Throat Dept. Also Res. M.O. At rate of £200.

Hackney Hospital, High-street, Homerton, E.—Res. Asst. M.O. £350.

[illegible] *-West London Hospital, Haverstock-* [illegible] for Out-patient Dept. At rate of [illegible]

Harrogate, Royal Bath Hospital.—Res. M.O. At rate of £150.

Hillingdon County Hospital.—Res. Asst. M.O. £400.

Hospital for Sick Children, Gt. Ormond-street, W.C.—H.P. and H.S. Each at rate of £100.

Ilford, King George Hospital.—H.S. At rate of £100.

Larbert, Royal Scottish National Institution.—Asst. M.O. £350.

Leigh Infirmary, Lancs.—Res. H.S. At rate of £175.

London Lock Hospital, 91, Dean-street, W.—Res. M.O. At rate of £175.

Manchester, Ancoats Hospital.—Hon. Asst. Phys.

Manchester Babies Hospital, Burnage-lane, Levenshulme.—Jun. Res. M.O. At rate of £50.

Manchester, Christie Hospital and Holt Radium Institute.—Res. M.O. £150.

Manchester, Crumpsall Hospital and Institution.—Med. Supt £1200.

Northwood, Mount Vernon Hospital.—H.S. At rate of £150.

Norwich Infirmary.—Res. Asst. M.O. £480.

Nottingham General Hospital.—H.S. At rate of £150.

Paddington Green Children's Hospital, W.—Hon. Surg. to Ear, Nose, and Throat Dept.

Preston and County of Lancaster Royal Infirmary.—H.S. and Cas. O. £150.

Prince of Wales's General Hospital, N.—Res. Sen. and Jun. H.P.'s and H.S.'s. At rate of £120 and [illegible]

Princess Elizabeth of York Hospital for [illegible] H.S. At rate of £125.

Royal Air Force Medical Service.—Medical Officers.

St. Alfege's Hospital, Vanbrugh-hill, S.E.—Res. Asst. M.O. £350.

St. Giles' Hospital, Brunswick-square, Camberwell, S.E.—Res. Asst. M.O. £350.

St. Mary Abbot's Hospital, Marloes-road, Kensington, W.—Temp. Asst. M.O. At rate of £250.

St. Mary Islington Hospital, Highgate-hill, N.—Res. Asst. M.O. £350.

Staunton-on-Wye, Herefordshire, Jarvis Charity.—Res. M.O. £150.

Sunderland, Royal Infirmary.—Sen. H.S. £200.

West London Hospital, Hammersmith-road, W.—Asst. Phys. for Diseases of Children.

West Riding of Yorkshire C.C.—School Medical Inspector. £500.

Westmorland County Hospital, Kendal.—H.S. At rate of £200.

Weston-super-Mare General Hospital.—Res. H.S. £150.

Winchester, Royal Hampshire County Hospital.—H.S. At rate of £125.

Windsor, King Edward VII. Hospital.—Res. M.O. £200.

The Chief Inspector of Factories announces a vacancy for a Certifying Factory Surgeon at Bromley (Kent).

Births, Marriages, and Deaths

BIRTHS

Avery.—On Feb. 3rd, the wife of Harris Avery, M.B., of Selsdon-road, West Norwood, of a son.

Davey.—On Feb. 2nd, at Rockleigh, Gloucester, the wife of Dr. E. N. Davey, of a daughter.

DEATHS

Bell.—On Jan. 31st, Squadron Leader Robert Ernest Bell, M.B., B.Ch., R.A.F. (retired), as the result of an accident.

Eichholz.—On Feb. 6th, at North End House, W., Alfred Eichholz, C.B.E., M.D., aged 63.

Dell.—On Feb. 1st, at The Slade House, Stroud, Charles Mackintosh Dell, M.R.C.S., L.R.C.P., aged 27.

Hallett.—On Feb. 5th, at Long Wittenham, Frederic Greville Hallett, Knight, O.B.E., sometime Secretary of [illegible] England and of the the Conj[illegible] Imperial [illegible]

Kerr.—On J[illegible] Hove, Squadron Leader George Douglas Kerr, M.R.C.S., L.R.C.P. Lond., late R.A.F., aged 70 years.

Lewis.—On Jan. 29th, 1933, at 5, Sketty-road, Swansea, Rhys T. Lewis, M.D. Lond., aged 38 years.

Oppenheimer.—On Jan. 31st, at Nice, France, Heinrich Oppenheimer, M.D., LL.D., Ph.D., Lit.D., late of College-crescent, N.W., in his 64th year.

Stephenson.—On Feb. 2nd, at Orsett-terrace, W., John Stephenson, Lieut.-Colonel, I.M.S. (retired), C.I.E., F.R.C.S., F.R.S.

Wemyss.—On Feb. 3rd, at Moray-place, Edinburgh, Herbert Lindesay Watson Wemyss, M.D., F.R.C.P.E.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

toxic. The procedure, quoting Cecil verbatim, is as follows :—

> "The patient is first questioned as to previous injections of horse serum, and as to history of hay-fever, asthma, or hives. An intradermal and a conjunctival test are then made with a 1 in 10 dilution of normal horse serum. If after 15 minutes these tests are both negative, 5 c.cm. of Felton's serum are slowly injected intravenously. If the patient shows no reaction to this first injection of serum, a second of 15 to 20 c.cm. is given intravenously from one to two hours later, and this dose is repeated every two to three hours until the patient has received approximately 100,000 units (equivalent usually to about 100 c.cm. of serum). The amount of serum administered on the following day is determined by the clinical condition of the patient. If his condition has improved and if his chart shows a decided drop in temperature, pulse-rate, and respiration-rate, the amount of serum administered is approximately one-half of that administered on the first day. If, on the other hand, the patient's condition is worse, or if it remains unchanged, the intensive treatment is continued. On the third day the same policy is pursued. If the patient's temperature is under 100° F., and if his condition is good, the general rule is to give one or possibly two 10 c.cm. injections to prevent relapse. We have found from experience that if any benefit is to result from serum treatment it is usually apparent after two or at least three days of treatment."

The difficulties and anxiety attending such a programme outside hospital require no emphasis. Even spacing out the injections to eight hours and giving larger quantities does not greatly simplify, and serum reactions, which are a genuine cause of apprehension, have not been wholly eliminated.

Treating alternate cases without preliminary typing, Cecil obtained a reduction of mortality from 36 per cent. to 28 per cent. in groups of cases numbering respectively 422 and 429. A reduction in the same ratio (provided all cases were seen early enough and considered suitable for serum) would convert the 16 per cent. Guy's Hospital mortality to 12 per cent., and the private practice 10 per cent., say, to 8 per cent.

Approximately two-thirds of all cases of lobar pneumonia are due to Types I. and II., and approximately one-third are due to Type I. infections. The mortality in Type I. cases has been reduced from 31·2 to 20·1 (Cecil) and from 30·9 to 16·6 per cent. (combined results of various investigators quoted by Cecil). In Type II.—the most virulent type—the results are less good, a reduction from 45·8 to 40·5 per cent. only being reported (Cecil), and from 37·7 to 24·6 per cent. (other investigators quoted by Cecil). The earlier treatment is instituted the better are the results. Cecil reports a reduction in mortality from 26·8 to 11·7 per cent. in Type I. cases treated within 72 hours of onset. I have seen no figures thus far which suggest that the incidence of complications such as empyema is influenced by serum therapy. Armstrong and Johnson [4] also state that complications and sequelæ are apparently uninfluenced by serum. The results obtained by the Scottish [5] and English [4] investigators, although their studies so far have been on a smaller scale, support the contentions of Cecil. All observers are agreed that there is an appreciable reduction in mortality and that early defervescence is more frequent among cases treated with serum. Similar claims, it is true, have previously been made on behalf of vaccine treatment and certain forms of drug therapy, but no such carefully controlled studies have been reported by their advocates. An unexpectedly early defervescence may also occur without specific therapy but hardly, perhaps, with the frequency observed in serum-treated cases. Finally, there is evidence for the specificity of Felton's serum in that the mortality of Type III. and Type IV. infections is not appreciably influenced by it. In other words, improvement depends upon something more than a "protein-shock" effect. Criticisms of the methods of control employed in the reported series could easily be advanced, for adequate controls in large scale human experiments of this kind are difficult to come by. Thus in the "alternate case" method it is clear that an accidental preponderance of cases of more favourable age and constitution in the treated group would lower the mortality appreciably. However, the factors influencing the liability to death or recovery in pneumonia are so numerous that precise analysis is impossible, and when various groups of reliable workers find essential agreement their opinions must be held worthy of acceptance.

Practical Difficulties of Serum Treatment

(1) These are firstly encountered in connexion with diagnosis, and particularly with diagnosis at a suitably early date. The doctor is not always called at the onset of the disease and two or three days must frequently elapse before he appears on the scene or before the diagnosis is certain. Typing requires a further 12 to 24 hours, even if a competent laboratory service be close at hand. Not all lobar pneumonias are pneumococcal and, although an abrupt onset, high fever, and rusty sputum are generally accurate tale-bearers, there are cases in which the differentiation of a pneumococcal from an "influenzal" or streptococcal pneumonia or a "mixed" broncho-pneumonia is none too easy. In recent years other types of pneumonia have been more common and pneumococcal pneumonia less common than formerly. Massive collapse in association with bronchitis, a comparatively benign condition, may also be mistaken for pneumonia.

(2) Even allowing that an early diagnosis is achieved and the case thought suitable for serum the necessary preliminaries and the frequent administrations of serum by the intravenous route must needs provide the busy practitioner with very real embarrassment. They may also be disturbing, both physically and mentally, to patients for whom we normally advocate the minimum of disturbance.

(3) In the case of a poor patient it must be decided whether to rely upon conservative treatment at home or to risk removal to a hospital where serum treatment can be instituted if the infection prove to be of appropriate type.

While grateful for new knowledge we must confess that it can greatly complicate judgment and practice. We would none of us willingly withhold a curative agent in an anxious disease, but while we know that there is, broadly speaking, a 4 to 1 prospect of spontaneous recovery and a 1 in 3 chance that the infection is of inappropriate type we may feel a pardonable disinclination to burden a patient with repeated doses of an intravenous remedy for an indeterminate advantage. On the other hand, we cannot put it from our minds that a certain small percentage of otherwise doomed cases may have the balance tipped in their favour by serum.

As an example of the judicial difficulties which may be encountered let me quote the case of a friend and colleague to whom I was called the day after hearing the arguments in favour of serum therapy set forth by its chief exponents.

> The patient's age was 63; his life had been healthy and hardworking. On July 23rd he felt chilly and unwell. The next day he remained at work still feeling unfit. On the 25th he felt well again. On the 26th he had a rigor while out in his car, and that night his temperature was 102°. I saw him on the evening of the 28th—i.e., the second day from the rigor and the fifth from his first symptoms of infection—and found signs of pneumonia at the right apex and at the right root behind. Respirations 30. Pulse 108. General condition good. Leucocyte count 25,000 cells per c.mm. A small specimen of rusty sputum

Malloch and Rhea [2] found a general mortality of 26·1 per cent., with a higher rate among those coming long distances by convoy or hospital train than among base details. Cecil,[3] in the United States, reports that the death-rate of pneumococcal pneumonia varies considerably with the class of patient studied, being lowest in private practice, somewhat higher in the hospitals of the better class, and highest in the large hospitals draining the slum areas. Thus the mortality at the Rockefeller Hospital is 19·5 per cent. and at the Bellevue Hospital 35·8 per cent. Among 422 cases (all types) untreated with serum Cecil found a mortality of nearly 36 per cent. Among 429 cases (all types) treated with serum there was a mortality of 28 per cent. Even this lower figure approaches twice the Guy's Hospital figure. It is clear that pneumonia is a more serious menace in the United States than in the British Isles.

Turning to morbidity in hospital cases Dr. Waterfield finds that approximately 90 per cent. of the cases which recover do so without disability, so that there is no overwhelming argument in favour of an additional therapy on this score, even though it be shown that serum is capable of producing an earlier defervescence.

Leaving statistical data let us next consider the factors which are commonly accepted as influencing prognosis in the individual. So far we have recognised that youth and good environment are favourable and that poor conditions and advancing years are unfavourable. Other prognostic indications have been repeatedly observed at the bed-side. The presence of a chronic disease or of alcoholism weights the scales heavily against recovery. Cyanosis is adverse, delirium by no means necessarily so. Wide extent of lung involvement, although frequently, is not always of bad import. A low and particularly a falling blood pressure gives cause for concern. The pulse-temperature-respiration ratio affords valuable guidance; while parallelism is maintained or pulse- and respiration-rate are slow in proportion to the temperature hopes are good, but if pulse- and respiration-rate rise unduly while the temperature swings or falls, there is cause for grave anxiety. A clean tongue and nourishment well taken are encouraging. A good leucocytic response, in the neighbourhood of 20,000 cells per c.mm., has always been accounted favourable, and a complete absence of leucocytosis as very unfavourable. Intermediate figures must be balanced with the clinical findings. The pneumococcus may be grown from the blood stream in the early stages of pneumonia in a certain proportion of cases. A profuse growth or persisting positive blood cultures as the disease advances are now known to be very adverse. Pericarditis and meningitis, other expressions of the septicæmic state, usually foretell a fatal termination. Pneumococcal peritonitis has its special incidence in childhood and may occur with or without evident pneumonia; the death-rate is high but recoveries occur.

It will be generally agreed that prognosis is most difficult during the first three days of the disease—the very stage in which additional help, if required, should be given. Nothing would give a greater impetus to the employment of serum therapy than the establishment of prognostic criteria which would separate at an early stage the 15 or 20 per cent. of cases with an otherwise hopeless prognosis from the 80 or 85 per cent. destined to recover spontaneously. At present reliance must be placed upon clinical judgment of the patient's constitution and reserves and of the extent of the infection combined with a routine leucocyte count, but we must acknowledge that appearances can be deceptive. We have all seen the "apparently hopeless" case recover, and the "apparently favourable" case succumb.

The Essentials of Non-specific Therapy

Although it cannot be quantitatively expressed it is not to be doubted that symptomatic treatment helps recovery, and that good or bad treatment may make the difference between life and death. A warm but fresh and well-ventilated room and a good nurse are probably to be accounted of greater value to the patient than all other measures combined. The nurse's mission is to secure the maximum of rest and sleep with the minimum of interference; to supply adequate light nourishment; to attend to the mouth and skin without unnecessary movement or fatigue; to limit the visits of relatives; accurately to keep those records which are of such importance to the physician as indices of progress or deterioration; to preserve optimism; and to administer oxygen and certain drugs at appropriate times. A fussy nurse, too insistent on professional detail or appearances, or too partial to heated rooms and the pneumonia jacket, can do as much harm as her wiser colleague can do good. While most patients are happier propped high with extra pillows, individual requirements vary and the elevation can be overdone. Occasional tepid sponging is a part of the routine. A fluid or semi-fluid diet with fruit-juices and plentiful drinks and additional sugar or glucose is usually the best. Stimulants can frequently be dispensed with altogether if adequate fluid and sugar are taken, or alternatively may be reserved for the anxious days before the crisis. Hypodermic stimulants such as strychnine and adrenaline are, to my mind, of dubious value. They are often given rather at the dictation of anxiety than of necessity, and if they produce a physiological response on the part of the heart or blood-pressure is it not rather by dint of "flogging the tired horse" and too transitory in its effect to be a real boon? Digitalis is commonly given although it is still doubtful whether it has any virtue in the case of a regular tachycardia and embarrassed function due to fever and toxæmia. Brandy is a food as well as a stimulant and its utility in certain cases and stages is generally approved. Oxygen, preferably given continuously through a nasal catheter, is obviously justified in the presence of cyanosis. For sleep, when pain is slight or absent, Dover's powder with aspirin may be enough for some patients and in small doses is a useful combination in the case of children. Morphine should never be withheld during the earlier stages in the adult case where sleeplessness and pain are prominent complaints. One quarter of a grain should be the dose, a sixth being too frequently disappointing in its effect. A light flannel jacket or shawl over nightdress or pyjamas is sufficient covering. Heavy poultices, thick or tightly fitting vests and pneumonia jackets are to be avoided, but a light linseed or antiphlogistin poultice is grateful in the presence of pleuritic pain. So far as is consistent with careful observation the patient should be spared repeated examinations of the chest.

The Method and Results of Serum Therapy

These have been ably summarised by Cecil.[3] The method is based upon successful protective experiments with artificially infected monkeys. Felton's serum has the double advantage over previous preparations of being concentrated, so that smaller quantities can be given at a time, and of being less indistinguishable from them may be the result of Mikulicz's disease.

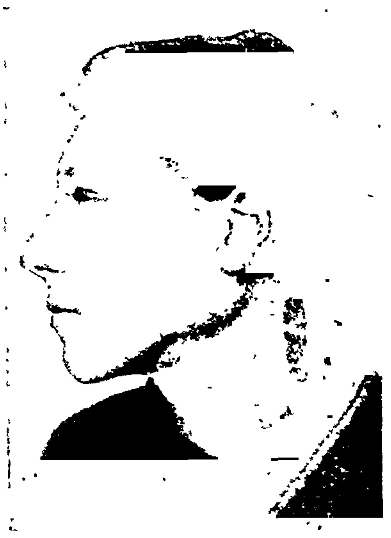
CLINICAL FEATURES

Of the 19 patients in the present series no fewer than 16 were women; the average age at onset was 29, with 11 and 53 as extreme limits; and the average duration of the disease was nine years. In 9 cases the condition affected one parotid gland, in 9 cases both parotid glands, whilst in the remaining case the pathological process had started in both submaxillary glands and later spread to both parotids.

A few of the patients dated the onset of the condition to an acute dental infection or a dental extraction, to an acute infection of the upper respiratory tract, or to some other acute illness; but in most of the cases no such suggestive ætiological factor was put forward. In one case, a boy of 11, the condition followed an acute suppurative parotitis which had necessitated surgical drainage.

The disease usually begins insidiously with an occasional feeling of fullness in one parotid region. This soon gives way to a slight swelling of one parotid, associated with a feeling of still greater tension in the gland. Some patients have noted a tendency for the attacks to be started off by a meal, in which case the parotid swelling may reach a considerable size during the course of an hour or so, whilst in other cases there has been a tendency for very acid foods to start the attack. The gland may take anything from an hour or two to reach its maximum size, though as a rule this is reached in the course of about 24 hours. The swelling then persists for a variable period, sometimes tending to subside at the end of 48 hours, and sometimes lasting as long as six weeks. In a few cases the actual resolution of the attack is accompanied by the passage into the mouth—through the duct of the affected gland—of pus, or more often muco-pus, with a foul taste.

FIG. A



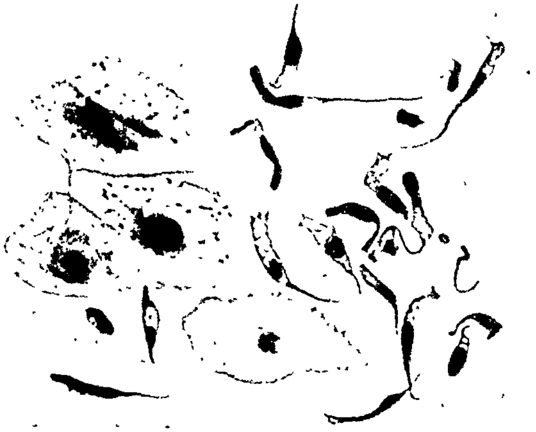
A patient with recurrent parotitis.

Between the attacks many patients are entirely free from symptoms; others complain of constant dull pain in the parotid region, whilst a few have persistent severe pain. Though, as mentioned above, an acute attack occasionally starts during a meal, it is unusual, between attacks, for these patients to suffer inconvenience during eating. A few of them learn in time how to avoid these more acute attacks by means of massage of the parotid; and this will be discussed later. The frequency of the acute attacks varies from one a year to one about every month.

With the passage of time there is an undoubted tendency for the other salivary glands to be involved in similar processes, and though in the present series unilateral parotid involvement was the rule at onset, in 9 cases the condition became bilateral, whilst in the case starting in the submaxillary glands the parotids were also eventually involved.

The sex-distribution of the condition is interesting; if the one post-operative case in the boy of 11 is omitted as not being a true "primary" case, then the ratio of females to males is eight to one. Many of the women patients showed a remarkable facial similarity, in the rather narrow and elongated type of head, in their sallow complexions, and in their general asthenic habitus. (Fig. A.) As a group they showed considerable nervous instability; several were inclined to outbursts of tearfulness, one was contemplating suicide, and one had a very severe form of mucous colitis. When one remembers the part played by the cranial autonomic system in the physiology of salivary secretion, it seems possible that these facts have a bearing on the disease.

FIG. B



The cells found in a catheter specimen of saliva during the quiescent stage.

PHYSICAL SIGNS

It is necessary to consider the physical signs both during the quiescent periods and during the actual acute attacks. In the quiescent phase there may or there may not be visible fullness of the parotid region; this usually depends upon the duration of the disease, for the longer it has lasted the more certainly will a swelling be apparent. All cases, however, reveal on palpation some enlargement of the affected gland. In the normal parotid the exact anatomical limits of the gland are very hard to define on palpation, but in glands affected with recurrent parotitis the margins are always well-defined and rounded; the normal anatomical limits are not overstepped, but the gland consistence is firmer than usual, and there is slight diffuse tenderness. These are the characteristic physical signs, but in some cases, where the pathological process affects only one lobule of the gland, the changes may be confined to this, whilst in others of more chronic type, which have lasted many years, there may be areas in the parotid of a more local or lobular type of enlargement with variations in consistence. On the other hand, there may be diffuse enlargement of doughy consistence. Bidigitally there is at times was obtained. An attempt to type the pneumococcus by Armstrong's[6] direct method was unsuccessful, but the next morning it was reported as Type I.

On July 29th there was considerable restlessness with delirium, and enough cyanosis to justify continuous oxygen at night. On the 30th the left upper and lower lobes became involved. On the 31st he looked distinctly worse. Respirations 30–36. Pulse 110, with frequent intermissions. Breathing was embarrassed by meteorism, which was relieved by pituitrin and a turpentine enema. There was also severe pleuritic pain below the left nipple. By August 2nd (the seventh day after the rigor) the temperature had fallen to 99·6°; the respirations to 24, and the pulse-rate to 92. After steady improvement for a fortnight he began to get up, but then developed a dry pleurisy first at the right and then at the left base without any serious rise in temperature, and with a leucocyte count of only 9000. The pleurisy took some weeks to clear, but the case gave us no further anxiety.

Here were some of the difficulties. Should I regard the day on which the typing was complete as the third or the sixth day of infection? Accepting it as the third day, should I be influenced by the patient's age and the knowledge that he had a Type I. infection and give him serum? Or knowing him to be abstemious and of sound constitution, and comforted by the good leucocytosis, should I rely on the old expectant measures? I chose the latter course, not without heart searchings, but in the event justifiably. In two other cases which ended fatally I have criticised myself afterwards for witholding serum, although at the time I had reasons for my conservatism.

Conclusions

It remains to attempt advice in practical form. At present no unalterable rules can be laid down with regard to the indications for serum in lobar pneumonia. As in all therapeutic decisions the final plan must be based upon the particular state and requirements of the individual patient. The method is clearly, and (unless it can be simplified) must remain, more suited to hospital than home conditions. It is contra-indicated in children and adolescents for the most part, since the natural recovery-rate is so high in this age-period. It may reasonably be decided to dispense with it in advanced age when interference is ill-tolerated, and the disease frequently provides a blessed escape from infirmities. I should personally hesitate to employ it in any subject with known allergic tendencies, for I am doubtful whether the ill-effects of serum shock at the beginning or of serum sickness at the end of a pneumonia would be proportionately counterbalanced by the benefits of the treatment. In previously healthy adults showing a good initial response to infection and a high leucocytosis, I should feel justified in withholding serum. We are thus left with adult cases giving cause for undue anxiety at an early stage and showing a failure of leucocytosis; alcoholics might be included in this group. To these it should be justifiable to give an early dose of Felton's serum, and to continue the treatment if the organism is found to be of appropriate type. The treatment is more worthy of consideration in Type I. than in Type II. infections. At present these restrictions would seem to me reasonable in institutions where costs must be carefully counted, and in private practice. Expense prohibits the treatment of poor patients in their homes. In such cases the difficult decision of whether or not to counsel removal to hospital must be made. If the disease has passed its third day and adequate nursing and attention can be secured, I should usually prefer to keep the patient at home and to forego the possible advantages of laboratory study and serum therapy. Removal, if necessary, should be carried out within the first 48 hours.

While the employment of serum in pneumonia on a wide scale cannot be advocated, its claims cannot be overlooked. It is furthermore possible that a collective investigation of prognosis and a more critical search for special indications may serve to lighten the physician's burden of decision, to simplify his task, and to reduce a little further the comparatively low death-rate from pneumococcus Types I. and II. which obtains in this country among previously healthy persons. Of our 15–20 per cent. of deaths, be it remembered, a certain proportion occur among "bad lives" which are unlikely to be reclaimed by any treatment. Others again are due to infective strains against which we have as yet no potent serum. With a suitable card system observers in general practice might, I believe, greatly assist a collective inquiry into the matter of prognosis. It is to be hoped that hospital and laboratory workers will continue their studies of method and indications, and that the firms responsible for the supply of serum will find it possible to reduce the costs.

RECURRENT PYOGENIC PAROTITIS

ITS PATHOLOGY, DIAGNOSIS, AND TREATMENT

BY REGINALD T. PAYNE, M.S. LOND., F.R.C.S. ENG.
CURATOR OF THE MUSEUM, ST. BARTHOLOMEW'S HOSPITAL, LONDON

(WITH ILLUSTRATIVE PLATE)

DURING the past five years, in the course of investigating some 250 patients with diseases of the salivary glands, 19 cases of recurrent pyogenic parotitis have been under my care. They present many features in common, and the condition seems to be a fairly well-defined clinical entity. Formerly the more obscure inflammatory lesions of the salivary glands were ignored by physicians and surgeons alike, and their treatment has too often been only symptomatic. With recent methods of investigation much new information has been brought to bear on the pathology of recurrent parotitis, and treatment can now more often be carried out on a rational basis.

Recurrent pyogenic parotitis is characterised by recurrent swellings of one or both parotids, and even at times in the more chronic cases involving the other salivary glands. The saliva from the affected glands shows characteristic changes and sialograms show certain well-defined lesions. The name is admittedly inexact, but it does emphasise the recurrent nature of the inflammatory swelling. Considered more from the pathological standpoint the condition should be regarded as a mild chronic sialodochitis, with recurrent exacerbations which lead to attacks of acute parotitis. Typically these attacks are mild, but occasionally they may become really acute, though rarely going on to suppuration; whilst, on the other hand, in a few cases the condition appears to be more chronic from the outset. Though these are usually referred to as cases of recurrent parotitis the word "pyogenic" has been added for the sake of greater accuracy, since a clinical condition almost demonstration of the ducts of the parotid with injection of lipiodol, has proved invaluable in determining the underlying pathological lesions. The technique of sialography has been described elsewhere.[1] It is simple and entirely free from risk if carried out during the quiescent phase, and in none of the cases investigated did it have any untoward effects. A normal sialogram is shown in Fig. I (on Plate).

The pathological conditions as revealed by sialography fall in the main into one of the four following types.—

(a) *Globular.*—Certain of the cases show minute spherical dilatations at the tips of the finest ducts—that is to say, in the region of the glandular acini (Fig. II., on Plate.) These dilatations are spherical in shape, variable in size, and rarely exceed 2 mm. in diameter. This process, which I have referred to as "bronchiectasis" of the parotid, may affect the whole of the organ, or only one or more of the gland lobules. Its degree may vary on the two sides and in different cases. At the same time it should be noted that in the type of case showing these pathological changes there is little or no abnormality to be made out in the configuration of the larger ducts of the gland.

(b) *Fusiform.*—In these cases the main brunt of the lesion has fallen upon the larger and the medium-sized ducts. These ducts lose their regularity and show along their course fusiform dilatations (Fig. III., on Plate.) In an early stage these may be comparatively small and rather irregular, whilst in an advanced condition each dilatation may be about half an inch long and a quarter of an inch wide, and more regular. This condition is never seen in the ducts towards the periphery of the gland.

(c) *Segmental.*—This condition is closely allied to the preceding, and it also affects the medium or larger ducts. These ducts, whilst preserving their general course, show a rather regular series of segmental dilatations, superimposed upon which is often some degree of tortuosity, the whole suggesting an effort to overcome obstruction. (Fig. IV., on Plate.) Again this lesion may affect one part only of the duct system.

(d) *Destructive.*—A fourth type of change may at times be made out in those cases where the recurrent exacerbations have been comparatively severe, and have gone on to gross suppuration inside the parotid capsule, with destruction of glandular tissue and ducts, followed by fibrosis and scarring. (Fig. V., on Plate.) In these cases the normal regular branching tree of the parotid duct system disappears and is represented by a small number of rather irregular ramifications of the finer ducts. Associated with this there may be some dilatations of the ducts and acini, usually of somewhat irregular type.

The explanation of the above variations in the radiographic picture is, apart from the destructive type, somewhat obscure. Why in one case of recurrent parotitis the brunt of the lesion should fall on the finest ducts, and in others upon the larger ducts, with the production of fusiform or segmental dilatations, is at present unknown.

As regards the submaxillary salivary gland, the only pathological condition met with in this series has been extreme dilatation of the larger ducts (Figs. VI. and VII., on Plate), nothing at all comparable to the changes seen in the parotid has been found.

ÆTIOLOGY AND PATHOLOGY

In some of the cases under consideration the commencement of the parotitis dates from an acute dental infection, a severe tonsillitis, or a sinus infection. At times the commencement of the use of dentures or neglect to keep these adequately cleaned has been responsible. The case following acute suppurative parotitis which had been drained externally has been referred to. Compared with the submaxillary salivary gland, the parotid is much more prone to acute pyogenic infections, the former being affected usually only in association with the presence of calculi. This peculiarity has led to a considerable amount of experimental work and the formulation of various hypotheses. It is certain that practically all forms of acute and subacute pyogenic parotitis are ascending infections and that blood-borne infections are almost curiosities. It is furthermore certain that in the post-operative buccal conditions which predispose to ascending infection of the parotid there is a marked exaltation of the number of micro-organisms in the region of the orifice of the parotid ducts as compared with the number in the region of the orifices of the submaxillary ducts in the floor of the mouth. The work in this connexion has been carried out by Prof. Seifert.[2] The explanation is said to be that the secretion of the submaxillary gland is particularly rich in mucus, whilst parotid secretion is almost free from it, and, as is known, mucus has a strong bactericidal action. Once catarrh of the parotid duct has occurred there is a tendency for it to persist and to give rise from time to time to attacks of subacute parotitis. The mucus secreted is in excess of the normal; duct cells are proliferated and eventually shed; and the combination gives rise to the plugs of muco-pus which cause duct obstruction with retention of secretion. Once this has happened bacterial infection can ascend through the stagnating saliva and produce the various stages of parotitis, unless the obstruction is relieved. Furthermore, on account of the extremely delicate nature of the ducts of the parotid the condition, once established, tends to pass into a vicious circle. Duct dilatation in varying degree results from the recurrent attacks of infection and duct obstruction.

The nature of the micro-organisms has already been referred to. If in these cases there is any gross cause of sepsis in the mouth there will be increased numbers of micro-organisms there to cause further ascending infection.

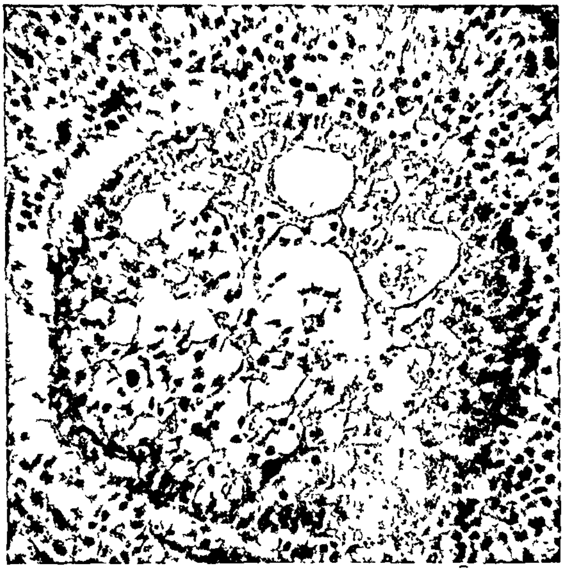
As regards the histology of the condition, very little in the way of accurate observation has ever been carried out. Only in one case of the series was there any justification for carrying out a biopsy. This was a case early in the series, with a typical history, but the physical signs suggested that there might possibly be malignant disease of the parotid. The section showed a parotid duct in which marked proliferation of the epithelial lining had occurred, partially obliterating the lumen of the duct (Fig. C.) Outside the duct there was an extensive round-cell infiltration. In view of the large numbers of epithelial cells which are constantly found in the saliva of these patients, it is almost certain that a great deal of proliferation of the lining membrane is going on.

INVESTIGATION AND DIFFERENTIAL DIAGNOSIS

The accurate diagnosis of recurrent pyogenic parotitis depends upon a careful history and a thorough examination of all the salivary glands, their ducts, and their orifices. A catheter specimen of saliva should be collected from the affected gland (it is not always possible to do this in the case of the submaxillary glands), and this should be examined for its cytology, bacteriology, and ptyalin content. Sialograms of the affected region should then be palpable thickening to be made out in the line of the parotid duct, whilst the orifice of the latter is usually normal. The changes found in the saliva are referred to later.

The actual exacerbations of the disease are in the first place due to some degree of blockage of the main duct, or of one or more of its larger branches, and upon the extent and nature of this the physical signs will depend. At first the condition is one of retention of parotid secretion behind a blocked duct, usually the main one, which may be complete or incomplete; consequently the gland swells, and there is associated pain and tenderness. Depending upon the degree of obstruction of the duct and the degree of associated infection, there will be a tendency for the infection to spread upwards into the smaller ducts and into the glandular acini. Clinically this spread is associated with mild fever, moderate constitutional disturbance, and considerable pain, swelling, and tenderness of the whole gland—a condition of acute pyogenic parotitis in which the suppurative process is confined to the lumen of the ducts and acini. In the present series of cases only one went on to gross suppuration, which first formed a confluent parotid abscess and eventually burst through the overlying parotid fascia; but in many of the cases extensive suppurative lesions drained adequately via the duct into the mouth. Two patients showed marked œdema over the parotid region and outer part of the orbit, but this resolved without external suppuration. In such cases as these the swelling of the gland may overstep the normal anatomical limits. During the more acute attacks the orifice of the parotid duct in the mouth may appear reddened and œdematous, and it may be impossible to express any secretion without prolonged massage of the gland.

FIG. C



Section of a duct of the parotid showing proliferative changes and surrounding round-cell infiltration.

THE SALIVA

To make out the characteristic changes in the saliva of recurrent parotitis, it is essential, of course, that it should be obtained by means of a cannula direct from the parotid duct, and this is usually easy. Personally I always use a simple glass cannula, the point of which is drawn out to a width of 1 mm., with a fountain-pen bulb attached, similar to the one used for sialography. With this it is easy to collect saliva and to see at once its gross appearance.

Appearance.—In the more chronic cases the appearance is highly characteristic. Saliva from a healthy parotid duct is clear, and microscopically is free both from epithelial and pus cells. Saliva from patients with recurrent parotitis is faintly, or even markedly, turbid, and suspended in it are numerous flakes of somewhat spherical shape, the larger ones being 1 mm. or so in diameter. These are plugs of mucus and cells, and in reality represent rolled-up casts of the ducts of the parotid. The number and the size of these vary from case to case and in the same person during different phases of the disease. On the other hand, the relatively milder cases may show nothing more than the diffuse turbidity of the saliva.

Cells.—When the saliva so obtained is examined by means of a Gram film the plugs are found to consist of shreds of mucus in which are embedded masses of cells. These cells are of two kinds, pus cells and epithelial cells. In the more acute conditions the former are more in evidence, whereas in the more chronic cases the epithelial cells predominate. Of the epithelial cells a large variety of shapes are found, some being tall and columnar with basal nuclei, others flask-shaped or truncated, and many large and rounded with small central nuclei. (Fig. B.) This variety is accounted for by the fact that in a well-established case of recurrent parotitis there are almost certainly proliferative changes in the walls of the ducts, and the resulting epithelial cells tend to become rather irregular. At times large areas of epithelial cells are present forming a definite membrane or representing casts of the smaller or larger parotid ducts. In the more fluid part of the saliva similar types of cells may be found in smaller numbers.

Micro-organisms are not as a rule seen in large numbers in the Gram film during the quiescent stage, but some of the larger ovoid epithelial cells are always closely packed with ingested bacteria. Cultures made during this stage usually yield salivary streptococci, *Staphylococcus aureus*, or diphtheroids. Often more than one organism is present, but in one case in the present series a profuse growth of pure pneumococci was obtained. The exact nature of the micro-organism does not appear in practice to make a large difference to the resulting clinical or pathological picture.

Mucus.—Parotid secretion from a healthy gland contains only the merest trace of mucus. This is derived from small glands situated in the walls of the larger ducts and does not originate from the gland substance proper, the cells of which are entirely serous. In pathological conditions where there is catarrh of the ducts the amount of mucus secreted is largely in excess of the normal. The question as to how far this is a protective measure is referred to again later.

Ptyalin.—During health the normal ptyalin content of parotid saliva has been shown in a series of cases to vary between 500 and 5000, or even 10,000 units. In four cases of recurrent parotitis where this investigation was carried out the figures obtained were between 100 and 250 units, which suggests that as a result of the infective and obstructive processes the functional activity of the gland was seriously depressed.

SIALOGRAPHY

The investigation of these cases of recurrent parotitis by sialography, or the radiographic

taken, which in the case of the submaxillary should include both intra- and extra-oral films, to exclude—though not necessarily absolutely—the presence of a calculus; and finally sialography should be performed when practicable to determine the site and severity of the pathological lesions of the ducts, and to serve as a guide to treatment. In all cases a complete blood count and a Wassermann reaction should be carried out. The following are the more *important conditions which have to be differentiated* from recurrent parotitis.

(a) *Mumps.*—Many of the patients in the present series had, in their initial attacks, and even in two or three of their subsequent attacks, been diagnosed as suffering from mumps. In this connexion certain points should be borne in mind. Firstly, a diagnosis of mumps in an adult should not be made too readily without a history of contact. Secondly, in a doubtful case of mumps a catheter specimen of parotid saliva will not show the catarrhal changes of recurrent parotitis, though it may show a few cells. Finally, for practical purposes recurrent attacks of mumps are unknown, and this diagnosis should never be made without excluding the possibility of recurrent parotitis.

(b) *Stone.*—A typical case of parotid duct calculus gives a characteristic history of a meal-time swelling with subsidence of the swelling, or almost complete subsidence, between meals—a state of affairs which is never seen in recurrent parotitis. When, however, infection is superimposed upon a small calculus, then the clinical picture may approximate to that of recurrent parotitis. In all cases, therefore, skiagrams are essential to exclude calculus, and in addition sialograms in the latter may localise a doubtful duct obstruction.

(c) *Mikulicz's Disease.*—When more than one salivary gland is involved in the process the question of true Mikulicz's disease may be raised. By this is meant a familial or acquired disease affecting one or more of the salivary glands, usually all of them more or less symmetrically, together with the lacrymal glands, in which pyogenic infection, calculi, uveo-parotitic polyneuritis, thyroid disease, blood diseases, lymphosarcoma, lead or other poisonings, syphilis, tubercle, and lymphadenoma have been excluded. In true Mikulicz's disease the saliva contains no evidence of any duct catarrh, and the sialograms are normal. At the present time I have under my care a patient who gives a history which would do for that of a recurrent pyogenic parotitis affecting both parotids and submaxillary salivary glands, but in whom there is no evidence that the condition is of bacterial origin. There is no sign of duct catarrh, the sialograms are normal, and the diseases enumerated have been excluded.

(d) *Uveo-parotitic Polyneuritis.*—This rather rare condition is associated with peripheral neuritis, inflammation of the uveal tract, and parotitis. As, however, the parotitis may sometimes, though not usually, be the initial manifestation, and one parotid may be affected after the other, with a tendency at times to recrudescence, the condition must not be forgotten.

(e) *Pre-auricular Lymphadenitis.*—A clinical condition which may occasionally cause some confusion is a recurrent form of lymphadenitis in the pre-auricular lymph glands. This confusion is the more possible because these lymph glands may be partly superficial to and partly deep to the capsule of the parotid gland. The inflammation is usually a chronic pyogenic one, in which case some cause is likely to be found within the drainage area of the glands; or occasionally the condition may be a tuberculous adenitis. In two cases of the present series recurrent bilateral pyogenic parotitis existed side by side with chronic pre-auricular lymphadenitis, for which there was an obvious cause.

(f) *Mixed Parotid Tumour.*—When recurrent parotitis affects only one lobule of the gland the physical signs may simulate a mixed tumour, but the other *investigations should lead to an accurate diagnosis.*

(g) *Malignant Disease of the Parotid.*—In the very chronic form of recurrent parotitis which has lasted many years, particularly if there has been a considerable amount of "destructive" suppuration, the physical signs may closely simulate malignant disease. Again the accurate diagnosis may rest with the special methods described.

LEGENDS TO ILLUSTRATIVE PLATE

FIG. I.—Normal sialogram of right parotid gland.

FIG. II.—Sialogram of right parotid showing globular type of dilatation. Some lipiodol remaining in the left parotid gland is also seen in the anterior part of the picture.

FIG. III.—Sialogram of left parotid showing fusiform type of dilatation.

FIG. IV.—Sialogram of the left parotid gland showing a segmental type of dilatation of the main duct and a similar change in the ducts corresponding to the socia parotidis.

FIG. V.—Sialogram of right parotid showing destructive type of lesion.

FIG. VI.—Normal sialogram of right submaxillary gland.

FIG. VII.—Left submaxillary sialogram from a patient with recurrent infection of the parotid and submaxillary glands.

TREATMENT DURING THE QUIESCENT STAGE

If it is borne in mind that recurrent parotitis is due to recurrent obstruction of some part or parts of the duct system, associated with mild pyogenic infection, it will be at once seen that the first principle of treatment is to keep the ducts of the parotid patent, and to keep the region of the duct orifice in the mouth as free from infection as possible. Infection leads to epithelial desquamation in the ducts, together with a marked increase in the mucus content of the saliva, and this combination leads to the production of plugs of muco-pus which cause obstruction and retention of secretion, and pave the way for ascending infection. During the quiescent stage treatment must be directed to the avoidance of a fresh entry on the vicious circle. The following are the more important lines of treatment.

Infections.—Any obvious cause of sepsis in the mouth, particularly in the region of the affected parotid duct, should certainly be dealt with. Especially is this true of infected teeth. At the same time a scrupulous hygiene of the teeth and mouth should be insisted upon. In some cases I have seen the condition has certainly been aggravated by the dirty state of the patient's dentures, and if these are ill-fitting they may sometimes press on the buccal part of the duct.

Massage of the parotid is by far the most important single item in the line of treatment. If duct obstruction can be avoided, then one can certainly say that the development of recurrent attacks of parotitis will also be avoided. In this connexion I have shown by means of lipiodol injections of grossly diseased parotids that it is possible to empty the main duct

and its branches after even a few seconds' massage of the gland. Patients, therefore, should be instructed to carry out prophylactic massage of the parotid. This massage should always be directed from behind forwards towards the angle of the mouth starting from three points—the tragus, the lobule of the ear, and just behind the angle of the jaw. It is most efficiently carried out by the thumb, and it should be demonstrated to the patient with instructions to carry it out for at least five minutes night and morning.

Diet.—In addition to the above, many patients are helped by making them start the day by taking the juice of half a lemon in a little water in order to cause an intense flow of saliva after the possible stagnation during the night. This should be done immediately after massage. At this point I may mention that some patients wake up in the morning with the parotid swollen on the side on which they have slept. Whilst the diet does not usually need alteration it should be impressed upon the patient that since thoroughly efficient mastication is the greatest single factor in the production of the normal flow of saliva, they should take their food rather dry and chew it very thoroughly.

DR. GRAVESEN: LEGENDS TO ILLUSTRATIONS ON PLATE

FIG. I.—Female, aged 20. Treated with right-side artificial pneumothorax for four years. Readmitted with a cavity in left apex near mediastinum. Tubercle bacilli present.

FIG. II.—Same case after induction of bilateral artificial pneumothorax. The apex cavity of the left lung is seen hanging in a stretched adhesion, hindering the collapse of the upper lobe.

FIG. III.—Same case immediately after cauterisation of the adhesion. The cavity has dropped into the middle of the artificial pneumothorax.

FIG. IV.—Same case three months after the cauterisation. The left-side artificial pneumothorax has changed into a selective one like that on the right side. No bacilli found.

FIG. V.—Female, aged 27 (the case mentioned at the end of the paper) with bilateral apical cavernous affection.

FIG. VI.—Same case after left-side apical thoracoplasty. (Carried out in January, 1931.)

FIG. VII.—Same case after bilateral apical thoracoplasty. (Operation on right side April, 1931.)

Operations.—Operation is but rarely necessary in the treatment of recurrent parotitis, but it may be indicated where the condition is severe or where it has failed to respond to other treatment carried out efficiently. It may consist in: (1) dilatation of the parotid duct; (2) slitting the orifice of the parotid duct, followed by dilatation; or (3) avulsion of the auriculo-temporal nerve. Dilatation of the parotid duct alone is not often of much value, since the orifice usually contracts quite rapidly after cessation of the dilatation. Slitting the orifice of the duct into the buccal portion can be carried out under local anæsthesia, and when it is followed by regular dilatation until healing is well established a wide patulous opening persists. Avulsion of the auriculo-temporal nerve is not as a rule either serious or difficult. It leads, of course, to paralysis of parotid secretion through destruction of the nerve-supply. Its use should be reserved for the more intractable cases.

Radiotherapy.—In the present series of cases X rays have been used on only two patients. One of these had been subjected to a prolonged course of treatment before I saw her, but without any obvious benefit. In the other case X rays were given with a temporary good result; but in neither were the previous observations sufficiently accurate to warrant deductions. It is further a moot point whether in these cases X rays do good by clearing up the infection and catarrh or by leading to atrophic changes in the glands. I am at present investigating the effect of small doses of X rays in a series of patients with proved recurrent parotitis. Sialograms have been taken, and the saliva has been examined for cells and organisms, and for its ptyalin content. After treatment is completed these investigations will be repeated and considered in relation to the clinical picture.

TREATMENT DURING EXACERBATIONS

During the actual exacerbation of the disease there is always either complete or partial obstruction of some portion of the duct system, often the main duct. Immediate treatment thus consists in the relief of obstruction, and is identical with that which should be undertaken from the outset in any case of acute pyogenic parotitis, whether recurrent or not.

The surgeon should first of all satisfy himself that the main duct is patent, as shown by the efflux of pus or muco-pus on massage of the parotid, and as much as possible should be expressed at once from the gland and ducts by this means. The patient should then be instructed to repeat the massage before and after each meal, and first thing in the morning and last thing at night. The diet again should be as solid as possible. Frequent hot mouth washes will help to keep the mouth clean and soften secretion in the duct. For the pain, the face should be bandaged over wool, and a rubber hot-water bottle applied, which will also tend to hasten resolution. It is far better in these cases to avoid all forms of external moist heat, which will only tend to make the skin sodden, and perhaps accentuate any tendency to external rupture.

With the above measures it is in general possible to tide a patient over the acute exacerbation, and when treatment is undertaken energetically the condition usually begins to subside after 36 or 48 hours, the saliva gradually becoming clearer and less purulent. If, on the other hand, it is impossible to get the duct working by massage when the case is first seen, or at any rate after the first 24 hours, further measures are essential if gross suppuration is to be avoided. In these cases it is sometimes possible by probing the duct, or by aspirating it with a cannula, to dislodge some of the muco-purulent plugs. At the same time in the more severe cases the duct orifice may be slit up for about three-quarters of an inch. The treatment of gross suppurative parotitis which demands external operative measures falls outside the scope of this paper.

AIR PAGEANTS FOR HOSPITALS.—It is proposed that between April and October next British Hospitals Air Pageants should give 200 displays in various parts of Great Britain to raise money for local hospitals. The demonstrations will be led by Mr. C. W. A. Scott, who made the record flight from England to Australia. The proposal has the support of the British Hospitals Association.

SELECTIVE LUNG COLLAPSE IN BILATERAL DISEASE *

BY J. GRAVESEN, M.D.
MEDICAL SUPERINTENDENT OF VEJLEFJORD SANATORIUM, DENMARK

(WITH ILLUSTRATIONS ON PLATE)

DURING recent years attention has been drawn more and more to the problem of selectivity in the use of collapse therapy. This therapy is increasingly accepted as the treatment "par excellence" for pulmonary cavities. Its object is now to establish sufficiently effective conditions for closing cavities and at the same time to secure the least possible interference with the function of the lung as a whole. It is on these lines that the idea of selectivity in collapse therapy is to be understood and carried out.

The adoption of this new principle considerably increases the scope of collapse therapy. It is true that it involves a more exacting demand for individual treatment. Both in artificial pneumothorax and in operative treatment it abolishes routine and uniformity of technique. To use lung collapse in accordance with the demands of selectivity it is necessary to work out a new plan for each individual case, and to carry out this plan in close reference to the particular conditions. Thus, this new idea can only be materialised at the cost of more intensive work and more exact touch with individual conditions. On the other hand, its advantages can be so great as fully to repay the greater trouble.

These advantages are a considerably reduced risk and a more assured result than when collapse therapy is used as a mere matter of routine. The possibility of saving as much as possible of the pulmonary function justifies an early application of the treatment in those cases of limited cavernous affections in which the surgeon is most apt to postpone intervention until he sees whether spontaneous healing or progressive destruction will take place. In such cases time is often wasted, and when at last the collapse is applied more radical measures are found to be necessary. An early use of selective collapse may often mean a short cut in the treatment. In more advanced affections, where the indication is beyond all doubt, there is no less advantage in saving as much pulmonary tissue as possible fit for function.

Even in unilateral cases the idea of selectivity is therefore of great value, but one of its special advantages is the possibility of extending the methods of collapse to cover not only unilateral—or chiefly unilateral—cases, but also cases where bilateral cavernous affection is present.

THE METHODS OF OBTAINING SELECTIVE COLLAPSE

In this connexion, as in many others, the example to follow is given us by Nature. The spontaneous healing of a limited affection often takes place through a retraction which causes the slightest possible damage to the rest of the lung tissue. We can observe how the affected part of an upper lobe gradually withdraws itself, the lobe being folded together like a fan towards the upper part of the mediastinum. When a lung under artificial pneumothorax treatment re-expands, the healthy parts fill up the pleural cavity while the affected part is kept behind by the retractive process of the tissue. This means that the selective effect of an artificial pneumothorax is provided by the natural tendency of retraction within the lung tissue itself. A selective pneumothorax is one that is kept refilled only as much as is sufficient to keep the affected part collapsed while the rest of the lung is more or less expanded.

In the earlier stages this principle demands smaller refills at shorter intervals than in ordinary artificial pneumothorax work. Also, more frequent revision by screening is needed in order to keep the lung in an ideal stage of selective collapse. Later on, when the pleura has become stiffer and the healthy parts of the lung adhere to the chest wall in an expanded condition, the continuation of the selective artificial pneumothorax will, as a rule, be as easy to maintain as a complete one, the refills being done at longer and longer intervals. In this way it is often possible to continue an artificial pneumothorax for several years on a gradually decreasing scale, the refills becoming smaller and less frequent, until at last the treatment is discontinued, provided that the cavity has not reopened under the slow gradual re-expansion.

ADHESIONS

The presupposition for such ideal management is, however, that there are no adhesions. Adhesions, as a rule, counteract the selectivity of an artificial pneumothorax. That does not mean that the effectivity is always hindered; by positive pressure the collapse of cavities may be obtained in spite of adhesions. But the adhesions are apt to make the artificial pneumothorax contra-selective. They compel us to collapse the healthy parts of the lungs much more than the size and localisation of the cavities indicate. The adoption of selectivity therefore means a greater use of intervention against adhesions. Where these are accessible, cauterisation has a larger field of indication. Nowadays adhesions are cauterised, not only when they cause the persistence of sputum and bacilli, but often merely because they prevent the selectivity of the artificial pneumothorax. When it is probable that a cauterisation will enable the healthier parts of the lung to attain a better function and will secure more ideal conditions for a gradual re-expansion of the affected parts, cauterisation is indicated even if the artificial pneumothorax has been clinically successful. Not only is the same result sometimes attained by less reduction of pulmonary function, but also the later re-expansion of the lung may be safer than if a stretch of adhesion has been allowed to counteract the selectivity of the collapse.

Broader surface adhesions still more greatly prejudice both efficiency and selectivity. It is common for an artificial pneumothorax to bring about complete collapse of a healthy lower lobe, while the affected upper lobe is kept more or less expanded by adhesion to the dome of the pleura. We often doubt whether it is of any use at all to maintain this condition. Now and then a good clinical result is obtained, but often at the expense of severe encroachment upon the respiratory functions. Here the principle of selectivity makes us proceed earlier than formerly to a replacement of the contra-selective artificial pneumothorax by a local operation, an apical thoracoplasty, or an apicolysis, after which the lower lobe is allowed to re-expand for continued function. In the less frequent case of an affected and adherent lower lobe and a partial artificial pneumothorax upwards, the artificial pneumothorax may be wholly or partly replaced by a phrenicectomy, after which the healthy upper lobe may be left for re-expansion.

In cases of more or less general adhesion, making artificial pneumothorax impracticable, the selectivity

---

* Paper read before the Tuberculosis Association in 1932.

of collapse is carried out by a keen individualisation of operative technique. The total thoracoplasty which is still adhered to by many schools as a matter of routine ought nowadays to be reserved for total destructive affection of a lung and for total empyema. In more limited cavernous affections it should be our aim to change the shape of the lung—and the thorax—to an extent that corresponds as closely as possible to the extension of the disease, and no more. Why should the whole of a lung be permanently excluded from function for the sake of a quite limited cavernous process of the apex? But there is still much opposition in certain quarters to partial thoracoplasties. The old ideas about the risks involved have handicapped development. The risks are there, but they can be neutralised by proper technical improvements. The risk of aspiration can be checked by a technique of anæsthesia and after-treatment which effectively counteracts any tendency to aspiration. The risk of missing the effect can be met by an operative technique which is built upon a thorough experience of the parts of the chest wall which it is most important to attack.

In such thoracoplasty it is necessary to work out the plan of operation which is best suited to the individual case. Most frequently the affection is apical, and special methods have been worked out to deal with these. Coffy has published his method of resecting the upper two or three ribs through an incision in the lateral region of the neck. Von Graf has suggested a more convenient and more adaptable way of attacking the upper ribs from behind. The different methods of apicolysis, plugging, and phrenicectomy have attained a wider scope in providing an operative collapse on strongly selective lines. This is not the moment for a discussion of the relative merits of these various methods—indeed, no general rules can be laid down in the matter of choice. We have to choose in each individual case the method, or constellation of different methods, which is most likely to produce the conditions required by the cavity or cavities present.

In one particular respect selectivity in thoracoplasty work has meant an appreciable advantage in technique. Partial operations can practically always be carried out in one stage. Since the introduction of selective thoracoplasty the necessity of two-stage operations has been reduced to a minimum, which, of course, goes far to reconcile patients to the operation.

THE USE OF BILATERAL COLLAPSE

Obviously, when collapse is indicated on parts of both lungs, it should be applied on selective lines. We must realise, however, that these cases have a particularly gloomy outlook. The presence of tuberculous cavities in one lung renders the prognosis serious enough; when both lungs contain cavities the way is, as a rule, barred for any kind of conservative treatment, even if the affections remain temporarily quiescent. Any result, even a relative one, that can be obtained by active intervention must therefore be welcomed as pure gain, and results have already been observed which justify the occasional adoption of bilateral intervention in cases where unilateral collapse has hitherto been contra-indicated.

Bilateral artificial pneumothorax has been in vogue for several years. Contributions to the subject fill the columns of most tuberculosis periodicals. It can be said to have passed its experimental stage and is now enrolled among the effective—or at least relatively effective—measures against bilateral tuberculosis.

Alternating artificial pneumothorax was tried for many years. Saugman was one of the first to make the attempt, as early as 1908. During several years he treated a series of cases alternatively on the two sides. His results were very discouraging; they were permanent in only 1 case out of 11. Other workers have had similar experience. Better results were only obtained when the bold step was taken of establishing the bilateral artificial pneumothorax simultaneously. The reasons for the improvement can now be seen. In the alternating method the more advanced lung was taken under treatment first, and during this treatment the other lung got worse. This often caused a discontinuance of the first artificial pneumothorax too early, and at the same time it provided a less satisfactory prospect for the second. By simultaneous application we can now, to a certain extent, avoid this twofold embarrassment; each lung can be treated at the time when indication is present, and the treatment can be continued for the length of time suitable for each. So far, the indications and technique of bilateral and unilateral artificial pneumothorax are not very different. The problem is just how to manage each of the bilateral collapses as if it were a unilateral one, and this problem is solved when the principle of selectivity can be made effective on both sides.

Special attention must be paid to a scrupulous technique in induction and refills. Any lung lesion produced by the needle may be twice as dangerous as a similar one in unilateral collapse. A tension-pneumothorax is a serious complication which in unilateral cases may be fairly easily managed, but in bilateral cases it is extremely dangerous. It has happened once at Vejlefjord Sanatorium, and the patient nearly died, but we succeeded in saving her with a good result. This experience made us abolish needles with side-opening for the refills in bilateral cases. The point of this needle will always go a little deeper than its opening, and an artificial lesion of the lung is therefore more likely to take place than when an ordinary needle, open at the end, is used.

Cauterisation is practicable even when bilateral artificial pneumothorax is established. It is only necessary to prepare for the operation by temporarily enlarging the artificial pneumothorax in which a stretch of adhesion is present, and correspondingly diminishing the other one. After the operation the refills are so continued as to re-establish a more just apportionment of the collapse. It has even proved possible to cauterise on both sides at different phases of the treatment.

COMBINATIONS OF METHODS

A more complicated state of affairs arises when artificial pneumothorax cannot be selectively managed on either one or both sides. We are further handicapped by the fact that the more affected lung is generally also found to be the more adherent. And yet, if a fairly good general condition is preserved and other circumstances encourage us to do something active instead of leaving the patient to his more than doubtful fate, a combination of operative treatment on one side and artificial pneumothorax on the other, or of bilateral operative measures, presents itself for consideration. Again, no general rules can be given for such combination. There are many different constellations for obtaining selective collapse by one or another operation on one side, selective artificial pneumothorax on the other, or by bilateral selective operations. But in this respect, as in all medical work, our aim must be *nil nocere.* It should not be forgotten that in this work we are moving on the edge of a precipice. On the other hand, the experience gained in bilateral artificial pneumothorax has proved that a comparatively large portion of the lungs can be excluded from function—temporarily and even permanently—without any immediate danger, and with less discomfort to the patient than one would suppose. We may well make use of this experience provided that we observe sufficient caution, not approaching too closely the limits which in artificial pneumothorax are found to be safe. Operative measures demand more general strength in the patient and more reserve power of function than does artificial pneumothorax, and the changes produced by operative intervention are permanent, and cannot—as can the artificial pneumothorax—be regulated to a more reduced scale.

It has proved possible to combine artificial pneumothorax on one side with phrenicectomy, plombage, or even partial thoracoplasty on the other. A bilateral phrenicectomy has been carried out with a relatively good result and without any serious disturbance of function. Other cases have been published.

BILATERAL PARTIAL THORACOPLASTY

For several years we have at Vejlefjord Sanatorium contemplated the possibility of performing partial thoracoplasty bilaterally. Theoretically this idea should be justified when limited cavernous affections are present in both apices, and general adhesion prevents artificial pneumothorax on either side.

The first case fulfilling the required conditions, a young woman, was admitted in the summer of 1930. The patient had a cavity the size of an orange in the right apex and one the size of an egg in the left apex. Artificial pneumothorax was impracticable on either side. With the intention of performing a bilateral apical thoracoplasty the right apex was operated on. This operation, however, was complicated by a severe hæmorrhage when the first rib was cut. The bleeding was successfully checked, and she survived the operation, but died four weeks later from a tuberculous pneumonia in the right lower lobe.

The next patient of this type, also a young woman, was admitted in the autumn of 1930. In the left apex there was a cavity about the size of a duck's egg, and in the right apex a cavity about the size of a plum. Artificial pneumothorax was tried on the left side, but was found impracticable. With a subsequent artificial pneumothorax of the right lung in view, a selective thoracoplasty was performed in January, 1931, on the left side, with resection of the upper six ribs. When the patient had picked up after this operation, artificial pneumothorax was tried on the right side, but here too it failed on account of synechia. Three months after the left-sided operation, in April, 1931, a thoracoplasty was performed on the right upper lobe, of the same extent but with less radical resections than on the left side. After both operations, but especially after the second, the patient showed symptoms of threatening œdema of the lung, but she got over this and has ever since made considerable progress. Whereas she had been running more or less fever for about one and a half years before the operations, the temperature has kept normal ever since. The expectoration, which had been rather copious, decreased to about 10 c.cm. a day, still, however, containing tubercle bacilli. Her mobility after the operations has been satisfactory and she has not suffered to any serious extent from dyspnœa.†

As far as can be gathered from the available literature, this is the first case of bilateral thoracoplasty yet published. It was performed exclusively on the basis of experience with other bilateral interventions, especially artificial pneumothorax. It has proved that bilateral selective thoracoplasty is possible, and that this active treatment can yield a result which, relative to the previous development and prognosis of the disease, may be considered decisive.

THE TREATMENT OF TUBERCULOUS CAVITIES OF THE LUNG

By L. S. T. Burrell, M.D. Camb., F.R.C.P. Lond.

PHYSICIAN TO THE ROYAL FREE HOSPITAL AND TO THE BROMPTON HOSPITAL FOR CONSUMPTION AND DISEASES OF THE CHEST

Tuberculosis of the lung begins as a small area of infiltration. This may heal leaving no damage or, at the most, a small scar which does not affect the health of the individual and is unsuspected, but may be found accidentally many years later at post-mortem examination. On the other hand, the infiltration may spread and lead to caseation and necrosis of the lung tissue. Even then healing may occur by the formation of fibrous tissue, but it often happens that the necrotic lung breaks into a bronchus and leaves a cavity. The walls of this cavity are composed of necrotic tissue through which other caseous masses may break, so that the cavity increases in size, and in rare cases the whole of a lobe may be converted into one large cavity. More commonly in a chronic case there are several cavities not directly connected with each other. When the caseous material has broken into a bronchus and been coughed up, the necrotic walls of the cavity may become converted into firm fibrous tissue and, if there is no spread of the disease into other parts of the lung, healing results.

It is clear, therefore, that there are three stages of tuberculosis of the lung to be considered : (1) infiltration ; (2) caseation ; and (3) excavation. This classification is the one usually adopted in arranging museum specimens, but it is not satisfactory for the clinician. A patient with a tuberculous cavity may be in the third stage of the disease, but he often has a far greater expectation of life than one with an acute tuberculous broncho-pneumonia without a cavity.

Broadly speaking, prognosis depends on the degree of activity in the lung tissue and not on the presence or absence of cavities. It is true that there are certain dangers dependent on the cavity itself. To mention two : there is the danger of a fatal hæmoptysis from an aneurysm of a vessel traversing the cavity, and there is the danger of infection and the formation of pus resulting in the daily expectoration of a large quantity of sputum. The cavity may act as a nest or incubator for tubercle bacilli and other organisms.

From the clinical point of view there are three types of cavity : (1) the recent cavity with a ragged wall of necrotic tissue ; (2) the cavity lined with a fibrotic wall, but containing pus ; and (3) the dry cavity with a firm fibrotic wall.

THE "X RAY" CAVITY

In addition there is the "X ray" cavity, which I will consider separately as there is some doubt whether it is a cavity or not. By "X ray" cavity I mean the annular shadow which is often disclosed by radiological examination of a patient who has no other sign or symptom of a cavity. Some of these annular shadows are without doubt true cavities, for they have been confirmed by post-mortem examination. They are not seen except in tuberculous cases. Moreover, it is not uncommon to see in the ring a fluid level which changes with position.

It has been remarked, however, that these annular shadows are always circular or oval, whereas a cavity is often irregular in shape. There is no history of sputum, temperature, or other evidence of necrosis of lung; there are no physical signs of cavity; if lipiodol is injected into the trachea it does not enter the ring: the shadows are apt to disappear.

---

† During the past year she has made constant progress, and tubercle bacilli are now absent from the sputum.

In one of my patients there were signs of infiltration in one lung, tubercle bacilli were in the sputum, and radioscopy showed a large annular shadow. I collapsed the lung by pneumothorax, but the patient developed acute bronchitis, and after the second refill I let the lung re-expand. A fortnight later, when the patient had recovered from the bronchitis, radiological examination showed that the lung had re-expanded and there was no annular shadow. It is difficult to believe that a genuine cavity could have been closed after two pneumothorax refills.

For these reasons it has been suggested that these annular shadows are not true cavities but local pneumothoraces, patches of pleurisy called pleural rings or bubbles of air in the lung tissue. When pneumothorax occurs in the apparently healthy it is usually due to rupture of a localised emphysematous bulla, and it is probable that these bullæ or air bubbles are more common than is generally believed. They are formed in the alveoli, which are stretched by air under pressure, thus causing a circular bubble of varying size. A valvular obstruction in a bronchus would allow air to enter but not to leave the bulla. Thus quite a large cyst might form, but it would disappear suddenly like a pricked bubble if the obstruction were removed and the air allowed to escape. It would also disappear by absorption of air if the valvular opening into the cyst become obstructed so that no more air could enter. Andrew Morland has emphasised[1] the importance of valvular obstruction which allows weakened alveoli to become pumped up and produce a cavity. There can be little doubt that these annular shadows indicate true tuberculous cavities or air cysts produced by a valvular opening into the air cells. They are certainly not due to pleurisy and adherence producing a pleural ring, nor are they local pneumothoraces.

It has been found at Brompton Hospital that when an annular shadow has been shown by radioscopy before death, a cavity in the corresponding position in the lung has invariably been found at post-mortem examination, though sometimes a cavity found post mortem has not been previously disclosed by radiological investigation. Air cysts are not found in the post-mortem room, although in the very few cases recorded of death after spontaneous pneumothorax in the apparently healthy a ruptured air vesicle has been found to be the cause.

It seems to me that when a definite annular shadow is shown in the lung by X rays there is probably a cavity, but that if on subsequent radioscopic examination that shadow is not to be seen, it does not follow that the cavity has closed. A small amount of secretion in the cavity or temporary congestion of its walls may make considerable difference to the radiological appearance. J. Sowerbutts has described[2] the course of a case showing an annular shadow and has discussed the probable causes of these shadows.

Although I believe that in most cases these "X ray" cavities are genuine tuberculous ones, I think they should be considered apart from the other three types of cavity. They do not produce symptoms and are consistent with a long life. It seems to me quite wrong to alter treatment because such a shadow appears on radiological examination. The presence of an annular shadow is not an indication for artificial pneumothorax or any other special form of treatment. I have already stated that these shadows are only found in tuberculous cases, and of course the tuberculous condition will require treatment apart from the "X ray" cavity.

DRY CAVITY WITH FIRM FIBROTIC WALL

It also seems to me to be bad practice to institute special treatment for the dry cavity with a firm fibrotic wall. In this case the presence of the cavity can be discovered by physical signs and confirmed by radiological examination after introducing lipiodol. Treatment intended to collapse the cavity usually fails, and often does harm, so is best avoided if the general condition of the patient is good and there is little or no sputum.

I know a woman of 75 who has a large cavity in the upper part of the right lung and, according to the out-patient notes at Brompton Hospital, has had it for over 50 years. She occasionally gets a little bronchitis, and at intervals tubercle bacilli have been found in the sputum, but on the whole her general health remains good. It would be wrong to try to collapse the cavity, and would have been equally wrong 10, 20, 30 or more years ago. I have seen several patients with this type of cavity doing well until pneumothorax or thoracoplasty had been performed in order to collapse it. There are usually areas of adherent pleura and adhesions and, even if these can be cauterised, the fibrotic condition of the lung prevents collapse of the cavity and it is only the unaffected part of the lung that collapses. Similarly with thoracoplasty the size of the lung is diminished, but in the chronic fibrotic case the cavities are not collapsed, as can be demonstrated by the injection of lipiodol after the operation.

In every clinic there are chronic fibrotic cases in which cavities have been successfully collapsed by pneumothorax and cauterisation of adhesions, and sometimes by pneumothorax alone. Many such cases are reported in the literature, but one is often left with the feeling that the patient was doing well before the treatment was started. Rupture of the cavity into the pleural cavity, cutting lung tissue with the cautery or the development of pyopneumothorax, are very definite possibilities and, although it is argued that a cavity is a potential danger, one should remember that certain methods of treatment are themselves dangerous. Experience teaches that life is prolonged by artificial pneumothorax in the early infiltration and subacute fibro-caseous stages of tuberculosis of the lung, but that it is shortened by pneumothorax in the chronic fibrotic stage.

There are exceptions to prove this rule, one being success which occasionally follows the collapse of a cavity producing symptoms in a chronic fibroid case.

FIBROTIC CAVITY CONTAINING PUS

In these cases life is rarely prolonged and the patient is generally seriously incapacitated; apart from this the sputum is unpleasant to the patient and a danger to others. An attempt, therefore, should be made to close the cavities and the best means is pneumothorax. Even in cases where radioscopy shows dense shadows and these, together with the physical signs, make it appear that pneumothorax will be impossible, it is often found that the lung collapses quite well, and if there are adhesions it may be possible to divide them and to get a satisfactory collapse. This method of treatment should always be tried first, unless of course there are any definite contra-indications to pneumothorax. Sometimes, in bilateral disease with cavities in the upper zone of both lungs, it is possible to produce a partial bilateral pneumothorax with good results. In bilateral cases, however, the treatment is rarely successful.

---

[1] THE LANCET, 1932, ii., 707.
[2] Ibid., p. 623.

If the part of the lung containing the cavity is adherent to the chest wall and cannot be collapsed even by cauterising adhesions, but the rest of the lung does collapse, it is bad practice to continue the pneumothorax. In such a case the refills should be stopped and phrenic avulsion, followed by thoracoplasty, performed. If the cavity is at the apex, a partial thoracoplasty may be sufficient, but is less successful than apicolysis in most cases. A complete thoracoplasty is usually necessary, and often gives very good results. If for any reason thoracoplasty is contra-indicated and pneumothorax has failed, sandbags may be placed on the chest for an hour or more two or three times a day in order to restrict the movement of the affected lung and to cause flattening of the chest wall. I know of a patient who supported bags weighing 82 lb. for a quarter of an hour at a time. Weights of 40 lb. are not uncommon.

RECENT CAVITY WITH RAGGED WALL

It is when the cavity is recent and is surrounded by a ragged wall of necrotic tissue that artificial pneumothorax gives the best results and is urgently indicated. Not only does it collapse the cavity, but it tends to prevent the formation of others and to check the spread of the disease. Cauterisation of adhesions may be necessary to make the pneumothorax successful. If pneumothorax cannot be induced, the patient should be kept in bed on absolute rest and sandbags should be applied to the chest over the diseased area. Phrenic avulsion, and still more thoracoplasty, is contra-indicated in such cases, although they may be possible and valuable later when the acute phase has passed and the patient is showing resistance to the infection as evidenced by the formation of fibrous tissue.

CONCLUSIONS

1. A tuberculous cavity in the lung is a potential danger. The danger may be great or small.
2. Treatment of a cavity is not without danger, which is slight in some cases, great in others.
3. The patient should not be exposed to treatment which is more dangerous than the cavity.
4. The annular shadow often shown by radioscopic examination of tuberculous lungs is probably due to a cavity in the majority of cases. In the absence of any symptoms or signs other than those of radioscopy, this type of cavity is not an indication for any special treatment.
5. A dry cavity in a chronic fibrotic case is best treated by the same means as a chronic fibrotic case without cavity. Attempts to close the cavity by pneumothorax or thoracoplasty are usually unsuccessful and often shorten the life of the patient.
6. When a cavity is accompanied by much expectoration, special treatment is indicated, because the disease is very likely to spread and the prognosis is bad. Artificial pneumothorax should be tried first, and adhesions divided if necessary. Failing this, phrenic avulsion and thoracoplasty or apicolysis may be tried, but if these methods are contra-indicated, the lung should be rested by the application of sandbags to the chest wall. Apicolysis is more successful than a partial thoracoplasty.
7. In the acute case with cavity formation, artificial pneumothorax is the best treatment. Failing this, the lung should be rested by sandbags. Phrenic avulsion and thoracoplasty are contra-indicated.

Clinical and Laboratory Notes

LYMPHOGRANULOMA (PORADENITIS) INGUINALE

INFECTION ACQUIRED IN ENGLAND

By Hugh S. Stannus, M.D., Ph.D., F.R.C.P. Lond.
PHYSICIAN TO THE FRENCH HOSPITAL, LONDON

With a Note on the Pathological Findings

By G. Marshall Findlay, O.B.E., D.Sc., M.D.
(*From the Wellcome Bureau of Scientific Research.*)

In a paper read before the Royal Society of Medicine[1] last October some account was given of the observations and researches made during the past few years which have led up to the recognition of the pathogeny of a group of conditions severally known as climatic bubo, lymphogranuloma inguinale, inflammatory stricture of the rectum, and genital elephantiasis (esthiomène). It has been shown that they are all due to an infection with an ultra-microscopic virus communicated venereally. Climatic bubo has long been known as a disease acquired in tropical countries. Lymphogranuloma inguinale is the rather unfortunate name which was given by M. Durand, J. Nicolas, and M. Favre, of Lyon, in 1913 to a condition which they described as occurring in France, in ignorance of its identity with climatic bubo. Further, there can be little doubt that this condition, sometimes called poradenitis, was delineated in the writings of syphilographers and others during the past hundred years, though usually referred to under the terms " bubon d'emblée " or strumous bubo.

The interest aroused by the writings of the Lyon observers has led to the recognition of the malady in ever-increasing numbers in continental countries, and in America, while the intradermo-reaction devised by W. Frei in 1925, and the demonstration in 1930 by animal inoculation, of an ultra-microscopic virus as the causative agent by S. Hellerström and E. Wassén, followed by the researches of C. Levaditi and his co-workers and of Marshall Findlay, have placed the means of exact diagnosis on a firm basis. At the time the above-mentioned paper was read allusion was made to the fact that no single case of the disease had been recorded in which the diagnosis was established and in which the infection was proved to have been acquired in this country, and it was stated that though the disease might be rare, cases were probably going unrecognised, a statement which elicited in the discussion the fact that no case had been seen at the St. Thomas's Hospital venereal diseases clinic, and that among 10,000 examinations at the Albert Dock Hospital V.D. clinic no case had been seen, with one possible exception and another doubtful case, the opinion being that cases of the disease were not being missed. At the time there was under care (H. S. S.) at the French Hospital a man admitted for bronchitis, who on examination was found to present the typical clinical picture of lymphogranuloma inguinale. His infection was acquired in London, and the virus has since been recovered in experimental animals. This case therefore is the first proved case of lymphogranuloma inguinale to be recorded whose infection was gained in this country, and I am convinced that similar cases will be recognised if looked for and subjected to diagnostic tests.

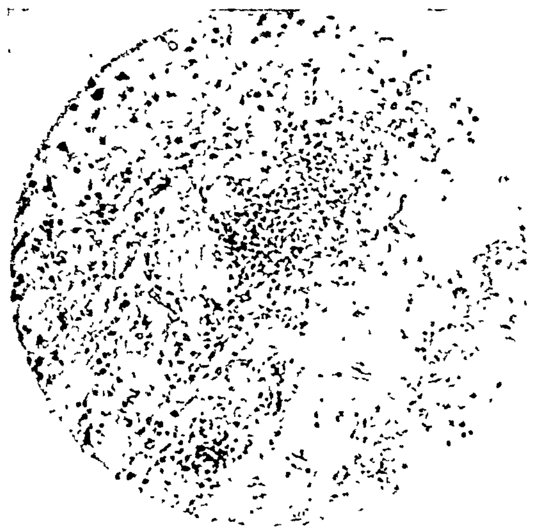
CASE RECORD

The patient, an unmarried Italian, a waiter, has lived in England without leaving the country for 15 years. His history includes gonorrhœa 18 years ago, and some bronchitis of recent years.

On or about August 7th, 1932, he had intercourse with an English girl in Soho. Previously he had not had coitus for many months. On Sept. 12th he knocked against the corner of a table and thought he had injured his left groin. A swelling appeared in the left inguinal region on the following day. Nine days later (Sept. 22nd) he consulted a doctor, who made a small incision into the mass and evacuated some pus and blood. During this ten days he had felt ill and shivery but had continued at work. About the same date as the bubo was opened he developed a cough for which he was admitted to hospital on Sept. 28th.



Section of brain of mouse with encephalomyelitis dying 52 days after intracerebral inoculation of pus from the inguinal bubo of the patient. (× 150.) Mayer's acid hæmalum and eosin.

On examination: temp., 99·6° F.; pulse-rate, 112; marked objective shortness of breath and increased respiration-rate; troublesome cough. Blood pressure, 210/100. Urine: 0·1 g. of albumin, no sugar, no abnormal elements. Blood: red cells, 4,920,000; white cells, 10,800; hæmoglobin, 102. At the bases of both lungs air entry was deficient; moist râles and low-pitched rhonchi present. The liver and spleen were not enlarged; with the exception of the groin no glandular enlargement was detected, and the other systems of the body were normal.

The left groin in its inner two-thirds was the seat of a somewhat sausage-shaped mass the size of an egg with the long axis parallel and just above the fold of the groin. It was hard but elastic to touch and non-fluctuating. The super-jacent skin was of a purplish colour, adherent, but not markedly infiltrated. Towards the outer end of the inguinal mass the small incision persisted unhealed and from it exuded a small amount of sticky whitish pus; the edges of the sinus were neither ulcerated, infiltrated, nor undermined. Below the fold of the groin another gland mass could be seen and felt, having the same characters as the one above; from it opened a small fistula which had appeared spontaneously. There was no urethral discharge, no evidence of gonorrhœa or chancroid infection. In the coronal sulcus on the left side was found what might be a tiny scar. The patient was uncircumcised and did not know whether he had had any abrasion there or not. The anus and rectum were normal.

On the skin of the legs, chiefly the thighs and on the abdomen, there was a scaly papular rash. The Wernicke reaction was positive. Frei's intradermo-reaction was negative both to a pooled climatic bubo antigen prepared by Mr. A. H. Walters, of the Albert Dock Hospital, to a climatic bubo antigen provided by Dr. Hamilton Fairley of the Tropical Diseases Hospital, and to a climatic bubo antigen given to me by Dr. Marshall Findlay, of the Wellcome Bureau of Scientific Research. All the controls were also negative. Some gland juice was withdrawn by aspiration rom the inner pole of the upper mass distant from the original area of softening as an inoculum for use on experimental animals. Treatment by neosalvarsan and bismuth was instituted on Oct. 8th; the patient was kept in bed, dry dressings were applied over the groin but nothing else was done.

Rapid absorption of the inflammatory mass in the groin began after the first injections and the sinuses were healed in two weeks.

The case beyond being a typical one of lymphogranuloma inguinale illustrates two points of interest—the negative cuti-reaction in the presence of an associated syphilitic infection, and the rapid clearing up of the condition under antisyphilitic treatment. These two points have been noted before and cannot afford to be forgotten if a correct diagnosis is to be reached.

PATHOLOGICAL FINDINGS

The material aspirated from the groin gland was inoculated intracerebrally into six mice, each mouse receiving 0·03 c.cm. Of these six mice one died 48 hours later as a result of the injection, while two survived. The remaining three died 6, 14, and 52 days after inoculation, those dying on the sixth and fifty-second days presenting nervous symptoms such as turning in circles, head retraction, and weakness, entirely characteristic of the infection produced by the virus of climatic bubo when injected intracerebrally in mice. The brains cultured aerobically and anaerobically in broth were sterile. Histological examination of these brains showed evidence of a meningo-encephalitis resembling that found in mice inoculated with the virus of climatic bubo. Brain material from the mouse dying 52 days after inoculation was subinoculated into five other mice which died 4, 9, 11, 13, and 21 days after injection with symptoms and histological appearances similar to those found in mice inoculated with material from known cases of climatic bubo.

A CASE OF NÆVOID AMENTIA

By Clifford Allen, M.B. Lond., D.P.M.

(WITH ILLUSTRATION ON PLATE)

The first case of nævoid amentia was apparently described by Kalischer[1] in 1897. Other cases have since been recorded.[2-13] In this country it was studied by Brushfield and Wyatt,[14] who did much to crystallise the facts known about the condition into a definite syndrome. In America, Harvey Cushing's[15] splendid work has thrown much light on the intracranial diseases of blood-vessels.

The characteristics of nævoid amentia are the following: (1) A nævoid condition of the trigeminal region (face or scalp) seldom crossing the midline but sometimes extending over parts of the body on the same side. (2) Fits which may or may not be Jacksonian in type. (3) Signs of damage to the pyramidal system. (4) Varying degrees of amentia. The condition is prenatal, and the extension of the nævus with increasing physical signs and symptoms is unusual. Apparently any degree of hemiplegia and amentia may occur, but the severer types usually die in infancy. The nævoid condition of the meninges can usually be seen by radiography as crescentic areas of calcification. (Fig. I. on Plate.)

The case recorded here is that of an adult woman aged 49.

FAMILY HISTORY

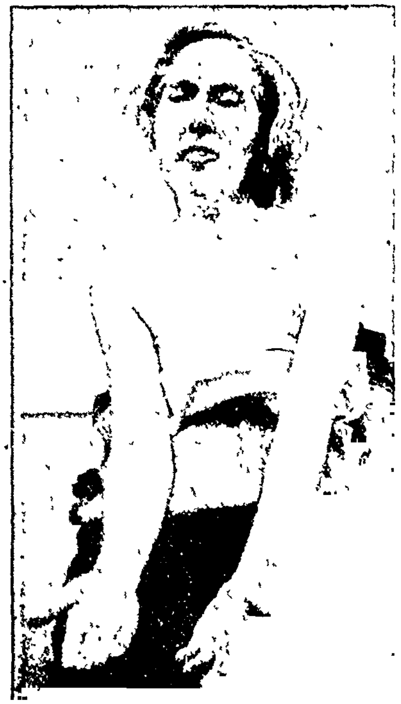
Her mother died, aged 73, from syncope. The father died, aged 69, from "valvular disease of the heart." There are three brothers, all of whom have died. One died, aged 26, from a "low fever." One died, aged 18, from appendicitis, and the other died at 6 months from unknown causes. Out of the patient's five sisters four have died—one of "heart disease," aged 47 ; one of influenza, aged 12 ; one of measles, aged 3½ ; and one of anæmia, in infancy. There is one surviving sister who is alive and well. (The high incidence of vascular disease is probably without significance.) None of the family, other than the patient, suffered from fits, spasticity, or nævi.

PERSONAL HISTORY

Her birth was a normal one. Her father was out of work, and her mother did washing until a few hours before the patient was born ! She appeared normal and had no fits until the age of 3. At this age she fell out of a high chair. She screamed out loudly but did not lose consciousness. She was picked up by her mother and soothed, but when she was placed down she had a fit. She had occasional fits following this. In spite of her epilepsy she went to school and appeared to progress fairly well. She was however promoted with the class, and was only in the fifth standard when she left at the age of 14. She never won a prize at school. Her sister (informant) saw her in a fit at the age of 16 ; all that was observed, however, was that her face was distorted, and the observer was too frightened or unobservant to notice whether there was any Jacksonianism. When the patient left school she stayed at home with her mother. She was incapable of earning her own living, but was able to run errands. She lived with her mother until six years ago, when her mother became ill and died. Even up to the hour of her death she appeared to have no realisation that her mother was dying.

When her mother was buried she asked to be allowed to live by herself, and as she owned a little property, which she had inherited, this was permitted by her relatives. Her financial affairs, however, were soon grossly confused, and she "spent a hundred pounds in no time." She bought a number of superfluous things (such as a vacuum cleaner), and had the one room in which she lived redecorated twice in two days. She had "taught" in Sunday-schools since the age of 18, and she filled her room with religious books and covered the walls with texts.

FIG. II



Photograph of the patient.

For the last two years she has lived in total darkness. This was apparently to prevent the motor-bus drivers at the garage opposite from looking at her. These complaints were apparently based on reference feelings. She soon showed signs of being hallucinated, and complained that these men were "talking scientifically" to her without opening their mouths. She then declared that people used to read out loud everything that she wrote, and that all her business was being broadcast by the wireless.

She became progressively worse. She refused to sleep in bed because she "had too much electricity in her body." She was dirty and insanitary in her habits. She set fire to her room on two occasions, but fortunately without serious result. At last she took one of her pupils from the Sunday-school home and kept this child alone with her all night without informing the child's parents. After this escapade it was obvious that she needed institutional care. She was certified and sent to Bexley Mental Hospital. She has settled down in these simplified surroundings and, although hallucinated and paranoid still, has been able to adjust herself satisfactorily.

PHYSICAL FINDINGS

She is a woman with iron-grey hair and a rather hirsute chin. There is a well-marked nævus almost in the midline of her forehead, but more to the right than the left. (Fig. II.) The optic discs are normal. There is a slight ptosis on the left, and her left eye is placed at a lower level than the right. The eye movements are normal. The pupils react to light and accommodation, also consensually. The palate moves normally. The tongue deviates to the left.

Her head tends to be held slightly to the left with slight raising of the left shoulder. In repose the left arm tends to be held in a semi-pronated position, but it swings normally when walking. There are no contractures, and her left arm is capable of free movement. The grip of the left hand is not so good as the right. When asked to grip tightly with her right hand she is noticed to grip her left fingers also. She does not grip her right hand when making an effort with her left. She contracts the fingers of her left hand when the left supinator jerk is being elicited. The musculature is poorer in the left arm, and there is a certain amount of agenesis. The limb is shorter, the bones feel smaller, and the fingers are thinner. The abdominal reflexes are present and normal. Her left leg is very slightly smaller than the right, but the difference is almost negligible. The knee and ankle reflexes are equal and normal. Both plantars are flexor. Sensation is normal. She has no physical signs of disease in her other systems.

INTELLECTUAL TESTS

She is rather dull and simple in her conversation. Although she was a Sunday-school teacher she could not say who Ananias, Aaron, or other prominent biblical characters were. She thought a Pharisee was one who made his living by telling lies !

The result of various tests is as follows: Burt's graded reasoning test gave a mental age of 7. Porteus tests to the age of 6 were reached. Burt's reading tests gave 8, and the Binet-Simon gave $8^{8}/_{12}$.

The outstanding features of this case are: the circumscribed lesion—practically a monoplegia ; the approximately midline position of the nævus ; the cessation of the fits ; and the age of the patient. The development of a psychosis in one suffering from such a combination of intellectual, physical, and æsthetic disabilities is hardly astonishing.

I wish to thank Dr. G. Clarke, medical superintendent of Bexley Mental Hospital, and the London County Council for permission to publish this case, and Dr. F. O. Walker for the photographs.

ROYAL HALIFAX INFIRMARY.—The annual report shows that last year there were 4241 new in-patients whose average stay was 17·1 days, and average cost £5 13s. 6d., a reduction of 7s. The average cost per bed for the year was £121 6s. 10d., a saving of £5 12s. 2d. per bed on the preceding year. At 14,632 the out-patients increased by nearly 900.

MEDICAL SOCIETIES

MEDICAL SOCIETY OF LONDON

A MEETING of this society on Feb. 13th, with Sir JOHN BROADBENT, the president, in the chair, was devoted to a discussion on the

Treatment of Peptic Ulcers by Duodenal Feeding

Dr. ERNEST YOUNG said that in America this method was extensively practised, and he thought it had not received adequate recognition in this country. For some years he had used it in most of his hospital and private cases of gastric and duodenal ulcer, and it had yielded better results than any other form of medical treatment. His method was to pass a soft rubber tube of small calibre into the duodenum, where it was retained for at least 21 days. Through this tube the patient received, at two-hourly intervals, seven liquid meals during the day. The main object of the treatment was to secure rest for the ulcerated viscus; as no food passed over the ulcer there was an opportunity of healing. The apparatus consisted of two parts: the thin rubber duodenal tube, and a small irrigator, supported by a filter. The rubber tube, 47 in. long, terminated in a silver-plated capsule. The flow of the liquid food through the tube was regulated by a stop-cock. It was very important that the tube should be as soft and pliable as was compatible with efficiency, because of the length of time it was required to remain in situ. It was his practice to pass the tube in the early morning, on a fasting stomach; the patient was sitting up when it was introduced, and it had been previously moistened with glycerin. When the 23-in. mark was at the teeth, the end of the tube was near the pylorus; no further effort was then made, but the patient sipped water until the 30-in. mark arrived at the teeth, the gastric peristalsis being relied upon to carry the tip of the tube into the duodenum. This last stage might require a few minutes or a few hours. If the liquid withdrawn was watery and acid it indicated that the tip had not yet reached the duodenum. Feeding could begin as soon as the tube entered the duodenum. During the 21 days that the tube remained in position the meals given through it consisted of one raw egg and a tablespoonful of lactose beaten with 8 oz. of milk; with, as an alternative, the egg beaten with 8 oz. of Benger's food and a tablespoonful of cream. If patients awoke in the night feeling hungry, an additional feed of the same character was given. On the evening of the last day of this active routine the tube was removed, and next morning the following diet table was commenced:—

Breakfast.—A scrambled egg, oven toast or breakfast biscuits with a little butter, a teacupful of China tea (no sugar) at the end of the meal.

Lunch.—Boiled fish, sieved potatoes, oven toast or breakfast biscuits, baked custard, a maximum of half a tumbler of water.

Tea.—Two cups of China tea (no sugar) and a few plain biscuits.

Dinner.—Breast of chicken, sieved potatoes, oven toast or breakfast biscuits, junket with a little cream, half a tumblerful of water.

On retiring, sip a tumbler of hot water.

This régime was kept up for 10 to 14 days, and gradually normal diet was resumed, this point being reached in a month or two. At first the tube might cause some soreness, but this was short-lived; in only one of his cases was it so great that the treatment had to be discontinued. If duodenal discomfort occurred shortly after the feeding, he gave a spoonful of alkaline powder in water by the mouth with the feeds for a day or two, and that generally disposed of the feeling. If the patient was constipated, a liquid aperient could be given through the tube: if anæmic, iron and arsenic could be given in the same way. The mouth should be washed two or three times daily. It was unnecessary for the patient to be kept constantly in bed.

With large gastric ulcers on the posterior wall, or a duodenal ulcer with a long history, it might be necessary to retain the tube for from four to six weeks, a control radiogram being taken every ten days. If in three weeks the X rays showed no change in the ulcer, operation should be advised, for a treatment which did not succeed in three weeks was not likely to do so in a longer course. Duodenal ulcer was more debatable. Dr. Young thought that neither this nor any other medical method should be tried if radiography showed deformity of the duodenal cap sufficient to cause pyloric obstruction. The treatment was suitable for cases of duodenal ulcer which had never healed after gastro-enterostomy. The most striking success in his experience had been achieved in cases of multiple ulcers; he had had six such cases in a few years. Five of them made a good recovery, the sixth had only just completed the treatment. He had followed up 75 cases in nine years: 16 stomach, 53 duodenum, 6 multiple in stomach and duodenum. Eleven of the stomach cases made an excellent recovery, 1 did not respond, and was found to have a malignant ulcer, 1 had an ulcer of the posterior wall and was referred to the surgeon, making a good recovery after gastrectomy; 3 he had not been in touch with. Six duodenal cases he lost touch with, 3 were still under treatment, and of the remaining 44, 11 had had relapses. Most of his failures were among his earlier cases, when his treatment was shorter And latterly he had been able, as a result of experience, to make a wiser selection of cases. He believed that for appropriate cases this method was shorter and more acceptable, and produced more satisfactory results than any other form of medical treatment.

A RADIOLOGIST'S VIEW

Dr. G. R. M. CORDINER said that one direct radiological sign on which gastric or duodenal ulcer could be diagnosed was visualisation of the ulcer niche. Gastric ulcers could be grouped into those with hyperfunction, those ulcers with compensated function, and those with decompensated function. The associated pylorospasm became more marked the nearer the ulcer was to the pylorus. In explaining the symptoms in these cases he emphasised the importance of a weakening of the whole digestive musculature owing to the continual effort needed to deal with obstruction. He thought that the first and second degrees of gastric ulcer should be treated entirely medically, provided that the treatment was adequate and that a sufficient standard of cure was demanded. Treatment of third-degree ulcers should be surgical. There was no difficulty in differentiating between the first and second degrees, but sometimes it might be difficult to state, radiologically, whether a given ulcer should be classified to the second or third degree. In ulcer of the second degree, if treatment by the tube was continued for a fortnight, there was a rapid return to normal function or hyperfunction, whereas in a third-degree condition, with pyloric antral stenosis, there was a marked delay in evacuation time even after the fortnight of intubation. With regard to the standard of cure, the clinical proof of cure was made more difficult because peptic ulcer tended to remain latent for months, even years, and absence of symptoms did not necessarily mean healing of the ulcer; only radiography could confirm or refute the clinician.

DISCUSSION

Sir WILLIAM WILLCOX held that the method described represented a really valuable advance. During the last four years he had adopted it for almost all the cases of gastric ulcer which had been under his care at St. Mary's Hospital. Under the old régime healing of the ulcer was a very slow process; and some of the cases which had been cured with the tube were ones which he would formerly have handed over to the surgeon. With regard to duodenal ulcer, his experience was that when the ulcer was not too near the duodenum treatment with the tube had been most successful, but if the tube was passed a good distance along the duodenum it was especially valuable when the ulcer was in the pylorus or an inch or so beyond. It was important to remember that in all these cases there was a general tendency to ulceration; the ulcer should be regarded as a localised manifestation of a general toxæmia.

Dr. STANLEY WYARD agreed that intubation was by far the best method of treating gastric and duodenal ulcer. Some of his patients complained of acid regurgitation with pain every time food was passed, and he found that in some this did not yield to alkaline powder, but was dissipated by giving minute doses of sulphuric acid by the mouth—i.e., acid sulph. dil. ♏v.

Mr. A. E. MORTIMER WOOLF spoke of a case of double ulcer which seemed about to perforate, and was in such a bad condition that the speaker dared not operate. He had asked Dr. Young whether the tube treatment would help in that case, and to everyone's surprise the ulcer had healed under the treatment, and the patient had remained well five years.

Mr. A. J. WALTON said that to-day no surgeon stated that no cases of the kind could be cured medically, nor could a physician be found who did not admit that surgery was sometimes the only remedy. There was a group of cases in which there was a short history (three or four months) of ill-defined attacks, in which there was not so much real pain as discomfort. He regarded these as no more than duodenitis, and under no circumstances would he operate on them. They showed no more than a hyperperistalsis and over-activity of the duodenum; no nitch was visible by X rays. Also there were cases of erosion, with either obvious bleeding or some occult blood, and these were not for surgical treatment either. If, on the other hand, there had been repeated hæmorrhages and a long history, he believed that operation should be carried out; and it was also required in cases showing fibrosis and definite stenosis. If a patient over 45 gave a short history of dyspepsia and his past history had been gastrically clear, his working rule was to regard the condition as carcinoma unless there was proof to the contrary. He had operated upon 1677 cases of peptic ulcer, and 822 of them were duodenal; yet it was almost universally accepted that duodenal ulcers formed four-fifths of all the ulcers in this region.

Dr. GEOFFREY BOURNE said that in the few cases in which he had tried it, the intubation method had given him better results than any other.

Dr. G. E. VILVANDRÉ said that pylorospasm was a diagnostic sign of the existence of duodenal ulcer. The really early sign of gastric ulcer was not the visibility of the nitch, but a localised spasm in that segment of the stomach which was supplied by the nerve serving the area; in other words, it was the reaction of the stomach to the presence of the ulcer. He felt very strongly that a number of surgeons who were carrying out gastro-enterostomy should not do so.

Dr. T. IZOD BENNETT said that in the last ten years 1200 cases of peptic ulcer had passed through his out-patient clinic, and a few—he did not know the proportion—had needed surgery. None of that large number had had duodenal tubage, and it would be wrong, he thought, to conclude that this method was necessary. His three-phase criticism of the method was: (1) it was tiresome to the patient, (2) it was an expensive form of treatment, (3) as a rule, it was wholly unnecessary. He agreed that there was now no radical difference of opinion concerning these cases among surgeons and physicians.

The PRESIDENT said there could be no doubt that duodenal feeding was often very successful.

Dr. YOUNG, in his reply, did not agree with Dr. Izod Bennett that the treatment was expensive. It did not distress the patient, for scarcely an ache or pain was complained of during the whole treatment.—Dr. CORDINER also briefly replied, emphasising the fact that other conditions besides ulcer would cause pylorospasm.

WEST LONDON MEDICO-CHIRURGICAL SOCIETY

A DINNER meeting of this society was held on Jan. 13th, under the presidency of Dr. JULIUS BURNFORD, when Mr. TIMBRELL FISHER opened a discussion on

Arthritis

He said that although in many ways an attractive hypothesis, the infective theory in the ætiology of arthritis could not be said to be definitely proved. Most workers agreed that bacteriological examinations of the joint fluids or tissues removed at operation and the blood of arthritic patients had been either negative or inconsistent. It had been suggested that the absence of organisms was due to the fact that the joints were hypersensitive and reacted in an allergic manner to minute doses of microbic toxin. Possibly some joints reacted in an allergic way, while others were actually invaded by organisms. The evidence appeared to be steadily accumulating that the streptococcus played an important part in the ætiology of chronic arthritis, and this raised other interesting problems such as the relation of these forms of arthritis to acute rheumatism. The ætiological problems attaching to arthritis merited attention from bacteriologists and biochemists. Such research could best be undertaken in an arthritic unit, where early cases could be exhaustively investigated and facilities for in-patients were available. Dealing with orthopædic aspects of the disease, Mr. Fisher said that in the more acute stages, when muscular spasm was prominent, every effort must be made, by extension or otherwise, to prevent deformity. The aim should be the retention of a mobile joint, but since ankylosis might occur, the joint should be placed in the optimum position, if necessary in some light form of apparatus, which was easily removable for physiotherapy. Every effort must be made in recumbent cases to avoid faulty posture. It was often overlooked that if a patient was propped up in a sitting posture in bed, a serious flexion deformity of the hips was apt to develop. The knees were often flexed over a pillow to give greater comfort, at the expense of crippling flexion deformity, and the feet, owing to the pressure of the bed-clothes, assumed a position of talipes equinus or equino-varus. The prevention of deformity in arthritis was of inestimable importance.

DISCUSSION

Sir **FREDERICK HOBDAY** made some observations on arthritis as found in horses; he mentioned that a good deal of arthritis was occasioned through working the animals before they were mature.

Dr. H. H. **MILLS** held that much osteo-arthritis was preventable if only there could be continued into later life, particularly during adolescence, the careful surveillance which was begun in infant welfare centres.

Dr. W. S. C. **COPEMAN** recalled the need for more accurate terminology. Whatever these cases might be called, they fell into two groups, the osteo-arthritic and the rheumatoid arthritic groups; but those writing papers on the subject often used different and confusing classifications. Dr. Copeman also referred to Mr. Fisher's statement that he was not sure of the cause of the alteration in blood-sugar tolerance in rheumatoid arthritis. Pemberton, in America, had suggested that it might have something to do with the fact that large areas of the capillary beds were closed off in this disease, the patients being always extremely pale and cold. Dr. Copeman had taken the blood-sugar tolerance of a patient with rheumatoid arthritis, which was abnormal, and then gave the patient a hot bath; immediately he repeated the test which then gave a normal result.

Dr. **CLEMENT NICORY** mentioned some work done under the auspices of the Medical Research Council which suggested that an excessive protein diet led to constipation and rheumatism.

Dr. **GERALD SLOT** said that it had been found at Carshalton the young children suffering from rheumatoid arthritis had been greatly benefited by intravenous injection of heavy metals (gold), but neither in acute rheumatic fevers, in its cardiac manifestations, nor in choreas, had any good results been obtained by this method of treatment. At Hammersmith Hospital also some cases of arthritis in patients not very old or weak had responded extremely well to heavy metal therapy.

Dr. **GORDON DEWES** said that the principle of rest for arthritic animals might be applied to children, who might, instead of being given salicylates, be kept in bed for some weeks and have their exercise restrained until they reached puberty.

Dr. T. S. **KEITH** suggested that there was a condition of vascular stasis in which the streptococcus thrived. He believed that streptococci were frequently present in the synovial fringe, but he did not think they were causal agents.

Dr. **HOWARD STRATFORD** said that if cold acted on the capillaries in the neighbourhood of the joint and caused congestion, the blood-supply to the joint might be lowered, so that organisms got a chance of causing trouble.

Dr. D. M. **SCRIMGEOUR** discussed a classification on the basis of X ray appearances; Mr. G. B. **WOODD-WALKER** referred to the mechanical arthritis set up by deformity; Dr. F. McG. **LOUGHNANE** mentioned the importance of the genito-urinary system as a focus of infection; and Mr. H. L. **ATTWATER** referred to the frequent association in middle-aged men of mild prostatitis with aches and pains in the joints.

WEST KENT MEDICO-CHIRURGICAL SOCIETY

A MEETING of this society was held at the Miller General Hospital, Greenwich, on Feb. 10th, when Mr. P. H. **MITCHINER** gave an address on

When to "Wait and See" in Acute Appendicitis

He began by speaking of the controversy excited by Sir James Berry's paper on the value of expectant treatment in acute appendicitis.[1] In the main he agreed with Sir James's teaching, but he could not associate himself with the implication in this paper that operation should not be undertaken in the first 48 hours of an attack of acute appendicitis. If a case is definitely seen within the first 12 hours after the onset of the attack, when there is so often uncertainty as to the exact diagnosis, he can see no harm, he said, in waiting for a few hours in order that other symptoms may manifest themselves and investigations be carried out; for in his experience no harm will result for waiting 24 hours after the onset of an attack of appendicitis before operating.

It must be remembered that there are definitely two types of acute appendicitis. Firstly, the type with obstruction of the lumen of a previously inflamed and usually kinked appendix by a concretion, and, secondly, the general infection of the appendix wall, probably commencing, as a rule, in the submucous coat, which is usually associated with a mild septicæmia from a blood stream infection. In the obstructive type the initial signs are intermittent colic, and pain usually starting at the umbilicus and subsequently settling over the appendix. This type in the early stages is very apt to be confused with ureteric colic associated either with stone or *B. coli* pyelitis, or with a true appendicular colic in children due to the presence of worms or some other irritant in the lumen of the appendix, or enlarged mesenteric glands. It is only a careful investigation of the urine, radiography, and examination of the tongue which will elucidate the diagnosis in these cases. Such an examination may entail the loss of a few hours, but it is a loss which can be met with safety, for, in the speaker's experience, so long as this type of appendix is removed within 24 hours after the onset of the attack perforation will not have occurred.

In the second type of attack a patient has often had some mild septicæmic condition associated not infrequently with sore-throat, possibly a mild influenzal attack, and the classical signs of appendicitis are present, the temperature seldom, however, raised above 99° F. excepting in small children where a temperature up to 101 ° F. may be met with. The pain again usually begins in the umbilical region, and the "appendix" whose symptoms start and remain at McBurney's point should be regarded with suspicion. Differential diagnosis in these cases is often difficult. Apart from cases of infective gastro-enteritis and disturbances due to unsuitable food, a perityphlitis may occur both in influenza or pneumonia, and referred pain in a spinal meningitis, or inflammatory conditions in the region of the diaphragm, not infrequently give rise to difficulty in diagnosing the condition correctly. In appendicitis, however, the tongue is usually coated and the breath has a peculiar and characteristic mousy smell.

In young girls rupture of a blood cyst in the ovary is extremely difficult to diagnose from appendicitis but in these ovarian cases the tongue is usually clean and the pulse unduly rapid for the slight temperature present. Salpingitis of course constitutes a great difficulty in diagnosis, and often such a diagnosis is impossible apart from operation.

---

[1] Trans. Med. Soc. Lond., 1932, lv.; THE LANCET, 1932, i., 1027.

In these early cases, therefore, seen within the first 12 hours where the diagnosis is doubtful, Mr. Mitchiner advises waiting for a few hours so that thorough investigation of the case may be carried out; many unnecessary operations will be thereby prevented. In cases seen from 12 to 48 hours after onset of the attack the diagnosis is usually obvious, and surgical operation is the only right and proper treatment in all these cases, for however mild the attack may appear clinically it is probably impossible to predict the ultimate course. Moreover, the mortality of operation in this period, when the inflammation is limited to the appendix, is no greater than that of operating on a quiescent appendix.

After 48 hours the patient may manifest one of two conditions. The inflammation may have localised to the immediate neighbourhood of the appendix, in which case the rest of the abdomen is flaccid and not tender, and a mass will be felt in the right iliac fossa or on rectal examination on the right side of the pelvis. In these cases the policy of "wait and see" is the only sound one. Where such a policy is adopted, as it is at St. Thomas's Hospital, it is necessary to keep the patient at rest, to give a diet consisting of fluids only, and to see that neither enema nor aperient is given. The patients must, however, be kept under daily observation, for in a very small proportion (about 0·5 per cent.) the local resistance may be overcome and a spreading peritonitis develop, while in about 1 per cent. the abscess becomes adherent to the abdominal wall and needs external incision.

It is the pulse which must be watched. The temperature is bound to be raised in the presence of a localised septic focus which here exists, and a certain amount of paralytic distension of the bowel is always met with. The only indication then for operation in these cases is a rising pulse-rate. "When I was a dresser at St. Thomas's Hospital," said Mr. Mitchiner, "these appendix abscesses were opened and drained across the peritoneal cavity which had previously been packed off. Even with this operation, however, the mortality was approximately 20 per cent. from peritonitis, which spread in spite of the packing-off of the operation area. It then became the custom to open the abdomen and leave a tube down to the appendix mass so that the pus might point along this when adhesions had formed around the tube. We soon discovered, however, in these cases that pus never did come up the tube but that the temperature dropped and the mass resolved. The next step was the substitution of a thin rubber drain for the tube, and this was quickly succeeded by an exploratory laparotomy when, if the mass was found to be isolated, the abdomen was closed without drainage. The results of this operation were excellent, but it struck some of us that it was submitting the patient to an unnecessary anæsthetic and operation, and so we took to observing the cases where a localised mass was present, and we found, as already stated, that the vast majority settled down provided all aperients and enemata were avoided."

In the second type of case met with after the 48 hours, perforation or gangrene has occurred in the appendix without localisation of infection by peritoneal reaction. No mass can be felt usually, and the pulse-rate will be found to *be rising steadily if a* half-hourly count is taken. More or less general rigidity of the abdomen is present, indicating a spreading peritonitis, and calling for urgent operation.

In cases of appendicitis of the "ambulatory" type, where the patient goes to the doctor with a mass in the abdomen which has been present possibly for ten days or so, it is always advisable to wait and see, the patient being treated on the lines previously indicated. In cases where expectant treatment has been adopted in dealing with the localised appendix mass, a subsequent appendicectomy should always be performed in about two or three months time, unless an acute attack supervenes, as it occasionally does, during this period of waiting, when immediate appendicectomy should be carried out.

Year.	* Quiescent.	Died.	Acute. First 48 hours.	Died.	Abscess present.	Died.
1904	—	—	21	9	83*	16
1914	188	2	258	20	52	5
1924	175	3	163	2	24 (No op.)	1
1932	124	0	246	11	24 (4 op.†)	3
—	—	—	—	—	47‡	1

* Operation in all cases. † 3 died, 1 alive.
‡ General peritonitis present.

In conclusion, Mr. Mitchiner summarised the figures for appendicitis at St. Thomas's Hospital for various years (see Table).[2] "From the foregoing remarks," he said, "you will see that I advise expectant treatment in all cases of appendicitis not seen earlier where localisation of the infection has taken place by the end of the first 48 hours after the onset of the attack. This treatment will be successful only if combined with rigid avoidance of the administration of any *aperient or enema.* I further suggest that it is advisable during the first 12 hours of an attack where the diagnosis is in doubt, to wait the few hours necessary to carry out the investigations which will definitely confirm the diagnosis of appendicitis before *operating.*"

MEDICAL SOCIETY OF INDIVIDUAL PSYCHOLOGY

At a meeting of this society held in London on Feb. 9th, with Prof. W. LANGDON BROWN, the president, in the chair, a paper entitled

Pathomimia Cutanea

was read by Dr. W. J. O'DONOVAN. In the course of his paper he pointed out that certain skin lesions are associated with certain types of personality. For instance, one of his patients, a man with cheiropompholyx, was, like others, suffering from this condition, nervous, and complained of inability to sleep and a poor appetite. Yet his face was placid, and his girth was increasing. In the same way patients with varicose ulcers display certain common characteristics. They are usually dirty, slovenly, and self-satisfied people, who cannot lift themselves out of dependency. Sometimes the ulcer may be the only means by which they can get individual care and attention. Local pruritus had similar psychological interest. Patients with pruritus ani, for example, are egocentric, with a tendency to exhibitionism and logorrhœa. The itching occurs at times of nervous stress, and the part played by suggestion in reinforcing local treatment further indicates the functional nature of the condition. "Red legs," a discoloration of the legs from ankle to knee produced by scratching, recalls the glove and stocking anæsthesia of hysteria, and suggests that "red legs" may correspond to the layman's hysterical itch.

ROYAL SOCIETY OF MEDICINE

SECTION OF THERAPEUTICS AND PHARMACOLOGY

At a meeting of this section held on Feb. 14th the chair was taken by the president, Dr. E. P. Poulton, and a discussion on

Iodine Compounds in Thyroid Disease

was opened by Prof. C. R. Harington, who dealt with the development of the treatment of goitre. Seaweed soup was said to have been used by the Chinese many centuries before Christ, and in the thirteenth century A.D. Arnaldus de Villanovus had prescribed a seaweed. Burnt sponge had been recommended in the sixteenth century and had been taken up in the middle of the eighteenth century in this country as a secret remedy; this had been finally revealed to a Dr. Wiliner and published by him in 1799. It had been repeated in Parr's Medical Dictionary in 1809 and had been regarded as a valuable if empirical remedy. During the Napoleonic wars there had been a shortage of nitrates for gunpowder and an extract of burnt seaweed had been substituted by one manufacturer for burnt-wood ash. As a result iodine had been isolated in 1812, and seven years later its presence in sponge ash had been demonstrated. Some years later a Genevese physician had independently tried iodine for goitre, with great success, but not without undesired results. Imprudent use of iodine had led to its schedule as a dangerous drug by one Swiss canton. The internal secretion of the thyroid had been demonstrated by G. R. Murray in 1891, and iodine had been discovered in it in 1895. The morphological chemical studies of J. Marine had shown the inverse relationship between iodine concentration and degree of glandular hyperplasia.

These observations formed the basis of iodine therapy in Graves's disease. Many adverse reports on this treatment had appeared, and bad results were ascribed to the fact that the disease was due to over-production of thyroid secretion. Another theory regarded it as a dysthyroidism rather than a hyperthyroidism, the excess of secretion owing its toxicity to want of iodine. This theory lacked experimental support; thyroxine short of iodine had never exercised any toxic effect in the laboratory. Moreover, iodine only benefited Graves's disease for a short period: during the response to iodine therapy, which was a rapid involution of the gland with storage of collagen. The "thyroid diarrhœa" theory of Kocher was more satisfactory; iodine by pressure-retention temporarily arrested the too rapid release of secretion and could only be regarded as a palliative. The cause of Graves's disease was probably outside the thyroid; in the adrenal or the pituitary. The most suitable mode of administration of iodine was in the form of diuretyrosine. The biological synthesis of thyroxine was probably from tyrosine, and one stage could be saved if the iodine was so given; there was no risk of iodism.

THE CLINICAL ASPECTS

Dr. R. Gardiner-Hill said that most simple goitres in London were sporadic, appearing during a crisis of female life or after an infective illness. Marked changes could be detected in the thyroid after natural and experimental infections. There were two types of simple goitre; the diffuse colloid and the nodular. The latter was probably a late stage of the former, though some writers regarded them as separate entities. Iodine seemed to have very little effect on the nodular type, but then nothing had any effect on this form; iodine should be given prophylactically in these cases in times of stress. Care must be exercised, as toxic symptoms had been said to follow iodine therapy. Iodine was of value in the very early stages of the colloid type, and might cause disappearance of the swelling if given within the first two years. It had also great prophylactic value, in times of stress like pregnancy, and in endemic areas.

In primary Graves's disease iodine was of transient value; if given continuously its effects passed off. Belgian workers, however, had recently claimed to be able to control these cases with iodine, increasing the dose whenever the basal metabolic-rate rose. Few physicians in this country would be so optimistic. With medical treatment alone primary Graves's disease always seemed to relapse. The gland showed a striking response to iodine at first, apparently becoming almost avascular; this response was a valuable preparation for operation. Not all glands reacted equally well; the small fibrotic glands which became toxic at the climateric did not harden up in the same way. In secondary Graves's disease the action of iodine was uncertain; there were many expressions of opinion but no well worked-out series of cases. There were two types again; diffuse and nodular. In Dr. Gardiner-Hill's records a very large proportion of both groups had started at puberty; the diffuse glands were in the younger patients and the nodular in the older. Nearly all the diffuse cases had been treated with iodine, which had not produced exacerbation of symptoms. Iodine had not controlled relapses but seemed to have benefited the patient after removal of septic foci. The diffuse type seemed best controlled by mild doses of X rays together with iodine. In the nodular group iodine must be given with caution, and the initial striking improvement was less often seen. The type should be treated surgically.

DISCUSSION

The President referred to Maurice Campbell's geographical work, which suggested that something in the thyroid caused toxic goitre. The best vehicle for the French tincture of iodine was tea. People in endemic areas must eat meat, which contained iodine; or were the victims, he asked, all vegetarians?

Mr. T. P. Dunhill said that iodine did a great deal of good for a limited time to a large number of patients. It should be given to early cases, but only with great caution, lest they be given so much and be kept from the surgeon so long that they lost a chance of surgical relief. Iodine would not "make any patient safe" for operation. In the primary toxic goitre it was very useful. A young patient developing toxic symptoms had plenty of gland epithelium left and would tolerate iodine, but the amount of iodine must be graded according to the amount of epithelium present. It was valuable in nodular goitres if given carefully. If it was not doing good it should be stopped and the surgeon called in.

Dr. George Graham emphasised the importance of dosage, advocating not more than grs. 1 to 1½ in the day. Larger doses might make the gland very hard, and operation almost impossible. Very few cases could be treated with iodine altogether. A very small dose—gr. ⅓—was useful after operation in many cases. Diuretyrosine might be expensive but iodine was very cheap.

Mr. C. A. **Joll** questioned whether iodine deficiency were the cause of endemic goitre; there was, he said, *considerable evidence to the contrary*. Sporadic colloid goitre was not infrequently seen in London, where there was an ample, mixed, iodine-containing diet. Dramatic results from iodine in primary thyrotoxicosis were only obtained in about 30 per cent. of cases, and a definite proportion showed no response at all. He usually began with a dose of 5 minims three times a day. The wide dissemination of optimistic statements about iodine had had the unfortunate result that most patients who reached the surgeon had already had iodine treatment and were very bad surgical risks. Iodine should be used as a preparation for operation. In secondary thyrotoxicosis large doses were *not of great value* after operation. Post-operative iodine should be given according to the state of the patient.

Dr. A. W. **Spence** defended Marine's views on the ætiology of goitre: iodine deficiency, which might be absolute or relative to the needs of the body. Rabbits fed on cabbage developed large hyperplastic goitres and Marine was trying to isolate the responsible substance, which seemed to be cyanine. Dried cabbage did not produce hyperplasia, which therefore was probably not due to an iodine deficiency. Definite hyperplasia was induced by injections of small quantities of cyanide. The cyanide prevented tissue *oxidation and the thyroid produced more thyroxine* to overcome the block. In the future some more fundamental substance than iodine would be found for therapeusis. A substance derived from suprarenal cortex would prevent the cyanide hyperplasia.

Dr. W. **Cramer** pointed out that the active hormone of the thyroid was secreted into a closed space—unlike any other hormone in the body. Possibly the real secretion was normally into the peripheral vessels of the acinus and only the excess appeared in the lumen. When the acinus was full the cells were pressed against the blood-vessels and no secretion could pass out. There was no great vascularity *in simple goitre*, but in exophthalmic goitre these vessels were very widely distended. If the distension could be reduced the condition might be alleviated.

Dr. **Gardiner-Hill**, in reply, *said that* he had recently used 10 minims of Lugol's solution three times a day as a pre-operative measure, but surgeons did not like too hard a gland. The most vascular goitres reacted best to iodine.

Prof. **Harington**, in reply, said that there was no form of experimental goitre that could not be prevented by iodine. If iodine deficiency was not the universal cause it was the commonest cause. The soil might be deficient in iodine near the sea, and the vegetables and the flesh of grazing animals would also lack iodine in these areas. Diuretyrosine was quite cheap.

CORK CLINICAL SOCIETY

Prof. C. Y. **Pearson**, in opening the inaugural meeting of this society on Jan. 27th, expressed his pleasure at being elected honorary president, and spoke of the importance of such societies to the medical profession. He urged that every member should try to contribute something so that it should have th advantages that come from regularity in attendance mutual *criticism, and the promotion* of professiona cameraderie and coöperation.

Prof. **John Dundon**, the president, then reporte the case of a man, aged 55, who had double castration performed 16 years previously for tuberculou orchitis and epididymitis, and now showed signs o renal and vesical tuberculosis; Prof. J. M. **O'Donova** described three cases of rupture of the lung in th course of *artificial pneumothorax treatment* fo pulmonary tuberculosis; and Dr. G. A. **Barte** read notes on a case of

Myringomycosis

The patient, a *young woman, complained* of discomfort, itchings, occasional severe pain, deafness and discharge for 14 days from the right ear. Examination revealed a thick membrane like blotting *paper covering* the membrana tympani and th adjacent canal walls. The membrane was greyish i colour, and there was a fur growing from the uppe portion; in this fur were minute droplets of blac pigment. The membrana tympani was somewha swollen but not perforated. Removal of the mass c fungus revealed a roughened, reddened drum membrane and canal wall showing a few punctat hæmorrhages.

Prof. M. Grimes *identified the fungus as of* th class *Aspergillus niger*, the species not yet worke out. The canal was treated with Mandl's paint, an apparently complete recovery took place in thre days, *followed by complete relapse in a* week. Th patient is at present under treatment. Reviewin published records Dr. Barter said that when thes saprophytes became parasitic on man they lost thei characteristics and became impossible to classif The condition was said to be more common in female (11 to 2). Probably otomycosis was commoner tha is suspected.

Dr. J. B. **Horgan** recalled a case in his experienc that responded to treatment with potassium permanganate.—Dr. W. J. **O'Donovan** suggested tha the fungus was an epiphyte, and that the staphylococci present on the original culture were possibl the real causes of the condition.

REPORTS AND ANALYSES

LIVER SALT

(JOSEPH LINGFORD AND SON, BISHOP AUCKLAND)

This preparation consists of a white powder whic on addition of water produces a clear sparklin solution. When analysed the following results wer obtained :—

Magnesium sulphate	21·1 per cent.
Sugar	28·0 „ „
Sodium bicarbonate	26·0 „ „
Tartaric acid	23·5 „ „

This is a well-balanced medicinal salt, aperient i character, which when dissolved in water effervesce freely. *It is clean and agreeable to the palate.* The suga present masks the rather harsh bitter taste natura to the Epsom salts, and on this account the preparatio will be appreciated by children. The method o packing merits a word of approval. The top of th tin is *invisibly lacquered*, to prevent *discoloration* and a rubber ring within the lid by pressing agains the top of the tin closely should prevent deterioratio of the contents indefinitely.

REVIEWS AND NOTICES OF BOOKS

Traitement chirurgical de la tuberculose pulmonaire

By A. CHARRIER and E. LOUBAT. Preface by E. LEURET. Paris: Masson et Cie. 1932. Pp. 366. Fr.65.

THE authors of this book have set out to supply an explicit account of the surgical therapeutic procedures for pulmonary tuberculosis in use to-day, and it is evident that great pains have been taken to make the record as complete as possible. After a short general introduction on collapse therapy, the book is divided into three main parts, which deal respectively with phrenic avulsion, pneumolysis, and thoracoplasty. Each section contains subsections on anatomy, operative technique, complications, indications, and results. In the operation of apicolysis, paraffin wax is advocated as the "fill," although the use of fat and muscle for this purpose is described. Of the three routes by which the operation may be performed the approach through the first intercostal space is advised. The posterior route is described and acknowledged to be useful, but the axillary incision is given three lines. This approach is, however, very commonly used in this country and America and has many points in its favour, with the sole disadvantage of a diminished quantity of overlying tissue. If it is performed by resection of a small portion of the second rib high in the axilla the operation is very satisfactory. Operations for partial thoracoplasty are well described, but some of them, especially those with an approach through the base of the neck, involve a very tedious dissection. The effect of such measures is necessarily very limited, and would hardly appear to justify such extensive operations, but pneumolysis and localised thoracoplastic procedures are looked upon with considerable favour in France. The indications and contra-indications of permanent collapsing operations are discussed, prominence being given to the value of preliminary phrenic avulsion in assessing the activity of the small, apparently healed focus in the opposite lung.

The chapter on the results of thoracoplasty deals with all the authors' reported cases, and they are analysed as far as possible to show the advantages and disadvantages of the different procedures adopted. Figures are quoted to show that the operative mortality is three times greater for the one-stage than for the two-stage operation, that it is greater in males than in females, and for the right side than for the left—all factors to be borne in mind when an operation is being planned. A short section at the end of the book deals with tuberculous empyema; here is outlined the treatment of the condition (1) when uncomplicated, and when associated with (2) mild and (3) severe secondary infection. The teaching here is orthodox, although the attempts to close pleural fistulæ by forced suction which fills the fistula by the prolapsed lung, as advocated by Redaelli, is a new suggestion which, we feel, is only likely to be effective on rare occasions; though in the original account of eight cases treated by this method closure of the fistula is said to have resulted in all.

The wisdom of using local and regional anæsthesia for thoracoplasty is debatable. It has obvious disadvantages, such as results from the mental distress of a conscious patient submitted to an extensive operative procedure, even when pain is almost completely eliminated; the difficulty in obtaining satisfactory and even anæsthesia over the whole operation area; the possibility of excessive absorption, or a specific idiosyncrasy of the patient for the local anæsthetic or adrenaline which is commonly used with it; and, lastly, the tendency of the local infiltration into the tissues to interfere with satisfactory healing, especially in patients whose resistance is primarily low. Where adequate gas-and-oxygen anæsthesia can be combined with local infiltration into the intercostal nerves, its use would appear to obviate most of the disadvantages mentioned above.

This book as a whole presents a balanced view of the modern surgical treatment of pulmonary tuberculosis.

The Biochemistry of Medicine

By A. T. CAMERON, M.A., D.Sc., F.I.C., F.R.S.C., Professor of Biochemistry, Faculty of Medicine, University of Manitoba; Biochemist, Winnipeg General Hospital; and C. R. GILMOUR, M.D., C.M., F.R.C.P.(C.), Professor of Medicine and Clinical Medicine to the University; and Physician to the Hospital. London: J. and A. Churchill. 1933. Pp. 506. 21s.

AN observer of books designed for the medical profession can obtain much quiet amusement by watching the changing fashions. Some years ago the number of text-books issued on physical chemistry for medical students was remarkable. To-day the fashion has changed slightly, and there seems to be a desperate attempt to force biochemistry upon the medical profession. Some 18 months ago the battle was directed against students, but to-day the post-graduate medical student, the practitioner, the physician, surgeon, and gynæcologist are the ones against whom the major attack is waged. This particular example of a long series of such text-books is written jointly by a professor of biochemistry and a physician, both of such high repute that we opened it with pleasurable anticipation. It is, however, disappointing. The book begins with a hotchpotch chapter entitled An Outline of Human Biochemistry. This includes general philosophic considerations, the composition of the diet, the elements of organic chemistry, general principles of enzymes, hydrogen-ion concentration, and so forth. The information given in the book as a whole is sound enough, especially from the biochemical point of view. The most modern and up-to-date section on medicine is that dealing with nephritis. The authors missed a wonderful opportunity when they failed to discuss in detail the biochemistry of Graves's disease; it seems a pity to leave this out, while including long and rather wearisome descriptions of lactosuria and maltosuria. The account of diabetes mellitus, particularly from the clinical aspect, leads one to doubt whether the authors are in the habit of conducting the practical treatment of this disease. The need for biochemistry in medicine is made clear, but the limitations laid down for the relation between physician and biochemist seem hardly likely to lead to the happy and fruitful development of their association. The authors suggest that a chemist, preferably with no medical knowledge, should be chosen as a collaborator by a clinician. Not only should the biochemist be an assistant, and merely an assistant, so far as relationship to the patient is concerned, but it rests with the clinician to "query the results and call for their repetition if he cases could be treated with iodine altogether. A very small dose—gr. ⅓—was useful after operation in many cases. Diuretyrosine might be expensive but iodine was very cheap.

Mr. C. A. Joll questioned whether iodine deficiency were the cause of endemic goitre; there was, he said, considerable evidence to the contrary. Sporadic colloid goitre was not infrequently seen in London, where there was an ample, mixed, iodine-containing diet. Dramatic results from iodine in primary thyrotoxicosis were only obtained in about 30 per cent. of cases, and a definite proportion showed no response at all. He usually began with a dose of 5 minims three times a day. The wide dissemination of optimistic statements about iodine had had the unfortunate result that most patients who reached the surgeon had already had iodine treatment and were very bad surgical risks. Iodine should be used as a preparation for operation. In secondary thyrotoxicosis large doses were not of great value after operation. Post-operative iodine should be given according to the state of the patient.

Dr. A. W. Spence defended Marine's views on the ætiology of goitre: iodine deficiency, which might be absolute or relative to the needs of the body. Rabbits fed on cabbage developed large hyperplastic goitres and Marine was trying to isolate the responsible substance, which seemed to be cyanine. Dried cabbage did not produce hyperplasia, which therefore was probably not due to an iodine deficiency. Definite hyperplasia was induced by injections of small quantities of cyanide. The cyanide prevented tissue oxidation and the thyroid produced more thyroxine to overcome the block. In the future some more fundamental substance than iodine would be found for therapeusis. A substance derived from suprarenal cortex would prevent the cyanide hyperplasia.

Dr. W. Cramer pointed out that the active hormone of the thyroid was secreted into a closed space—unlike any other hormone in the body. Possibly the real secretion was normally into the peripheral vessels of the acinus and only the excess appeared in the lumen. When the acinus was full the cells were pressed against the blood-vessels and no secretion could pass out. There was no great vascularity in simple goitre, but in exophthalmic goitre these vessels were very widely distended. If the distension could be reduced the condition might be alleviated.

Dr. Gardiner-Hill, in reply, said that he had recently used 10 minims of Lugol's solution three times a day as a pre-operative measure, but surgeons did not like too hard a gland. The most vascular goitres reacted best to iodine.

Prof. Harington, in reply, said that there was no form of experimental goitre that could not be prevented by iodine. If iodine deficiency was not the universal cause it was the commonest cause. The soil might be deficient in iodine near the sea, and the vegetables and the flesh of grazing animals would also lack iodine in these areas. Diuretyrosine was quite cheap.

CORK CLINICAL SOCIETY

Prof. C. Y. Pearson, in opening the inaugural meeting of this society on Jan. 27th, expressed his pleasure at being elected honorary president, and spoke of the importance of such societies to the medical profession. He urged that every member should try to contribute something so that it should have the advantages that come from regularity in attendance, mutual criticism, and the promotion of professional cameraderie and coöperation.

Prof. John Dundon, the president, then reported the case of a man, aged 55, who had double castration performed 16 years previously for tuberculous orchitis and epididymitis, and now showed signs of renal and vesical tuberculosis; Prof. J. M. O'Donovan described three cases of rupture of the lung in the course of artificial pneumothorax treatment for pulmonary tuberculosis; and Dr. G. A. Barter read notes on a case of

Myringomycosis

The patient, a young woman, complained of discomfort, itchings, occasional severe pain, deafness, and discharge for 14 days from the right ear. Examination revealed a thick membrane like blotting-paper covering the membrana tympani and the adjacent canal walls. The membrane was greyish in colour, and there was a fur growing from the upper portion; in this fur were minute droplets of black pigment. The membrana tympani was somewhat swollen but not perforated. Removal of the mass of fungus revealed a roughened, reddened drum membrane and canal wall showing a few punctate hæmorrhages.

Prof. M. Grimes identified the fungus as of the class *Aspergillus niger*, the species not yet worked out. The canal was treated with Mandl's paint, and apparently complete recovery took place in three days, followed by complete relapse in a week. The patient is at present under treatment. Reviewing published records Dr. Barter said that when these saprophytes became parasitic on man they lost their characteristics and became impossible to classify. The condition was said to be more common in females (11 to 2). Probably otomycosis was commoner than is suspected.

Dr. J. B. Horgan recalled a case in his experience that responded to treatment with potassium permanganate.—Dr. W. J. O'Donovan suggested that the fungus was an epiphyte, and that the staphylococci present on the original culture were possibly the real causes of the condition.

REPORTS AND ANALYSES

LIVER SALT

(JOSEPH LINGFORD AND SON, BISHOP AUCKLAND)

This preparation consists of a white powder which on addition of water produces a clear sparkling solution. When analysed the following results were obtained:—

Magnesium sulphate	21·1 per cent.
Sugar	28·0 „ „
Sodium bicarbonate	26·0 „ „
Tartaric acid	23·5 „ „

This is a well-balanced medicinal salt, aperient in character, which when dissolved in water effervesces freely. It is clean and agreeable to the palate. The sugar present masks the rather harsh bitter taste natural to the Epsom salts, and on this account the preparation will be appreciated by children. The method of packing merits a word of approval. The top of the tin is invisibly lacquered, to prevent discoloration, and a rubber ring within the lid by pressing against the top of the tin closely should prevent deterioration of the contents indefinitely.

THE LANCET

LONDON: SATURDAY, FEBRUARY 18, 1933

THE LANCET COMMISSION ON NURSING

Exactly a year ago the Final Report of The Lancet Commission on Nursing was issued. It created more immediate interest than those responsible for its production had ventured to anticipate. The publicity it received was indeed unprecedented for a technical report of that nature, and must be attributed to the widespread appreciation of the curious situation which the Commission was called into being to investigate. At a time when other professions and occupations were grievously overcrowded, and parents and headmistresses were searching eagerly for careers for the rising generation of young women, the hospitals were advertising in vain for candidates for training and for trained nurses to take posts as sisters and staff nurse. Early in 1931, when preliminary inquiries were being made by the Commission, recruitment for this service was found to have reached such an anxious position that of the 600 odd hospitals responding to a question from the Commission on this point, one-fifth failed to secure suitable candidates as sisters, and one-half failed to secure staff nurses and probationers of the standard they required. The reasons given by the girls themselves, and confirmed by parents, headmistresses, and advisory employment bureaux, were variants of the following: long hours, poor pay and prospects, lack of freedom, undue restrictions when officially off duty, and the dual strain of ward work and study, especially since the introduction of State examinations. The gap between leaving school and entering hospital was held to allow the deflection into other less satisfying occupations of many girls who would have taken up nursing had they been able to enter the profession direct from school, or at least to make effective use of the interim between obtaining a school certificate at 16 and the age of admission to hospitals. The 60 recommendations designed to renew the popularity of nursing as a profession were framed by a Commission whose very composition was a guarantee that all points of view would be respected. It consisted of experienced nurses, chairmen of hospital boards, and doctors, reinforced by an economist and women associated one with a secondary school, one with a college, and a third with an employment committee. It is of interest that one of the nursing members of the Commission has recently been elected by State registered nurses to the General Nursing Council, and the selection of the honorary secretary as one of the five members of this Council nominated by the Minister of Health is a gratifying tribute to the work of the Commission.

A survey of the comments made upon the Report of the Commission, at its issue and since, reveals much praise and little specific criticism, and, as was recently pointed out at a meeting devoted to its consideration, one recommendation became an election issue among the candidates for the General Nursing Council. We are aware that the praise accorded to the format, arrangement, and arguments of the Report in some quarters has masked reluctance to admit, in spite of their firm statistical basis, the premises on which certain of the conclusions and recommendations are founded. A number of hospital authorities, following private inquiries, have expressed publicly their satisfaction in finding that the recommendations of the Commission reflect their current practice: from other institutions it has been suggested that with the amendment of regulations in one respect, such as the giving of a whole day off instead of a half day per week, any adjustments required are complete. A more searching study might have revealed points of disagreement between the recommendations of the Report and the existing conditions, which have been ignored as details, but to which the nursing members of the Commission would have attached considerable importance. The limitation of hours of night duty to 57 a week, the allowance of 40 minutes for the main meal of the day and of three clear hours off duty independent of meals every day, and, not least, the scale of salaries of ward sisters, for example, are not details, and reforms here are still wanted. It is clear that the times are hardly propitious for innovations which would directly or indirectly increase the cost of running a hospital, but those which cannot now be adopted could with advantage be tabled for consideration in the future. The need to make changes in conditions of service for the express purpose of attracting candidates for training has during the past year become less urgent, because the influx of suitable young women into the nursing profession has greatly increased. The following factors must here have been influential: (1) the economic depression, during which any form of training associated with board, lodging, and pocket money has obvious attractions; (2) the improvement in conditions of service, as in certain municipal hospitals; (3) the advertisement of nursing as a profession associated with the publicity given to the Commission's report. To what extent each factor has played a part can hardly be estimated. The hospitals will find it safest to assume that (1) is the principal cause, and to make plans for a future in which the resumption of normal economic conditions may again engender a critical attitude on the part of possible candidates to the relative claims of nursing among other forms of social service open to women.

It is an old saying that a square peg will not fit a round hole. In the past the manner of adjustment in hospitals has been to chip the edges off the peg, or at least to rub off its corners, not without risk of some permanent damage to its structure. It is also possible to bring about and maintain a firm and permanent attachment by altering slightly the shape of the hole, and The Lancet Commission have shown how this may be done considers that they do not fit in with the symptoms exhibited."

It is curious that a professor of biochemistry should subscribe to this sort of one-sided criticism. The principles of clinical diagnosis, founded on signs and symptoms, are surely not so firmly established as to justify the physician in querying the figures of a biochemist if the results of observation point different ways. The biochemist might well retort with a suggestion that the physician should look again and make a further examination. We feel that the progress of medicine demands the coöperation of physician and biochemist in some better balanced relation than that of master and servant.

Chemical Wave Transmission in Nerve

By A. V. HILL, F.R.S., Foulerton Research Professor of the Royal Society; Honorary Fellow of King's College, Cambridge. London: Cambridge University Press. 1932. Pp. 74. 5*s*.

Prof. A. V. Hill is well known as an attractive lecturer on complicated subjects. So great is his reputation in this direction that no conference of physiologists seems complete, whether it is held in England, Germany, France, or America, without an address by him. His selection to deliver the Liversidge lecture before the masters and fellows of Christ's College, Cambridge, was welcomed, as will be the small volume based upon his lecture. The book contains little that is not already known to the expert who attempts to follow this extremely difficult and ever-changing subject. But to those not familiar with the remarkable advances made by Prof. Hill and his colleagues the book will be of the utmost value. In it will be found, written in the most interesting manner, a readable description of the modern views on such difficult questions as transmission of impulses through nerves, chronaxie, and the effect of iodo-acetic acid.

A Text-book of Pathology

Fifth edition. By W. G. MACCALLUM, Professor of Pathology and Bacteriology, the Johns Hopkins University, Baltimore. London: W. B. Saunders Co., Ltd. 1932. Pp. 1212. 50*s*.

THIS work requires no introduction to English readers, for it is used as a standard text-book in many teaching schools. Apart from a style which makes easy reading, the special feature of the work is the way in which Prof. MacCallum has planned his teaching on ætiology. Types of injury rather than the location of the lesions are made the basis of classification. To the student who has covered the subject as usually set out in text-books of general and special pathology, this approach gives a fresh and a more comprehensive view of the meaning of pathological processes. The book is therefore of special value to advanced students.

In the fifth edition many alterations have been made reflecting the changes in views in the last four years. A short new chapter entitled Disturbances of Lipoid Metabolism has been introduced to cover Gaucher's and Niemann-Pick's diseases, the lipoidosis of Schüller and Christian, and xanthoma. Rearrangements and additions have been made in the chapters on tuberculosis in order to discuss the importance of the allergic reaction in this disease and its bearing on the form and distribution of the lesions. Recent work on the function of the parathyroid glands and on the importance of the disturbances of the calcium and phosphorus metabolism in rickets is noticed, and short sections have been added to include undulant fever, tularæmia, psittacosis, and post-vaccinal encephalitis. A large number of illustrations have been added and a few of the old ones are represented by substitutes. The reproduction is excellent, and throughout the work the publishers have maintained a high standard.

A Synopsis of Surgical Anatomy

By ALEXANDER L. MCGREGOR, M.Ch. Edin., F.R.C.S. Eng., Lecturer on Surgical Anatomy, University of Witwatersrand; and Assistant Surgeon, Transvaal Memorial Hospital for Children. Bristol: John Wright and Sons, Ltd. 1932. Pp. 609. 17*s*. 6*d*.

THIS book, which has a foreword by Sir Harold Stiles and an introduction by Prof. Raymond Dart, presents parts of applied anatomy in rather a novel way. They are dealt with neither from a regional point of view, nor from a clinical standpoint, but are grouped under multiple headings which have some connexion with both of these outlooks. The result will prove, we think, acceptable to the senior student for whom the work is mainly intended. The parts are presented almost as in a note book, and are illustrated by useful little diagrams. We have read through the work with no little profit and believe it will be found very useful.

Fungous Diseases

By H. P. JACOBSON, M.D., Dermatologist, Los Angeles General Hospital. London: Baillière, Tindall and Cox. 1932. Pp. 317. 30*s*.

A COMPREHENSIVE survey of the fungous diseases on clinico-mycological lines was overdue, and will be welcomed by physicians interested in diseases of the skin. In this compact readable volume is recorded all that the clinician needs to know. For the purposes of nosology the subject is divided into three main groups: (*a*) those infections in which the skin is mainly involved, (*b*) those in which there is or may be a primary cutaneous or mucocutaneous focus with frequent systemic involvement, and (*c*) those with primary systemic effect and occasional involvement of the skin or mucous membrane. No hard line of division can be drawn between these groups, but such a classification is more convenient for clinical purposes than one based on the terminology of the mycologist, or the finer differentiation of cultural appearances in the laboratory. Some knowledge of elementary terminology, however, is essential, and the average need is well met in the introductory chapter on Specific Considerations. The ensuing 100 pages are devoted to a clinical and mycological study of the dermatomycoses—i.e., the ringworms and moniliasis, which includes thrush and the yeast-like infections. These pages will repay close attention. They are full of clinical and therapeutic detail, and the illustrations also will be found of value; those desirous of learning more will avail themselves of the extensive bibliography. The succeeding chapters are devoted to diseases only rarely met with in this country, such as maduromycosis, sporotrichosis, blastomycosis, and actinomycosis. Except for the last named their occurrence is so unusual as to cause quite a stir in dermatological meetings when, perhaps once in a year, a case is exhibited.

This book provides a valuable and accurate exposition of the state of our knowledge in the field of clinical mycology, and should be cordially welcomed.

beds and rigid asepsis. Similarly, in any ward, single cases can be "barrier-nursed." The tendency in recent years in this country has been to construct at fever hospitals series of completely separated glass-walled single-bedded rooms, entered, as a rule, from an outside verandah. In these rooms patients suffering from any infectious condition or none can be safely housed without spread from one room to the next, the same aseptic technique being, of course, imperative. But such units constitute only a small proportion, and usually a quite inadequate proportion of the total accommodation of any hospital and, in any case, essential as they are, cannot solve the problem of the unavowed "incubating" child.

A bold attempt has been made to solve this problem at the new children's hospital at Basle, a detailed description of which has recently been given by E. WIELAND.[3] In considering the means that should be adopted for reducing the introduction of infection to a minimum, the authorities rejected a device which is in use at several continental children's hospitals—viz., the quarantine block into which all new admissions are received. In order to be effective children must be detained there, before admission to the wards, for three weeks, which is the longest incubation period of the common infections. Such long detention would result in considerable disorganisation at an institution of this type. Further, it is pointed out, a quarantine block does not prevent the introduction to the main wards by visitors or careless staff of influenzal infections; or the transference of such infections from child to child. In the construction of the new hospital, which is adjacent to the old, three main principles were adopted: complete separation of the clinics and administrative units from the hospital proper; complete separation of individual ward blocks from each other, structurally, administratively, and as regards nursing: and the substitution of small sick rooms for large wards. The new hospital contains no large wards at all. Although it was recognised that the ideal, from the point of view of introduction of infection, was the single-bedded room, as at the Pasteur Hospital, the expense of such an arrangement made its general adoption impossible. Moreover, the child completely isolated from its fellows tends to become restless and unhappy. The next best was the two-bedded room and, with the exception of a few four-bedded rooms for older children or surgical cases, the hospital block is composed of series of these standard or unit-rooms. Glass was chosen for the walls, not only because of its hygienic and psychological advantages, but because it permits of easy supervision of patients, points which are well recognised in this country. Each room, which is completely self-contained as regards lighting, heating, and sanitary and nursing appliances, has an entrance from a corridor and an exit on to a balcony facing south, the balcony being subdivided by low glass partitions. Abundant sunshine and fresh air without draughts are provided for by high double windows with three divisions and glass doors with panels which may be readily opened outwards or inwards. Direct communication between one room and the next is provided by lockable glass doors in the partitions. These doors were ultimately found to be a weak spot in the design. Three adjacent rooms constitute a complete nursing unit staffed by a sister and nurse. When the hospital was opened it was hoped that this three-room system could be employed with success for a scheme of ward-quarantine. A central four-bedded room was regarded as the sick room proper, the two adjoining two-bedded rooms being reserved for the isolation of any children from the central room who might develop suspicious symptoms. The transfer having been made, the communicating door was locked, thus enforcing access from the corridor. Provided that the well-known aseptic precautions of barrier nursing were maintained, the child in the side ward was effectively isolated. This scheme worked very well as long as one or other of the side wards happened to be available when it was wanted; but, if all three rooms were already occupied, as in times of pressure they were, the system broke down and the only consolation was that the number at risk in the central room was small. WIELAND considers that during the two years' working of the hospital the two-bedded standard room, which may in emergency house a third patient, has proved most successful in minimising infection, although he admits that the communicating doors were a mistake which will not be repeated. He thinks that a happy solution has been found for the modern demand for individualised hospital treatment without undue increase in nursing staff or running costs.

When the old hospital comes to be rebuilt, WIELAND is confident that the two-bed system is the one to adopt. As he remarks, nothing prolongs and increases the cost of hospital treatment for children so much as the appearance of secondary infection. There is nothing to be said, from this point of view, in favour of the large ward. The smaller the ward-unit the better. Where, in existing institutions, the wards are large, it is essential to provide ample isolation accommodation of one type or another for the reception of the suspicious case.

"EARLY" EVIDENCE OF TUBERCLE

AT a meeting of the Liverpool Medical Institution last month several speakers proclaimed the modern doctrine that in the diagnosis of pulmonary tuberculosis physical signs are of relatively little value, and that X ray examination is of paramount importance. Physicians of an older generation are wont to deplore such reliance upon the results of ancillary investigation, as opposed to those of clinical examination. We are often reminded of the old masters of the arts of physical examination who, without the assistance of pathological laboratory or X ray department, successfully diagnosed the presence and nature of disease within the body cavities. Actually it is by no means certain that the skill of the older physicians with little derangement of the organisation of the hospital or (still more important) without harm to the patient for whom the hospital exists. The square is an apt metaphor for the fourfold loyalties which a nurse owes to the patient, the hospital, the doctor, and to her own profession, especially to younger members of it. The fact that these loyalties may conflict, or at different stages of the nurse's career may assume different proportions, must not be ignored. The long years of training are designed to give her not only technical skill, but a balanced outlook. This is not easy to acquire without more leisure than a student of nursing has at her disposal. It is the more important that her previous education should fit her to adapt herself to her surroundings while retaining the critical spirit which will enable her to do her share, later on, in modernising her chosen profession. We welcome, therefore, a certain liveliness on the nursing front, whatever its cause, and are proud that through THE LANCET Commission on Nursing we have been able at least to clear the ground on which these young people will ultimately build, unencumbered by traditions which have lost their significance while retaining those which still have value.

◆

CONTROL OF INFECTION IN CHILDREN'S WARDS

WHEN children are aggregated in residential institutions it is impossible entirely to prevent the introduction, from time to time, of the common bacterial or virus infections. Apart from the resulting morbidity, and perhaps mortality, the functions of the institution are curtailed for the time to a degree which varies with the type of infection, the numbers and age-groups of those exposed and, above all, with the size and spacing of the sleeping quarters, whether these be the dormitories of a public school or orphanage or the wards of a sick children's or fever hospital. The last-named institutions are far from exempt from the introduction of infections other than those for which the children are actually admitted; the problem of the medical administrator is the safe disposal of the child who, suffering from a disease which may or may not itself be infective, is in addition incubating some unknown infection. If the fact of exposure is elicited on admission suitable measures for segregation can be taken, but, more often than not, no history of exposure is obtainable although it has been systematically sought. The child is admitted to an ordinary ward, the other susceptible inhabitants of which become, in due course, at risk. Against certain of the specific infections which may be introduced prophylactic measures are available. Passive immunisation with diphtheria antitoxin is no new thing and nowadays it is no longer absolutely necessary to close a ward infected or cross-infected with scarlet fever or measles. The source of infection having been, if possible, traced and removed, the injection of scarlet fever antitoxin (with or without the prior performance of the Dick test) or of convalescent or adult-immune measles serum will protect the remaining inmates for a number of days. Provided that all new susceptible admissions are similarly protected whilst danger of infection is still to be apprehended, the ward can continue to function with a high, but not absolute, degree of safety. But even if the similar protective properties claimed for convalescent chicken-pox and mumps serum are upheld upon further trial, these are only measures directed against a few of the specific infections which have already made their presence manifest.

The danger, however, is not confined to the so-called specific infections. With the exception of diphtheria, which is readily controlled, and infections of relatively rare occurrence, like enteric and cerebro-spinal fever which are still more readily controlled, these specific infections are not in themselves lethal. It is the introduction of non-specific infections such as the virus of the common cold or of "influenza" and the mixed flora of broncho-pneumonia amongst children already ill that is much more to be feared, not only from the impossibility of control but from the serious clinical consequences. The potentialities of these non-specific infections have perhaps been more fully appreciated by continental pædiatricians, from GRANCHER onwards, than by ourselves. GRANCHER, more than 40 years ago, realised the danger of ward infections from acute respiratory and intestinal conditions and introduced at the Enfants Malades movable screens which, when placed around cots, provided at least a measure of segregation of potential sources of infection. GRANCHER'S success prompted his pupil HUTINEL, in 1894, to construct at the Enfants Assistés his famous "boxes." These were true cubicles, the glass divisions not reaching to the ceiling, and were formed by subdividing an ordinary ward. The two lateral series of cubicles were divided by, and entered from, a wide central corridor. Each cubicle had its own window and accommodated two children. Boxes on HUTINEL'S plan are still in use in at least one large fever hospital in this country. In true cubicles of this type, provided the use of separate utensils and coats and a scrupulous technique of hand-washing is rigidly adhered to, all the common infections, save two, can be safely nursed without spread by droplet spray from one cubicle to the next. But, as the late FOORD CAIGER and others have shown, measles in the early catarrhal stage, and particularly chicken-pox in its earliest stage, cannot be so nursed without spread. Complete structural separation and asepsis is necessary for the safe management of the two diseases in these early stages. The same limitations apply, as E. H. R. HARRIES showed,[1] to the bed-isolation or invisible barrier nursing advocated by C. RUNDLE and A. H. G. BURTON,[2] though this system is highly successful in other conditions and is also economical, since no structural alterations are necessary. Given a well-trained nursing staff, and this is essential, any ward can be quickly converted to a bed-isolation ward, the system depending entirely upon adequate spacing of the

ANNOTATIONS

THE CHEMISTRY OF CARCINOGENESIS

It sometimes happens that investigations proceeding along different lines converge quite unexpectedly. The latest developments in the chemistry of carcinogenesis are a case in point. First, the patient work of organic chemists on the chemical constitution of cholesterol and allied substances has led to the provisional construction of a constitutional formula whose skeleton—if one may use the term—is a combination of four rings of carbon atoms This ring system is completely saturated, each carbon atom having all its free valencies combined with hydrogen atoms. Secondly, work on the sex hormones has brought about the isolation of the follicular hormone, œstrin, which is capable of inducing an œstral cycle in castrated animals; and the suggestion is made that it is derived from the sterols by a process which involves a partial loss of hydrogen atoms with the formation of a benzene ring in the skeleton of the four rings of carbon atoms. Hitherto these views on the constitution of œstrin have been derived solely from analytical data accumulated on naturally occurring crystalline œstrin: but striking support of their correctness has been provided from the purely synthetic aspect by Mr. J. W. Cook, D.Sc., of the Cancer Hospital, and Prof. E. C. Dodds of the Middlesex Hospital, and their co-workers, whose description of the œstrogenic activity of a ketotetrahydrophenanthren has already been mentioned in these columns. Thirdly, we have the investigations of Prof. E. L. Kennaway and his colleagues of the Cancer Hospital, who have synthesised a number of pure organic compounds capable of inducing cancer when applied locally to the skin. Here again consideration of the known chemical constitution of these carcinogenic substances has indicated the possibility that they are formed from the sterols present in the cells by an abnormal metabolism involving a similar process of dehydrogenation.

Now both œstrus and carcinogenesis have as one of their essential features cellular hyperplasia. It has been found, too, that the injection of coal-tar which can induce cancer also produces œstrus. The next step was therefore to test whether the several pure organic substances of known carcinogenic activity are capable of inducing œstrus. It was found that two of the most potent carcinogenic compounds, 5 : 6-cyclopenteno-1 : 2-benzanthracene and 1 : 2-benzpyrene, are capable of exciting œstrus. In addition several other pure organic substances, not identical chemically with œstrin, have been prepared synthetically which produced œstrus. This interesting story is told very briefly in two letters to *Nature* (Jan. 14th and Feb. 11th) by Dr. Cook and Prof. Dodds. Their experiments show that there are a number of pure organic substances which can induce œstrus, as there are a number of pure organic substances which can induce carcinogenesis, and that some of these substances are both œstrogenic and carcinogenic. Experiments are now being undertaken to show whether œstrin itself has carcinogenic power.

These findings lend strong support to the suggestion of Prof. Kennaway and Dr. Cook that carcinogenic substances can be formed from the sterols of the cell by an abnormal metabolism; but it must not be concluded that this affects the pathological conception of cancer as being at its inception a local disease. Sterols are present in every cell, and it is quite conceivable that when a sharply localised group of cells is placed under abnormal conditions they may locally produce abnormal products of sterol metabolism.

INSULIN FOR THIN PEOPLE

Because of its action in aiding the utilisation of carbohydrate and indirectly the metabolism of fat, insulin has been used experimentally in the treatment of a large number of conditions other than diabetes, of which the marasmus of infancy and tuberculosis are examples. Dr. Harry Blotner, writing from the medical clinic of the Peter Bent Brigham Hospital, Boston, reports[1] the results of treatment with insulin in 19 subjects (7 men and 12 women) who had been chronically underweight for years but were otherwise physically healthy. In all but one case previous attempts to gain weight by dietetic and hygienic means had been made and had proved unsuccessful. During the investigation the patients were recommended to eat a liberal unmeasured diet. The dosage of insulin given was in most cases 10 units three times a day, 20 to 30 minutes before meals; in two cases 10 units were given twice a day, and in three 15 to 20 units were given three times a day. The periods over which insulin was administered varied from 1 to 12 weeks; records were kept of the weight and general condition of the patients before, during, and after insulin therapy, and in seven cases estimations were made in addition of the red cell count, blood-sugar level, blood-urea and non-protein nitrogen concentrations, the basal metabolic rate, and the phenolsulphophthalein excretion. It was found that each of the patients began to gain weight at once when insulin injections were started, and that the gain was either moderately rapid and continuous throughout the period of treatment (sometimes continuing after the injections had been stopped), or else the gain in weight was at first rapid and subsequently became stationary irrespective of whether insulin was continued or not. In 13 cases the weight remained constant or went on increasing after the omission of insulin during periods of observation varying from 6 weeks to 14 months, while two patients lost eight and five pounds of the weight gained within the succeeding six months. The total gain in weight varied from 4½ to 31 lb., the added fat being as a rule distributed generally over the face, neck, breasts, abdomen, back, and buttocks. Blotner emphasises the tonic effect of the treatment and the improvement in the sense of well-being experienced by every patient. The red cell count showed an average increase of 400,000 after the administration of insulin, and the circulating blood volume an average increase of more than 10 per cent. during this period, the latter increase affecting plasma and corpuscles proportionately. This finding is regarded as evidence against the increase of weight being due to œdema; in addition, the relation between water intake and output was found to remain unchanged during and after insulin therapy in those cases examined, while in no case was there any diuresis after leaving off insulin. There seemed to be little danger of hypoglycæmia when the patients were provided with a liberal diet. It was striking that 6 of the 19 subjects showed local skin hypersensitiveness to insulin at the site of injection from one to six weeks after the beginning of treatment—a high incidence of the sign considering its comparative excelled that of their successors. The physician of to-day can still diagnose the presence of fluid in a pleural cavity, of pneumonia in a lung, or of phthisis when the disease is firmly established, as surely as could his predecessors. Like them, however, he cannot by himself distinguish with certainty between pulmonary excavation due to tuberculous caseation and cavitation of the lung due to other causes, nor can he diagnose a deep-seated tuberculous invasion of the lung tissue, whether cavitation be present or not, without the help of radiography. The touch and hearing of a blind man may indeed be more sensitive than those of a man with good eyesight, because he has learned to concentrate on the faculties he has retained, to compensate (so far as may be) for those he has lost. But if this be granted, the observations of a blind man, however sensitive his touch, still have not the value of those of a person who sees as well as feels. And if it be true that the older clinicians excelled those of a later generation in the arts of percussion and auscultation—a thesis difficult to prove—it is equally true that no amount of clinical receptiveness will enable one to detect physical signs of disease when those signs are non-existent. Radiography has proved that pulmonary tuberculosis is not detectable by physical examination unless the lesion has certain characters, and is situated near the surface of the lung. It is essential that this fact should be recognised, for if students are taught that incipient pulmonary tuberculosis can be detected by the method of light percussion and attentive auscultation, many lives will be lost which might otherwise have been saved.

---

[1] Jour. Amer. Med. Assoc., Jan. 14th, p. 88.

There is here no divorce between clinical acumen and what are called scientific methods. The practitioner must learn to recognise the clinical danger signals before he can apply his scientific knowledge; no degree of skill in microscopy or radioscopy can compensate for ignorance at the bedside. But unfortunately, in the past, far too much stress has been laid on the importance of minute differences in percussion note or barely perceptible changes in respiratory murmurs. The student who, like MACAULAY, could recognise only two tunes, the National Anthem and the other, was discouraged at the outset of his career; the practitioner whose hearing had become blunted by the passage of time found a post-graduate course in modern methods of percussion equally depressing. But common sense is more valuable in the diagnosis of pulmonary tuberculosis than an artistic imagination. Far too little emphasis has been laid on the importance of such elementary observations as the patient's appearance, the history of a hæmoptysis especially in a young person, evidence of exposure to infection, the serious significance of lassitude at a period of life when physical energy should be abounding. Few students have been taught to realise the sinister implications of a furtive and evasive attitude on the part of a patient whose cough has driven him to the doctor, or the almost conclusive evidence afforded by the adolescent's indignant denial of hæmoptysis or any other symptom which he thinks may be interpreted as an indication of consumption. A lack of clinical observation rather than defective clinical examination is responsible for a failure to realise the need for sputum tests and X ray examinations until physical signs reveal the presence of disease so advanced that a cure can no longer be expected.

Much attention is devoted to-day to such surgical procedures as thoracoplasty, adhesion-cutting, and phrenic avulsion in the treatment of pulmonary tuberculosis. Our own columns this week testify to the place they take in the thoughts of those whose work brings them into daily contact with phthisical patients. The ingenuity displayed in the treatment of advanced tuberculosis is praiseworthy and the skill displayed by surgeons who have specialised in thoracic operations is admirable. But such desperate expedients as thoracoplasty would seldom be necessary if early diagnosis was the rule rather than the exception. Pulmonary tuberculosis in the stage of the "*rundherde*" or "*frühinfiltrat*" readily yields, as a rule, to rest, whether the patient is put to bed and kept there till resolution occurs or whether he is subjected to an artificial pneumothorax carried out before there has been time for adhesions to form. The appalling death-rate among young consumptives will continue to be a reproach to the medical profession until medical students and practitioners understand the importance of the danger signals of disease, the unreliability of physical signs, the necessity for repeated sputum tests, and the immense importance of X ray examinations in the diagnosis of early lesions.

◆

THE PHARMACOLOGICAL LABORATORIES

IN a preface to the seventh annual report of the pharmacological laboratories of the Pharmaceutical Society of Great Britain, Dr. J. H. Burn, the director, says that the publication of the new revision of the British Pharmacopœia may be held to mark the completion of the first period of the laboratories' activities. During the seven years which have passed a great deal of the research has been directed to pharmacopœial problems, and the examination of manufacturers' samples has provided experience which has been available to those responsible for the biological methods introduced into the Pharmacopœia. In the new Pharmacopœia there are no less than 27 monographs which deal with animal products or with substances requiring biological tests, while the biological methods in the appendix occupy nearly 40 pages. Since the Pharmacopœia is essentially a book for the use of the pharmacist, the figures indicate how far these new remedies have entered his sphere of work. Seven years ago the lack of familiarity on the part of the pharmacist with these substances would have made it difficult to introduce so many into the Pharmacopœia, and Dr. Burn believes that the establishment of the laboratories has played a part in changing this position. The laboratories have been the means of giving the pharmacist a growing acquaintance with biological methods and with the principles which underlie them. Gradually a closer connexion between pharmaceutical and medical science is being gained, which was impossible so long as the pharmaceutical outlook was directed to chemistry only, and not to biology also.

up an agreement and final Act intended to supplement the Geneva agreement, after reviewing the position and considering "what further measures can be taken to bring about the suppression of the use of opium for smoking ?" These new agreements set up Government monopolies in opium, provided for registration of smokers and rationing supplies, for opening a special opium account showing the revenue and expenditure, and for the treatment of addicts. The conference also concluded "that no radical measures for the suppression of the practice of opium-smoking are practicable while the production of opium continues on an enormous scale." This obvious conclusion lends force to the preparations which are on foot at Geneva for achieving the limitation of the production of the opium poppy and the coca leaf to the amounts required for medical and scientific purposes.

STAINLESS STEEL IN DENTISTRY

THE high price of gold has materially affected the dentist, who has always used this metal in the making of various appliances used in the mouth as well as for filling teeth. Hence much interest is being taken in the suitability of stainless steel for dental appliances, and it seems likely that in time this metal will largely replace precious metals in the construction of dentures. The first effort in this direction was made in Germany during the war.[1] The firm of Krupp experimented in the use of stainless steel with much success, and since then this metal has been widely used with excellent results. At first it was found difficult to strike up steel to the shape of the mouth, on account of its refractory nature as compared with gold. But Krupp's have a laboratory where models of mouths are sent with instructions from the dentist; the steel plate is struck up to the design marked out and tags are attached to it to which the vulcanite supporting the teeth adheres; and the dentist is then able to proceed with the remaining stages in the making of the denture. In this country progress in the use of steel has not lagged far behind, and a large number of steel dentures have been made and have proved highly satisfactory. The advantages of steel are its lightness, strength, and cheapness. It is not possible to cast the metal, as is often done with gold, so that the adaptation to the mouth is not as close. But in suitable cases the retention appears to be good. One of the difficulties hitherto has been the attachment of tags or bands to plates, since soldering is difficult and the joint not always secure. For this reason the use of steel for orthodontic appliances has only been tried tentatively; for in such appliances it is essential to be able to solder springs to move the misplaced teeth. But the introduction of spot-welding by electricity seems likely to overcome this serious defect. De Coster, of Brussels, has devised an apparatus capable of effecting this, and in this country F. I. and W. I. Robertson[2] have also evolved a satisfactory technique for the purpose, so that it may now be said that the last obstacle to the use of stainless steel for many purposes in dentistry has been overcome. For orthodontic purposes this material seems to be ideal. It is elastic, springy, non-tarnishable, and can be drawn out into wires of any gauge, while its cheapness is such that a supply sufficient to last the dentist his whole professional life can be bought for a few pounds. There is no doubt that gold must still be required for various purposes, but before many years stainless steel will probably have replaced precious metals for dentures and orthodontic appliances. This will be a definite advantage both to patient and dentist.

ANÆSTHETICS ABROAD

A PAPER in the January issue of the *British Journal of Anæsthesia* describes the prevalent methods of anæsthesia in France as demonstrated by the answers to a questionnaire circulated by the author, Dr. Flexer-Lawton, in coöperation with Dr. Desmarest, chief surgeon of the Ambroise-Paré Hospital, Paris. The most remarkable fact that emerges is the little progress that the employment of gas-and-oxygen appears to have made hitherto in that country. This is no doubt only a natural corollary to the comparatively backward state of France—as of other continental countries—as regards specialists in anæsthetics. There are scarcely any men in these countries comparable to the large body of practitioners in this country who hold the post of anæsthetist to a big hospital and devote all or almost all of their professional activity to giving aæsthetics and teaching others how to give them. Consequently any method which requires much practice or involves the use of complicated apparatus makes little appeal to those giving anæsthetics abroad, for they are for the most part men whose ultimate ambition is not to give anæsthetics at all but to act as surgeons. Another result of this state of affairs is the preponderance of local over general methods; for the local analgesic does and preferably should remain in the hands of the surgeon. Forty-two of those who answered the questionnaire expressed a preference for ether, 42 for Schleich's mixture (a combination of ether, chloroform, and ethyl chloride), and 11 for chloroform. Naturally most of those who answered made it plain that they did not use solely their favourite anæsthetic but exercised a certain amount of selection according to the requirements of individual patients. The use of avertin seems to have achieved a certain amount of popularity among French surgeons, but with this exception we find little mention of any of the "basal narcotics" in the article. Dr. Flexer-Lawton concludes with the pious wish that in a little while there will be in France both anæsthetic journals and anæsthetic schools.

THE TREATMENT OF SARCOMA OF BONE

THE treatment of sarcoma of bone offers a problem difficult of solution, for it is notorious that whatever measures are adopted the chances of cure are exceedingly small. Discussing the question with reference to sarcomata arising in the neighbourhood of the knee-joint, H. J. Laméris[1] has recently stated that of his own cases the proportion surviving for as much as two years after operation (amputation or disarticulation) is less than 25 per cent. The growth tends to spread longitudinally in the medullary cavity when once this is invaded; hence, local removal is apt to be followed by local recurrence. The great obstacle to cure is however the well-known tendency of bone sarcomata to undergo metastasis to the lungs. Disarticulation as an alternative to local removal is not an operation to be lightly undertaken when it is remembered that in most cases it is useless as a curative measure, since the lungs are already infected. With regard to treatment by means of X rays or radium, Laméris points out that, although sufficient time has not yet elapsed for a definite conclusion to be reached, the rarity in diabetics. Blotner regards the increase in weight as being due to improved absorption and assimilation, and to the increased intake of food (suggested by the study of the nitrogen excretion in the urine) brought about by the tonic action of the insulin, and possibly to some extent by the psychological effects of treatment.

SIR JOHN ARTHUR THOMSON

Sir (John) Arthur Thomson, for 30 years professor of natural history in the University of Aberdeen, was probably the writer best known to the public as an interpreter of zoology from its bases to its multiple phenomena. He was a great teacher, and made a mark early in his career by his instructional courses on biology at the Edinburgh medical school, while his Gifford Lectures, delivered before the University of St. Andrews in 1915, proved him to be a profound thinker with a broad philosophic outlook. It is possible that the profuseness of his contributions to popular literature rather obscured than revealed his scientific qualifications; if this has been so an injustice has been done to the value of his work. His popular disquisitions over a great range of natural history were thoroughly grounded on learning and experience, and the ease of style and simplicity of doctrine were invaluable qualities for an appeal to public attention. The number of persons to whom the simple and even the elaborate phenomena, illustrating the story of life, have been made comprehensible by his voice and pen must be enormous, and the man who thus made straight the paths of science for adventurers into a difficult country was a public benefactor.

SIGHT TESTING AND DISPENSING

Is it or is it not to the interest of the whole community that the prescription of glasses for errors of refraction should be in the hands of qualified medical men and women? For many reasons we believe that it is. Opticians are divided into two sections: the majority who test the sight of all who desire it, and rely upon the sale of spectacles for their profit; and the minority who agree not to test the sight or prescribe glasses but to confine themselves to the dispensing of surgeons' prescriptions. The customers of the first section comprise the majority of the general public, including most of the insured persons entitled to ophthalmic benefit, and the profits of these opticians depend upon the number of customers they can attract and of glasses purchased. Appealing as they do direct to the public, advertisement in its various forms is one of the essentials of commercial success. Dispensing opticians, on the other hand, depend mainly on the recommendation of ophthalmic surgeons, whose prescriptions are quite useless unless they can rely on their being accurately dispensed in well-fitting frames. According to a latter recently circulated by the Association of Dispensing Opticians, the proportion of patients dealt with by the prescribing opticians to those bringing prescriptions from qualified surgeons is about six to one, and the tendency at present is for this preponderance to increase. The National Ophthalmic Treatment Board, which was set up through the coöperation of the dispensing opticians with the British Medical Association some three years ago, with the object of providing specialist aid for patients to whom an ordinary fee is prohibitive, has had a certain amount of success, and there is now a fairly wide choice of opticians, not only in central, but in greater London and in the provinces, who decline to do any eye-testing at all.[1] It is a regrettable fact, the letter states, that a large number of surgeons still send their patients to sight-testing opticians and not to the local dispensing optician to have their glasses made up. The more ambitious section of the sight-testing opticians, represented by their journal *The Optician*, have for years been endeavouring to qualify themselves, not only to deal with errors of refraction and muscle balance, but also to recognise such conditions as cataract and glaucoma. If they succeed in their endeavours to achieve State registration the distinction between ophthalmic surgeons or "oculists" and opticians, already found sufficiently hard to grasp by the large public, will inevitably become still harder. All ophthalmic surgeons who believe in the importance of keeping the treatment of visual defects of whatever kind in medical hands should take these facts to heart.

OPIUM-SMOKING IN THE FAR EAST

It is reported from Rangoon that the Burmese Government suffered their first defeat in the Legislative Council on Feb. 11th when the Minister for Forests moved that the draft agreements, adopted by the Opium Conference at Bangkok in November, 1931, should be ratified so far as it applied to Burma. The motion, which does not appear to have been debated, was defeated by 30 votes to 23. According to the commission of the League of Nations which visited the Far East there are more opium eaters than smokers in Burma. The smokers are chiefly Chinese. In Upper Burma all consumption of opium by Burmans is illegal, but in Lower Burma there are many registered and unregistered addicts. "In 1924 the Government decided to register all opium-smokers in order to give effect to the stipulations of the Hague Opium Convention which obliged Governments to take steps for the total suppression of opium-smoking, but carried no such obligation with regard to the eating of opium." It will be remembered that at the Hague Opium Convention of 1912 the contracting Powers pledged themselves to bring about the gradual and effective suppression of the manufacture of smoking (or prepared) opium, and to prohibit its import and export either immediately or as soon as possible. The Geneva conference of 1925 by a protocol relaxed these requirements, and postponed the suppression of smoking opium until not more than 15 years from a date when a commission should have decided that the illicit export of the drug from producing countries no longer constituted an obstacle to the reduction of opium-smoking in consuming countries. A commission which was set up in 1928 and reported in October, 1930, was instructed to inquire as to the situation in the Far East, the measures taken to carry out the agreements of 1912 and 1925, and the difficulties which the illicit traffic presented to the fulfilment of these obligations. That commission fixed no date from which the 15 years of grace were to run, but it arrived at the conclusion "that the limitation and control of poppy cultivation would alone assure the total suppression of opium-smoking." It also pointed out that in some Far Eastern territories opium provided a source of revenue for balancing their budgets, "sometimes as much as one-third of the total revenue being obtained from opium." In November, 1931, a conference held at Bangkok drew

SPECIAL ARTICLES

ESSENTIALS OF A NATIONAL MEDICAL SERVICE

ON Feb. 3rd Sir HENRY BRACKENBURY, chairman of the council of the British Medical Association, addressed a large meeting at Brighton on the Essentials of a National Medical Service. The chair was taken by Dr. J. O. SUMMERHAYES, and the meeting was arranged by the local division of the B.M.A.

Sir Henry laid down four conditions for any national medical service, namely :—

(1) The service must offer scope and opportunity for the achievement of the three-fold aim of modern medicine: curative, preventive, and constructive.

(2) Any service of the kind should afford opportunities for clinical and laboratory research.

(3) The service should be based upon the provision of a general practitioner for every individual, and the relationship between doctor and patient should be, as in private practice, primarily, if not solely, between those two, with no one else intervening, and should be a free relationship—free both in the sense that the doctor was not confined to some limited or prescribed system within which he must treat his patients, and in the sense that there was free choice both of patient by doctor, and, especially, of doctor by patient.

(4) The service must be a complete one, providing not only general practitioner service, but consultant and specialist services, various ancillary services, and necessary hospital accommodation.

He went on to say that the medical profession was in favour of providing this national medical service only for those who could not provide what they required for themselves. Its attitude in this matter was determined not by monetary considerations (for it was conceivable that an agreement might be negotiated on the widest basis which would be equally remunerative to the doctors), but it was because of their jealousy for the preservation of the fundamental conditions in the relationship of doctor and patient, which were completely preserved in private practice. As to the method of provision, the profession would favour an extension of the compulsory insurance system, partly because experience had shown that within that system it was possible to preserve the fundamental conditions of relationship just mentioned, and also because under that system a certain amount of experience had already been accumulated. He emphasised the desirability of unification in administration of the health services of the country, especially in bringing together the machinery responsible for public health and poor-law administration, and that responsible for the insurance medical service. In all these questions of administration the medical profession should be consulted, represented to some extent upon the authorities concerned, and trusted as completely as possible in matters of internal professional discipline.

Turning to institutional provision, he pointed out that hospitals were shifting away from the old voluntary basis to an increasing basis of self-support. It was very necessary, in view of this development, that the services of the medical and surgical staff should be recognised financially in some form or other, and a hospital staff fund was one of the features of the modern hospital conceived of as a piece of machinery within the national medical service. In conclusion, he referred to certain other ideas which the profession would like to see carried into effect. One of these was the employment as far as possible of the members of the local medical profession by local authorities in discharging their functions towards certain classes of individuals or in respect to certain diseases. Again, practitioners should be brought into closer relationship with, or be considered an integral part of, the public health service of the locality; the services should not be walled off from one another. The present period during which fresh enterprise was held up on the ground of economy constituted, he said, a breathing-space during which it was a very good thing to explore certain ideas and to endeavour to obtain harmony and agreement as far as possible, so that when a scheme was brought forward it might move to fruition with the widest possible consent.

THE TSETSE FLY

IN 1925 a Tsetse Fly Committee was set up as a sub-committee of the Committee of Civil Research (now absorbed into the Economic Advisory Council). This body was charged to prepare a practical scheme of British inquiry and action aimed at controlling the tsetse fly as a carrier of human and animal trypanosomiasis and at a preventive and curative treatment of that disease in man and animals. It has now issued its report.[1] A preliminary report published in 1925 recommended that research should be centralised under a trypanosomiasis committee and assisted by parliamentary and local government grants and by subscriptions. This proposal did not, however, meet with the approval of the officers administering the various territories, and since 1927 the Tsetse Fly Committee has itself acted as an advisory committee on human and animal trypanosomiasis.

It is now established that nagana (trypanosomiasis of animals) is caused by any of three trypanosomes: *T. brucei*, *T. congolense*, and *T. vivax*. Often all three are found together in one animal, but *T. brucei* is the important agent in horses and dogs, and *T. congolense* and *T. vivax* in cattle, the former being the more virulent. The course of the disease varies very greatly, according to the infective agent, to the host, to the conditions, such as rain, food, work, and intercurrent disease. Different strains vary widely in virulence. Besides the recognised acute, subacute, and chronic forms of infection there is a latent or dormant form, characterised by an absence of anæmia and other signs of ill-health. It is common in all the East African territories; in Northern Nigeria 20–30 per cent. of cattle show it. Host and parasite have attained an equilibrium which may last throughout life, but is easily upset by a change in conditions of food and work and by exposure to such a disease as rinderpest. This "premunity" may be to local strains of trypanosome only, and it is more easily acquired by the young than by the adult. At present, authorities do not know whether the "immune" herds are really immune or whether their resistance is only to local strains or is a "premunity." Some preliminary cross-breeding work has suggested that resistance is transmissible.

DIAGNOSIS AND TREATMENT IN ANIMALS AND MAN

Recent work has shown more and more the difficulties of diagnosis. Inoculation of Halarsine and Antimosan causes an increase in the number of circulating parasites, and may prove useful. Complement fixation and the adhesion phenomenon are results so far reported are not encouraging. While locally the initial effect of treatment is often marked, growth usually recommences after a short time despite continued applications, while the problem of pulmonary metastases has also to be faced.

---

[1] Economic Advisory Council. Tsetse Fly Committee Report. London: H.M. Stationery Office. 1933. Pp. 27. 6*d*.

Laméris holds that early and radical operation is the best procedure, since on rare occasions a cure has resulted. It may be argued, also, that even if cure is not to be expected the patient's condition, both physical and mental, may be so much improved by removal of the primary growth as to justify operation. The psychological effect of a non-possumus attitude on the surgeon's part may be profoundly depressing; and by the mere fact that something has been done for him the patient's life may be rendered much more tolerable, even if it is not lengthened. It does not, however, follow that so mutilating an operation as disarticulation is the best measure. Many surgeons advocate less radical procedures, such as free local removal followed by grafting, on the ground that if metastasis has not already occurred this will be sufficient, while if it has occurred no operation is of any avail. The decisive factor in prognosis is the stage, early or late, at which the patient comes under treatment.

PSEUDOMENSTRUATION

THE histological alterations in the uterus and ovaries during the sexual cycle were first worked out on the human female, and largely through the work of R. Schröder it became evident that ovulation was limited to the intermenstrual phase. As a result, gynæcologists accepted the view that menstrual bleeding was always preceded by ovulation. Later, however, G. W. Corner and others found that in monkeys (*Macacus rhesus*) cyclical bleeding often occurs in the absence of ovulation; and C. Mazer and A. J. Zizerman[1] now claim that they have demonstrated anovular bleeding in women. In macaques such "pseudomenstruation" consists of disintegration of what is called the "interval" type of endometrium; according to the views quoted in our leading article of Jan. 21st (p. 146) this "interval" endometrium has hypertrophied under the influence of œstrin but has never undergone a pregestational stage under the influence of a corpus luteum. Mazer and Zizerman base their belief in human pseudomenstruation on three pieces of evidence. In the first place, it has sometimes happened that at abdominal operations on regularly menstruating women who were at the end of the menstrual cycle no corpus luteum was seen in the ovaries. Secondly, they have found that in these cases the female sex hormones were absent from the circulating blood before menstruation. Thirdly, they state that in a series of 41 cases of functional sterility, scrapings from the uterus of 12 patients had the structure of an interval endometrium without premenstrual—or rather pregestational—hypertrophy, although they were taken shortly before menstruation was due. They imply that in cases of this kind the sterility can be explained by assuming absence of ovulation and replacement of normal menstruation by anovular cyclical bleeding. In this country, at least, little reliance is placed upon the demonstration of a corpus luteum in the ovaries by inspection alone; it is a well-known experience that often a corpus luteum can only be demonstrated by incising the ovaries. Again, there is not the same confidence about the female sex hormone test as there seems to be in America. The third piece of evidence they bring forward, however, is much more important, and further work is immediately required to corroborate these histological findings. They are in direct opposition to those of Schröder in Germany and of Wilfred Shaw in this country.

LORD SYDENHAM

THE public career of the late Lord Sydenham is so well known that no comment upon it can be required for the information of our readers. A great scientific soldier and military administrator he sat on Lord Esher's Committee on War Office Reconstruction and later proved himself an admirable governor of Bombay. But he had a direct and important connexion with the medical profession through his acceptance of the position of chairman of the Royal Commission on Venereal Disease appointed in 1913 by Mr. Asquith. Here his comprehension of the difficult medical and social problems that had to be dealt with proved of eminent service, and as a result he became chairman of the National Council for Combating Venereal Diseases (as the British Social Hygiene Council was first entitled). Here he found the work hard and sometimes distasteful, but he proved himself an excellent chief.

RESEARCH SCHOLARSHIPS IN HÆMATOLOGY

THE Lady Tata Memorial Trust was founded in April of last year by the late Sir Dorabji Tata, of Bombay, in order to promote the advancement of medicine by research into the diseases of the blood, with special reference to the leukæmias. Research scholarships and fellowships, and grants in aid of research work, are to be given in part to Indians and institutions in India, and in part to workers in other countries. Two scholarships, each of the value of £400, will be open for award in June, 1933, to men or women in the British Commonwealth, exclusive of India, for research work on blood diseases, with special reference to leukæmias. Each will be tenable for a year, from Oct. 1st, and renewable up to a normal maximum tenure of three years. The scholarships will ordinarily be awarded on a whole-time basis, but a candidate holding a part-time teaching post may be allowed to retain this if this will not prevent him from giving his chief interest and energies to the research. Applications in proper form must reach the secretary, Dr. H. S. Patel, Lady Tata Memorial Trust, Capel House, 62, New Broad-street, London, E.C.2, before April 15th.

TRAINING IN MENTAL HEALTH FOR SOCIAL WORKERS

IN our advertisement columns last week appeared an invitation from the London School of Economics and Political Science to social workers to apply for admission to a one-year course of theoretical and practical training in mental health. Substantial scholarships are available to successful candidates, and the obtaining of a certificate to knowledge of the principles of social science makes a sound introduction to a career that is useful alike to those who follow it and to the public. The training in mental science will be directed towards the qualification of social workers to help in clinics for the treatment of adult mental patients, and for child guidance; indeed, where mental behaviour constitutes the difficulty, the social worker, with the equipment to be obtained at the school, should be prepared to cope with it. Applications for scholarships should be made before May 1st to the secretary of the London School of Economics (Houghton-street, Aldwych, London, W.C.2) who will furnish further information.

---

[1] Amer. Jour. Surg., 1932, n.s. xviii., 332.

counsel for the plaintiff, sounds substantial until the other side can be heard. The medical profession must not be over-confident of the safeguard which the Act provided; it is a preliminary obstacle which a plaintiff may manage to surmount. Juries, as the author of the catechism truly says, are reluctant to find anyone insane. Mental patients seem to find it easy to produce abundant evidence to prove themselves to have been at all times of sound mind. One might add that the certifying doctor can be certain that members of his own profession will go into the witness-box to attack with their *ex post facto* criticisms the opinion he formed when examining the patient long ago.

A Lunatic Wandering at Large

Although juries dislike finding verdicts of insanity, they feel (like the rest of the general public) a horror of the dangers of the escaped lunatic. Such dangers, when they occur, deserve publicity; they help to remind the ordinary citizen of the protection which the certifying doctor supplies. On Feb. 4th at Willesden police-court a story was told of a mental patient, found at large, who was brandishing a knife and threatening murder to his wife. The man, it seems, had been certified insane and had been sent to the county mental hospital, being released therefrom on his father's promise to send him to a private institution. From the latter he had been allowed out on parole to live with his father at Mitcham. When he visited his wife and children at Willesden and put them in fear, a warrant was obtained for his arrest. But on the following day the warrant officer had to apply for the withdrawal of the warrant, which had been issued on a misunderstanding of the law. An insane person cannot commit the offence of murder or attempted murder or any other offence. The warrant officer explained to the court that the case was one for the Lunacy Commissioners. Police officers in the district, although they had no power to arrest him, had been warned that the patient was a dangerous lunatic who, if seen, should be detained pending the decision of the authorities. Section 15 of the Lunacy Act directs constables and relieving officers who have knowledge that any person (whether rate-aided or not) wandering at large in their district is deemed to be a lunatic to apprehend him forthwith and take him before a justice who must then call in a medical practitioner and, after examination and inquiry, make any necessary order for the patient's detention in an institution for mental patients. The wife's solicitor protested against his client's being left unprotected against a possibly murderous assault. He asked that at any rate the warrant should not be withdrawn until he had an opportunity to go to the High Court for a mandamus. The magistrate allowed the warrant to remain from the Saturday morning to the following Monday, and the situation has presumably been met by re-establishing control and supervision over the patient.

THE MANCHESTER HOSPITALS.—Manchester Royal Infirmary last year admitted 11,465 in-patients, and treated 48,998 out-patients, of whom over 29,000 were accident cases. The year closed with a deficit of £8423; legacies were £11,000 less. The proposed new wing containing 100 pay-beds is estimated to cost £90,000.—Last year there were 2585 in-patients at Manchester Royal Eye Hospital, and 10 more beds have been added, making a total of 160. There were 28,422 out-patients, an increase of 920, and 137 paying patients.—Several of the Manchester institutions are being fitted with talking-film apparatus, notably the epileptic colony at Langho, and the tuberculosis sanatorium at Baguley. The Crossley sanatorium, on the borders of Delamere forest, which is attached to the Manchester Consumption Hospital, has already had a first performance.

BUCHAREST

(FROM OUR OWN CORRESPONDENT)

PROPRIETARY REMEDIES *v.* DOCTORS

OWING to the economic depression the Rumanian medical profession outside the capital, Bucharest, is suffering from unheard-of idleness. Three-quarters of the population are unable to pay for the doctor's services and therefore do not ask for them; the remaining quarter, because money is very scarce, under the influence of mass psychology are trying to save all unnecessary expenses, including of course the payment of a physician. Medical help is sought only when there is great danger or when the patient is already on his death-bed. This unhappy state of affairs is being exploited by manufacturers of proprietary medicines, some of whom are advertising their wares widely, shrewdly enumerating a whole series of indications which will wheedle the last pennies out of the people. Even in the smallest village, in the most unimportant journals, the Laboratoires —— are proclaiming that their products cure arterio-sclerosis, Bright's disease, and almost everything else. This same firm advertises a sandalwood preparation which is supposed to cure gonorrhœa in all its stages, cystitis, prostatitis, and "hypertrophy of the prostate." To such bombastic advertisements even the educated classes fall victim, and thus perhaps delay the proper medical treatment until too late. The Medical Chamber, recognising the damage that such proprietary medicines are doing to the careworn medical profession, is proposing to the Ministry of Internal Affairs that advertisements of such remedies in the newspapers should be censored by a special board appointed by the Ministry of Public Health, under penalties which might be contributed to the fund for the widows and orphans of physicians. The memorandum will argue that it is the duty of the State to protect its subjects from obvious frauds. If a jeweller sells a brass ring and passes it for a gold ring, he is liable to severe punishment. In the same way if a credulous man buys a medicine which is stated to cure hypertrophy of the prostate and it does not, he is cheated and the beguiler deserves just as much punishment as the fraudulent jeweller. The medical profession awaits the decision of the Ministry with great curiosity.

VENEREAL DISEASES IN THE ARMY

A census of venereal patients, be it made with ever so much care, is always incomplete, partly because of the great number of irregular practitioners or quacks who compete with medical men in treating venereal diseases. Owing also to the long duration of these infections, those affected often lose patience and go from one medical man to another, with the result that the same patient appears in the records several times. In the military statistics, however, all these difficulties of the enumeration are avoided and trustworthy data are obtained. According to these, the prevalence of venereal diseases per 1000 men in the army was 69·8 in 1929 and 67·4 in 1930. The amount of syphilis is held to be decreasing, because in 1930 and since that year the soldiers have been examined once a week by venereal specialists, and if anything is found they are sent to special hospitals where they are kept until radically cured. Those suffering from syphilis are recalled every three months for a course of treatment through the first year, and afterwards, for two years, they undergo a blood test every six months.

very reliable for some forms, and could probably be adapted for all, but require the facilities of a laboratory. The formol-gel test is four times as accurate as microscopic examination for the *T. soudanense* infection of camels, in which the mercuric chloride test is also very delicate and accurate, though it is unreliable in other animals. The success with the camel encourages the hope that equally reliable methods may be found in other animals, but at present reliance has usually to be placed on microscopic examination of blood films and gland smears.

Many drugs have been tried without success. Tryparsamide has little curative value but will protect against *T. vivax* long enough for cattle to be driven safely through a fly belt. The efficacy of Naganol depends on the strain; it is effective against *T. brucei* and *T. soudanense*. Antimony tartrates are useful for *T. congolense* and *T. vivax*, but most of the animals so treated are "premunised" rather than cured; these drugs are cheap, but are not without dangers such as parenchymatous hepatitis. Antimosan seems to have the properties of the tartrates without their drawbacks, but it is more expensive.

Other than drugs and fly eradication, the methods of control of animal trypanosomiasis are: breeding immune herds, isolating infected animals quickly, dipping, chemical prophylaxis, immunisation, and the prevention of rinderpest. Losses in a herd can be kept very low if the disease is diagnosed early and the victims removed at once. Repeated arsenical dipping retards the development of the infection, but dipping is of little prophylactic value. Trypanocidal agents can protect animals for a very short period, but the method has not otherwise offered much promise. Nor have attempts at immunisation yielded satisfactory results up to date, but it seems probable that animals could be "premunised" against the two or three species of trypanosome with which they are likely to come in contact. It has been urged, however, that the existence of large "premunised" herds would favour the multiplication of flies and provide a reservoir of infection.

IN THE TREATMENT OF HUMAN TRYPANOSOMIASIS

The two drugs chiefly studied since 1925 are Germanin (Bayer 205) and Tryparsamide. The former is curative in the early stages of *T. gambiense* infection, but less certain with *T. rhodesiense*. The present tendency is to give germanin first and a course of tryparsamide later, but tryparsamide is the drug of choice if the central nervous system is implicated; it can be given intravenously, intramuscularly, or subcutaneously. So satisfactory are the results that Congo natives have now as much confidence in the treatment of sleeping sickness as in that of yaws. Germanin has an additional prophylactic value; it seems definitely to prevent the development of an infection. One authority recommends a quarterly dose of a gramme.

Since animals may form a reservoir of infection for *T. rhodesiense*, an important preventive measure in Tanganyika is bringing the natives out of fly-infested forests and establishing them in large clearings.

CONTROL OF THE FLY

Over large stretches of Africa no economic progress will be possible until the tsetse-fly problem has been solved. In extreme cases at present it may be necessary to evacuate the population and leave the fly in possession. The cost of extensive bush clearance is prohibitive, and reclamation by settlement has a limited application, as the bush rapidly springs up again if the clearings are not cultivated. A cheap and effective way of poisoning trees has been discovered, but some varieties are not susceptible to it. More and more ways of killing trees are being evolved, and properly organised grass fires will eradicate the fly for several years. Tsetse areas are sometimes divided into manageable blocks by strip clearings, and in Tanganyika experiments are being made with game barriers. Some tsetses cannot live in dense thicket, and fly barriers can be made by planting broad strips of thicket; this is a very promising development. Satisfactory progress has also been made in catching the flies with hand nets and traps.

There is no royal road to the elimination of the tsetse fly; the measures required differ according to the kind of fly, the nature of the country, and the habits of the natives. Most valuable pioneer work has been done in Tanganyika, where 70 square miles of tsetse-infected bush have been cleared and reoccupied. Throughout another 80 square miles flies have been eradicated or greatly reduced by grass fires, and a corridor clearing has given access to a fine stretch of 150 square miles of grazing. The committee looks forward confidently to the time when it will be possible in suitable areas to eradicate the tsetse at a relatively small cost. The work, however, needs a special staff of trained men. Research for improved methods is a problem of great urgency and practical importance, and the committee hopes that every effort will be made to provide the necessary funds for this work, the successful conclusion of which is vital to all the fly-infested territories of Africa.

MEDICINE AND THE LAW

Hints for Lunacy Certification

FOR doctors who are called upon to perform the duties and incur the risks of lunacy certification a catechism has been compiled and published by one who has experience of the pitfalls of this class of work.[1] The startling amount of damages awarded in the Harnett *v.* Bond litigation is a reminder that the risks are serious. A practitioner who wishes to be on the safe side of the law might do much worse than study the 17 questions which make up the catechism. They are too long to learn by heart but a duplicate set of them is conveniently printed on pages intended to be detached and carried in the pocket for quick reference. If, after studying them, the practitioner can feel that his certificate meets all their requirements, he need fear no verdict in the years to come. Here, for a sample, are questions 7 and 8 in the series. "Have I certified this patient on hearsay evidence or (as I should) only on what I observe myself? Have I made every endeavour to prove that the facts communicated by others are facts?" Doctors who approach the unwelcome task of certification without the confidence of experience will find it worth while to take trouble. It is a mistake to suppose that the Mental Treatment Act of 1930 gave them immunity. The protection given by the Act was a matter of procedure rather than of principle. In cases of the Harnett *v.* Bond type the plaintiff has to prove either bad faith or want of reasonable care. He cannot now proceed with his claim unless the High Court is satisfied that there is "substantial ground" for his allegation of bad faith or want of reasonable care. But any sort of claim, if stated *ex parte* by eloquent since, as a general rule, there is more variation in this department than in the wards. Having seen all the new patients, I see a few of the old patients—those who have to be followed up as of special interest. A visit will be paid to the out-patient theatre to supervise the injection of varicose veins and the performance of other minor operations by the students when there should still be time for a grateful cup of tea at 4.30 P.M., when a lecture has to be delivered on some surgical condition. My chief assistant will have arranged for the cases to be demonstrated and have had a series of pathological specimens illustrating the condition set out on the bench. At the end of the lecture a short cinematograph film illustrating the method of operating on this particular surgical condition is shown, and there can be no doubt that teaching through the cinematograph has come to stay.

---

[1] Safeguards in Compiling a Certificate for the Insane. By Horace B. Hill, M.R.C.P. London: Arthur H. Stockwell, Ltd. Pp. 31. 2*s.* 6*d.*

On the two afternoons devoted to operations the list keeps me busy till 6.30 P.M., or even later. If possible, nursing-home patients are visited before dinner, unless consultations on the way home have been arranged at the last moment. This situation is a good example of the strain of the surgeon's life, already alluded to. The dilemmas cannot be escaped from, but have to be met in accordance with circumstances, as dictated by the respective seriousness of the simultaneous calls upon time. As a rule the public is reasonable; where it is not one must put the best face possible on the situation. Dinner should be the most important meal of the day, taken at leisure, but often an emergency call to a distance, an extra case on the list at the hospital, or a consultation arranged at a late hour to suit the convenience of a patient or a practitioner may interfere with the time-table.

THE EVENING

Medical societies exist in profusion in London; they still continue to multiply, and the doctor is often lured into speaking at an evening meeting when he would certainly advise other people to stay at home and take it easy. But if he has been booked to join in a discussion he must go, and from such interchange of experiences he gains valuable breadth of view. Or he may have to attend a medical board meeting in the evening, held at his own house or that of a colleague; while he may have an examining appointment, compelling him to mark papers for a weary period; and just as he has got settled down the telephone rings, and the car has to be requisitioned in order that he may perform an emergency operation in a cottage hospital to which he is attached. It is true that on journeys such as these he may find an opportunity for thinking about the plans for the morrow, but sometimes the concentration needed cannot be found. On arrival, the patient is seen, and if a diagnosis is made, showing that operation is needed, the patient is given an anæsthetic, the area is prepared and the operation is performed with the coöperation of the local practitioner. The time taken over this operation may be short or considerable, and trouble over the administration of the anæsthetic may complicate matters—one has to be prepared for many things—but sooner or later the operation is completed and, considering everything, the patient is returned to bed in quite a good condition. Where such emergencies occur during the period of examinations, the task of completing the marking of the papers has to be undertaken in the small hours of the morning, as the marks are required for the viva voce examination which takes place in the afternoon of the following day. Of course, I am not here describing an average evening, but am indicating what may occur and have to be provided for. When the emergency operation coincides with the immediate necessity of marking examination papers the position is a particularly trying one.

And there are other things besides urgent professional calls which may bring home to the hospital surgeon that his evening time is not his own to dispose of, though he has many uses to which he wishes to put it. I have indicated, in speaking of the general work associated with his job, the part to be played by the hospital surgeon in the administration of the hospital and the school. These activities bring with them evening work. Articles for medical papers, the hospital reports, and the medical journal of the school may have to be prepared, the reports of sub-committees may have to be drafted or scrutinised, lectures have to be put into shape, calling for the reading of the literature, at any rate, of one's own subject. And a book may be on the stocks. I say nothing of social engagements in the evening outside those of a professional character. Here every one is a law to himself or herself, as far as independence permits, but I have heard what "all work and no play" make of Jack.

The hospital surgeon's life is not a restful one; it is sometimes a hard one, and its material reward is capricious. He never knows what his next case is likely to be, but as new things turn up they provide recurring stimuli. The dilemmas of practice may sorely try him—this is a matter of temperament—but the triumph over them yields compensating satisfaction. He whom the life suits would not exchange it for any other.

THE SERVICES

ROYAL NAVAL MEDICAL SERVICE

Surg. Comdr. F. G. H. R. Black is placed on the retd. list.

Surg. Lt.-Comdr. J. H. B. Crosbie to be Surg. Comdr.

The following appointments are notified: Surg. Comdrs. C. G. Sprague to *Vindictive;* A. G. McKee to *Curacoa;* and A. E. P. Cheesman to *Malabar*, for Bermuda Dockyard.

ROYAL ARMY MEDICAL CORPS

M. S. W. Bisdee and J. Walsh to be Lts. (on prob.).

Lt. (on prob.) M. S. W. Bisdee is secd., under the provisions of Art. 213, Royal Warrant, for Pay and Promotion, 1931.

Lt. (on prob.) G. A. Kane resigns his commn.

ARMY DENTAL CORPS

H. C. Dobbie to be Lt. (on prob.).

INDIAN MEDICAL SERVICE

Lt.-Col. H. E. Stanger-Leathes is apptd. Hon. Surg. to The King, and promoted Bt. Col., vice Maj.-Gen. C. Hudson (retd.).

Col. W. R. J. Scroggie retires.

COLONIAL MEDICAL SERVICE

Dr. K. C. Mackenzie has been appointed Medical Officer at the Gold Coast; Dr. J. R. Forde has been promoted to Senior Medical Officer at the Gold Coast: and Dr. J. F. C. Haslam becomes Chief Medical Officer, Barbados.

DEATHS IN THE SERVICES

The death is announced from Melbourne of Major-General Sir George Cuscaden at the age of 76. Sir George, who during the war was Director-General of the Australian Medical Service, had previously seen service in the Egyptian War of 1882.

MONMOUTHSHIRE ISOLATION HOSPITALS.—Dr. D. Rocyn-Jones, the county medical officer, reporting upon isolation hospital facilities in Monmouthshire, states that "there is not in existence at present a single hospital in the administrative county which can be regarded from all standpoints as satisfying the requirements of the Ministry of Health in the matter of adequate facilities and arrangements for the isolation of the infectious sick." He adds: "It can be definitely stated that the facilities for the isolation of the infectious sick in the administrative county have never been adequate, and perhaps it would be truer to say that they have been woefully lacking, and this lack of provision in many instances has been responsible, in a large measure, for the fatalities resulting from infectious disease." There are 189 beds and 8 cots, whereas on the recognised ratio of beds to population there should be not less than 345. It would therefore be necessary to make provision for 200 additional beds, but probably the population ratio need not be strictly adhered to if some system of pooling could be adopted, in which case it should be sufficient to provide for 120 extra beds. The provision for small-pox patients is satisfactory.

THE DOCTOR'S DAY

"Come, tell me how you live," I cried,
"And what it is you do!"

XV.—THE HOSPITAL SURGEON

THE life of a hospital surgeon is so varied that in many respects no two days are alike. He pursues a certain routine, which is liable to be sadly upset by emergency calls when these take him out of his town, and other engagements have to be fitted in where best they can be. The contrast of the surgeon's day with that of the established consulting physician is striking in one respect, the surgeon is called upon to do much more work at the teaching hospital, while many fewer medical emergencies occur in hospital practice. A ward round is made by few hospital physicians daily, and seldom occupies more than two hours in ordinary circumstances, but it is quite ordinary for the operation list of the surgeon to involve five or six hours' work. In collaboration with pathological and research departments the physician's time is more fully taken up, but when procedure is dictated by special findings the surgeon may have before him lengthy work still to do, and work that has to be done by a special time. And it is this that puts upon the surgeon the real strain—his time scheme at the hospital and elsewhere is ever at the mercy of emergencies.

Nowadays it is the custom at many hospitals for all members of the staff to do their share of work in the out-patient departments, and an excellent plan it is. The days are past when the assistant surgeon saw out-patients only and did emergency operations, while the work of the full surgeon was confined to in-patients and to operations performed on certain set days. The developments of general and special surgery, first gradually and then rapidly, rendered such an arrangement obsolete. The teaching hospital may now demand four half-days a week from the surgeon; one half-day is spent seeing out-patients, another in a ward round, while the other two are allocated to operations.

During the university term certain lectures and demonstrations have to be given in the medical school. There are also numerous student societies, each of which requires a president every year from among the honorary staff. There are also clubs and societies in connexion with the nurses, the massage students, the X ray students, hospital almoners, and many others, all of which at one time or another welcome—may I say are insistent upon?—the attendance of a member of the honorary staff at their different functions. A large number of subcommittees of the governing body of the hospital consist chiefly of lay members, but these rely in great measure on the judgment of members drawn from the medical and surgical staff. Remembering how much trouble has arisen in the past because members of the governing body have not taken the feeling of their medical colleagues on some essential point before coming to a decision, the surgeon, however busy, feels it his duty to attend the committees of which he is a member, with such regularity as he can make possible.

The following is a picture of a typical day in the life of a surgeon to a London hospital and school, and is written from that aspect; but while any centre of medical training will have its particular features, dependent upon size, locality, and tradition, the surgeon's life will follow much such a pattern.

THE MORNING

Breakfast at 8, a glance at the morning paper and a hurried review of letters, most of which will be duly sorted by the secretary when she arrives an hour later. At 8.30 the car is ready to take me to a nursing home where I see one or perhaps more patients. Perhaps a dressing has to be done, or some stitches taken out; and then a patient at another nursing home, possibly two or three miles away, has to be visited. At 9.30 an operation has to be performed at still another nursing home. Why is such an itinerary necessary? Cannot all the patients be housed in the same nursing home? It would be all to the good of the surgeon if they were, but to-day patients take a pride in choosing their own nursing home. One says: "I want to go into such and such a home because Mrs. X went there and was comfortable and well-looked after"; others have reasons of locality, amenities, and so on to support their private preferences. The question of fees is an important one to-day, although it was often not discussed in advance in the golden pre-war time. The average patient now wants an estimate of the whole extent of his probable expenses before he decides what home he will patronise, and the male patient now is as prudent as the female.

Since the war many hospitals have instituted private wards and I think that these have come to stay. In such wards middle-class patients can be treated for very modified fees, the alternatives being cheap nursing homes or the ordinary public wards. If the private wards in the London hospitals have the effect of causing inefficient nursing homes to close down it is all to the good, since abdominal operations performed in small rooms with poor lighting and equipment cannot be for the benefit of the patient, nor, in such circumstances, can the surgeon do his best work. Operations, except minor ones, should not be performed in nursing homes unprovided with an operating theatre or a lift; it is unfair to the patient, to the surgeon, and to the nurses. However, I must not digress, during a picture of a working day, into a discussion of the difficult situation of the middle-class surgical or gynæcological patient.

The operation, the impending performance of which has been mentioned, begins at 9.45. It may be a radical amputation of the breast for cancer and the operation takes just under the hour, the surgeon being assisted perhaps by his house surgeon who has come from the hospital especially to help. After the operation the relatives of the patient are interviewed and a prognosis is given; the surgeon motors back to his house to see patients. In the intervals letters are dictated to doctors and sometimes to patients. And then come consultations. It is true that some surgical cases do not take up much of the consultant's time, as for instance a hernia. On the other hand, a nervous patient with a thyrotoxicosis may demand nearly an hour's careful study before a decision as to the proper line of treatment can be given. Often arrangements have to be made for the patient to go into a nursing home for further investigation and for a consultation with a physician. Perhaps the practitioner's diagnosis of "chronic appendix" is one which requires to be sifted most cautiously, in order that such conditions as salpingitis, cholecystitis, gastric or duodenal ulcer can be eliminated. It is not possible to calculate the time that will be required for consultations, or what may constitute an average morning, but as a rule half an hour must be allowed for each patient. It is aimed that the last patient should depart by 1.15 P.M., when a light luncheon is followed by the dictation of a few more letters, arising perhaps out of the consultations.

THE AFTERNOON

At 1.30 I am again in my car en route for hospital. On out-patient days patients who have been especially sent up to be seen by their own doctors are taken first. The students who have written clinical notes on these cases read them out and are asked questions about the patients. Diagnosis and the differential diagnosis are discussed and the line of treatment that should be adopted. If the case is an injury to a bone or to a joint it is removed to the X ray department, a skiagram is taken, when a report will be forthcoming in about half an hour. The surgeon who likes teaching gets ample opportunity in the out-patient department, which is normal in size," in such a case the amount f enlargement must be very small and not capable of assessment from the weight of tissue extirpated. Further, to quote from Mr. Joll's excellent book,

> "The size and weight of the gland under apparently normal conditions are known to vary somewhat widely n different countries, at different ages, under varying onditions of diet, and in different physiological phases such as puberty, adolescence, pregnancy, and so forth."

And finally, pre-operative administration of iodine may alter the weight of the gland.

With regard to the histology of the tissue removed; of my six cases submitted to operation four showed a hyperplasia-involution process, areas of hyperactive tissue being interspersed with areas of involution. In one a densely calcified nodule was present in a gland which showed definite areas of hyperactivity. In the remaining two many involution areas were present but no tissue was definitely hyperplastic. This appearance can be accounted for by the fact that all the patients received iodine treatment prior to operation.

I am, Sir, yours faithfully,
JOHN R. H. TOWERS.

St. Mary's Hospital, W., Feb. 13th, 1933.

THE INDUSTRIAL DOCTOR

To the Editor of THE LANCET

SIR,—As medical officer in charge of a clinic serving the interests of a firm with numerous employees, I also was interested in the day of "An Industrial Doctor," and share Dr. Castellain's regret that the author made no reference to the question of coöperation with medical practitioners and hospitals.

The industrial doctor in a large concern has facilities for diagnosis and treatment, such as X ray apparatus, skilled massage and remedial physio-therapeutic aids, not possessed by private practitioners; he also has behind him his firm's resources to assist its employees in obtaining specialists' opinions, convalescence, and various forms of special treatment. By treating at the factory clinic cases of illness that do not involve absence from work he prevents to a large extent the development of more serious disease, and saves his firm, the patient, and the panel doctor much trouble and loss of time. By coöperation with the private practitioner during an employee's sick absence the industrial doctor is able to assist and expedite recovery and when necessary arrange for light work during the final stage of convalescence. Where, as is the case with my firm, panel benefits are made up to full pay during sick absence, subject to length of service and the factory doctor's satisfactory report, such coöperation is, of course, essential in the patient's interest. Ambulatory accident cases, coming under the provisions of the Employers' Liability and Workmen's Compensation Acts, as well as the various dermatoses, are best treated at the factory clinic, as they can be kept under close medical supervision and seen daily, instead of only once a week as is more usually the case at hospitals or panel surgeries. The value of keeping the injured workman in close contact with his place of employment, and stimulating his desire to resume work by suitable remedial measures will be obvious to all who have studied the problems of industrial psychology.

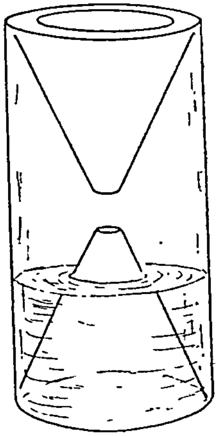
In practice it is found that fully 99 per cent. of insurance practitioners not only coöperate with, but also welcome the work of the industrial doctor, and appreciate his aid in caring for the health and welfare of the industrial population. There are many other aspects of this work not touched upon by your contributor, doubtless owing to limitations of space, but I am sure he feels, as I do, that few other branches of practice offer such opportunities of useful and interesting clinical work.

I am, Sir, yours faithfully,
London, W., Feb. 10th. N. HOWARD MUMMERY.

CHLOROFORM IN CHILDBIRTH

To the Editor of THE LANCET

SIR,—At the present moment many attempts are being made to find a safe method for the administration of anæsthetics during labour by the patient herself, for employment in cases attended by midwives. Chloroform capsules have been extensively tried by many hospitals, and, excellent as they appear to be, I venture to suggest that the inhaler here described, which I have had constructed, offers a simpler and safer method for the use of chloroform. By reference to the drawing it will be seen that the inhaler, which can be made of either glass or metal, embodies the same principle as the unspillable inkwell. When it is charged with chloroform, it is impossible for the liquid to be spilled, and yet a free air passage through the instrument and over the surface of the chloroform is permitted. In this way only air and chloroform vapour are breathed. The air does not pass through the chloroform but merely over its surface.



The chloroform can be administered by the patient if she simply holds the inhaler to her nostrils; another method—but probably not suitable for use by midwives—is to insert the inhaler into the narrow end of a rubber funnel, the broad end of which is applied to the face. The broad end should be convoluted to allow sufficient airway, or the funnel itself can be made of wire and merely surrounded by a portion of lint. So long as the patient administers the anæsthetic herself, I believe that there can be no danger, as no great concentration of chloroform can be obtained, and should unconsciousness supervene the administration of the anæsthetic will cease as the patient's hand falls away from the face. If the inhaler is made of metal it will not break if dropped.

Such instruments have the following advantages:—

(1) No sudden concentration of chloroform can be administered.

(2) There is no necessity for the patient to break anything so that, even when semi-conscious, she is still in a position to administer the anæsthetic.

(3) They are cheap to make and can be sold completely sealed.

(4) They are simple to operate. To put the instruments into use it is only necessary for the nurse to puncture both ends of the inhaler with a sharp-pointed instrument, as, for example, scissors; or as an alternative, screw plugs can be inserted in the ends.

(5) When exhausted they can be returned to the chemist who, for a small charge, would replace the exhausted inhaler with a new one fully charged.

(6) The old inhaler can be recharged and resealed by the chemist.

(7) When for use in maternity hospitals or by a doctor there is no need for it to be sealed, as the inhaler can be replenished by simply pouring chloroform in through one end.

(8) It is impossible to overfill, for the chloroform will overflow from one or other end.

CORRESPONDENCE

A TRIBUTE TO SIR ROBERT JONES

To the Editor of THE LANCET

SIR,—The death of Sir Robert Jones, of Liverpool, has taken from us one of the most distinguished of English surgeons, the creator of modern orthopædic surgery, and the founder of the British school of orthopædics. Many of his colleagues, patients, and friends feel that a last tribute should be paid to his memory, in recognition of his services to the cause of surgery and to multitudes of patients, and to recall his service to the Army during the Great War. Sir Robert Jones was regarded throughout the world as the greatest orthopædic surgeon of all time; it is only fitting that his supreme merit should be recognised in this way, and that his example should constantly be brought to mind as an incentive and encouragement to those who come after.

It is hoped to be able to arrange to include in our benefactions Liverpool, the Royal College of Surgeons of England, and perhaps other bodies with which he was associated, if, as we feel sure will be the case, an adequate sum of money is received in response to this appeal.—We are, Sir, yours faithfully,

DERBY,
Chancellor of Liverpool University; Secretary of State for War 1916–18 and 1922–24.

ARTHUR STANLEY,
Chairman, British Red Cross Society; Treasurer of St. Thomas's Hospital.

HOLBURT J. WARING,
President, Royal College of Surgeons.

MOYNIHAN,
Past-President, Royal College of Surgeons; Chairman, Army Medical *Advisory Board.*

E. FARQUHAR BUZZARD,
Regius Professor of Medicine, Univ. of Oxford.

W. LANGDON BROWN,
Regius Professor of Physic, University of Cambridge.

J. W. DOWDEN,
President, Royal College of Surgeons, Edinburgh.

FRANK CRAWLEY,
President, Royal College of Surgeons, Ireland.

HAROLD B. FAWCUS,
Director-General, Army Medical Services.

WICKLOW,
President, Central Council for the Care of Cripples.

GEORGIANA BULLER,
Vice-Chairman, Executive Committee Central Council for the Care of Cripples.

THE ADMISSION OF WOMEN TO THE G.M.C.

To the Editor of THE LANCET

SIR,—The letter by Dr. Jane Walker and Dr. Letitia Fairfield, suggesting the desirability of the election of a woman member on the General Medical Council, we feel sure voices the opinion of all medical women. It seems appropiate that as women now share in the work of all branches of medicine, that a place should be found for one of them on such a thoroughly representative body. Candidates are available whose opinion and advice could not fail to be of value in many matters which come within the province of the Council.

We are, Sir, yours faithfully,
RUTH NICHOLSON,
MARGARET JOYCE,
VERA FOLEY.

Liverpool, Feb. 13th, 1933.

To the Editor of THE LANCET

SIR,—I should like to support the appeal of Dr. Jane Walker and Dr. Letitia Fairfield for the election of a medical woman to the General Medical Council. Just as women are now members of the House of Commons and of most public bodies throughout the Kingdom, so it seems only just and natural that there should be at least one on the G.M.C., seeing that they constitute nearly 10 per cent. of the names on the medical register. Previous to each step which has been taken during recent years in the admission of women to public life there have been gloomy prophecies of the disastrous results which would inevitably follow as a result. Not one of these dismal vaticinations has ever materialised; the presence of women on public bodies of the most varied character has been abundantly justified by experience. Similarly, I believe the election of a woman on the G.M.C. would add to the carefulness of its deliberations and to the wisdom of its decisions, and would make it even more representative than at present of every side and aspect of professional life.

Experience in connexion with other medical bodies has already shown that there would be no difficulty in finding a suitable woman candidate.

I am, Sir, yours faithfully,
J. WALTER CARR.

Cambridge-terrace, Regent's Park, N.W., Feb. 10th, 1933.

MASKED HYPERTHYROIDISM

To the Editor of THE LANCET

SIR,—I read with great interest Mr. Cecil Joll's letter in your issue of Feb. 4th. The presence of thyrotoxicosis in association with a thyroid gland which is *strictly* normal in size is difficult to prove. It must, however, be accepted that gross cardiac disturbance may result from thyroid intoxication when the gland is neither visibly nor palpably enlarged even in a very thin individual; this point I attempted to emphasise in my paper. In addition, although there may be no increase in size the consistence of the whole or a part of the gland may be altered, and this alteration appreciated by palpation. If then, as Mr. Joll says, "thyrotoxicosis never occurs in association with a thyroid gland

Pathology and Bacteriology, and it may be that someone referring to the literature in the future may be led into error. As this was, I believe, the first case in this country in which the diagnosis was made during life and subsequently confirmed, I would add that the credit for making the diagnosis belongs to Dr. B. Barling, under whose care the patient was.

I am, Sir, yours faithfully,

G. W. GOODHART.

Group Laboratory, Archway Hospital, N.,
Feb. 11th, 1933.

CAVITIES IN PULMONARY TUBERCULOSIS

To the Editor of THE LANCET

SIR,—Cavities in tuberculosis of the lungs are most undesirable items in this disease, and if present should be if possible closed by some means or another. The principal dangers of an open cavity are hæmorrhage, continuance of sputum with tubercle bacilli, and reinfection of other parts of the lungs. To my mind the presence of a cavity is one of the chief indications for collapsing the lung, thereby causing the cavity to close, and so inducing it to heal. If collapse of the whole lung should prove impossible or inadvisable, then in many cases the cavity, usually an apical one, may be closed by an extra-pleural plombage. The mechanical means at our disposal for this purpose of obliterating cavities are several. Artificial pneumothorax, a procedure where the scope and chance of success has been greatly enlarged by the recent developments of methods of adhesion cutting. Phrenic avulsion, an intervention which will often induce a cavity, even an apical one, to become smaller and eventually heal. Extra-pleural plombage, which is a local operation and by present methods proving to be very satisfactory. Finally, there is extra-pleural thoracoplasty, a procedure which is rather losing ground owing to the developments of other less severe methods of dealing with the situation.

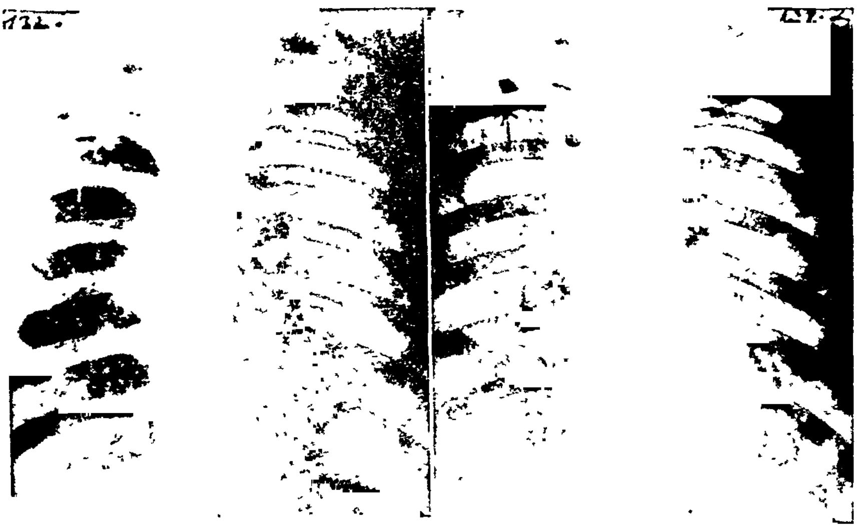

FIG. 1

FIG. 2

Radiogram showing the cavity in the lung before and after two months' treatment.

I would always give, however, a certain time before interfering, unless there are good reasons for immediate intervention, because sometimes these cavities, even quite big ones, heal by themselves without any surgical procedure, and occasionally in a very short time. This is extremely interesting and seems almost impossible. The following case is one instance among a few of which I have had experience :—

Male, aged 26. Admitted to the Victoria British Sanatorium, Davos, on Oct. 13th, 1932. Radiogram (Fig. 1) showed a large oval-shaped cavity in the right lung. Blood sedimentation test 28 mm. in first hour and 58 mm. in second hour. Artificial pneumothorax contemplated and explained to the patient. One month later blood sedimentation test was 18 mm. in first hour and 40 mm. in second hour. On Dec. 13th—i.e., two months later—a further radiogram was made which showed the cavity practically closed (Fig. 2). Blood sedimentation 7 mm. in first hour and 24 mm. in second hour. Thus in two months, with no treatment except rest and calcium by the mouth, this quite large cavity was almost closed.

I am indebted to Mr. P. G. Sutton, M.S.R., of the X Ray Institute, Davos, for the radiograms.

I am, Sir, yours faithfully,

BERNARD HUDSON, M.D., M.R.C.P.

Victoria British Sanatorium, Davos-Platz,
Switzerland, Feb. 8th, 1933.

PANEL INVESTIGATION BY REFERENCE

To the Editor of THE LANCET

SIR,—Your weekly article in Panel and Contract Practice is usually so good that you will perhaps allow me to draw attention to an inaccuracy in your note this week on Investigation by Reference, where you say (p. 331):

> "It seems preposterous that a practitioner should be put to the trouble involved in defending his reputation before a medical service subcommittee because he criticises to the clerk of the committee the working of a clause of the regulations with which he was unfamiliar."

I do not think this has ever happened, and so far as London is concerned I am confident that it never will. Any doctor is at liberty to put forward criticisms ; it is only thus that the regulations can be improved ; but for one to be constructive it is advisable that the critic make himself familiar with the regulations, and had this doctor done so he would have learnt that the proper channel for such criticisms is through the panel committee to the Insurance Acts Committee which deals with the Ministry of Health. It is quite useless to describe a clause as "autocratic" when writing to an official who is only doing his duty.

But it was not for the reason stated above that this case was referred to the medical service subcommittee. Your article says (p. 330, column 1) he "concluded his letter to the committee with the following sentence : 'The remuneration received for the treatment of panel patients does not encourage me to give any more than very ordinary treatment.'"

(9) It can be easily sterilised by boiling.

(10) The inhaler I have had constructed measures 3 by 1½ in. *and the distance between the two open ends is ¾ in.*

This inhaler is at present being tried out by me at the City of London Maternity Hospital, and at the Jewish Maternity Hospital.

I am, Sir, yours faithfully,

Harley-street, W., Feb. 8th. R. CHRISTIE BROWN.

BED TENTS FOR ADMINISTERING OXYGEN

To the Editor of THE LANCET

SIR,—In your issue of Feb. 4th (p. 245) Dr. Poulton writes that the first bed tent for administering oxygen was devised by me. This was a wooden chamber, *into which the bed could be comfortably run, fitted* with windows, and with an oxygen supply and a fan circulating the air. It was built for me at the London Hospital before the war, and was in use when the King and Queen visited the hospital as Prince and Princess of Wales. I then had a chamber made of metal and glass, into which the spring mattress, carrying patient and bedding, could be run. Finally I thought of the bed tent, and this Sir Robert Davis, of Messrs. Siebe Gorman and Co., made for me; the firm's new model is described by Dr. Poulton. I did not add a cooler to this tent because I arranged a fan to blow over the patient's face, and also had the bed *put near an open window. In this tent I kept patients* for many hours a day, and found that continued oxygen treatment had a beneficial effect on chronic ulcers of the leg. One such ulcer, skin-grafted by Dr. Leonard Colebrook, healed very quickly. The bed tent was shown to the Physiological Society, but clinicians showed no interest in it, although it offered great advantages for treatment of pneumonia and other troubles. The Americans copied the bed tent and added a cooler; several models are now on the market, but not one of the pamphlets describing this invention, so far as I have seen, has given any credit to me. The American bed tents and Dr. Poulton's differ materially only in the adding of a cooling device, which is an improvement.

I hope the bed tent will now come into use.

I am, Sir, yours faithfully,

LEONARD HILL.

Ranelagh-road, S.W., Feb. 10th, 1933.

EARLY DIAGNOSIS OF MALIGNANT DISEASE

To the Editor of THE LANCET

SIR,—In his letter in your last issue Mr. Donaldson says that in most cases carcinoma of the cervix starts on the vaginal surface of the cervix and can be suspected in the early stages. No one can disagree with this, but my own experience is that in women who have had children it is easier to suspect cancer than to say positively that cancer is not present. Large numbers of women who complain of no gynæcological symptoms are found to have lacerations and erosions of the cervix. Who is prepared to say that malignant change is not taking place at the base of a small tear or at the edge of an erosion? The only way for the "specialist" to feel safe is for him to examine all these cases under an anæsthetic and possibly excise pieces for section. How many unnecessary operations this would lead to I shudder to think. Surely our duty is to educate the public to visit their doctors when they notice a change in the behaviour of an organ—as well as when they are ill, uncomfortable, or in pain—rather than to demand that they should come at regular intervals asking to be assured that there is no disease. The good doctor suspects and excludes cancer without his patient ever thinking of the dread word, and there is quite enough cancerphobia about without encouraging more of it. To ask a doctor to exclude cancer in an apparently healthy person is asking the impossible. In certain situations this can be done, but in others even a "specialist" is helpless, and failure in one case would undo all the good resulting from the successful examination of many others.

I am, Sir, yours faithfully,

ARNOLD L. WALKER.

Harley-street, W., Feb. 14th, 1933.

To the Editor of THE LANCET

SIR,—Some misapprehension appears to have arisen over some remarks which I made at the opening meeting of the London Cancer Society, and which inspired the words in your annotation to which Mr. Malcolm Donaldson has objected. My short paper was incorrectly reported (owing to the illness of the secretary) and the draft was not submitted to me before being sent to THE LANCET.

I made no reference to periodic medical examination. Although I agree with Mr. Donaldson as to the ideal of such a procedure, I feel, with you, that it is hardly practicable at the present time. The main purpose of the first part of my paper was to emphasise the frequency with which patients consult their doctors for symptoms which are entirely attributable to cancerphobia. These patients, in my experience, rarely use the word cancer and make no specific reference to their fears; I believe, in fact, that many of them are not conscious of the source of their trouble. The responsibility rests upon the doctor to disabuse their minds of all possibility of malignant disease, and this can only be successfully achieved if the reassurance is accompanied by the use of the word cancer. It is of little use to say to such a patient that nothing abnormal can be found. He (more often she) only suspects that the truth is being concealed. If, however, we say, in so many words, "there is no sign of cancer, tumour, or malignant trouble of any sort," symptoms which have resisted all sorts of treatment will not infrequently clear up forthwith.

I believe that subconscious cancerphobia is almost as frequent as conscious fear of the disease. But the important point is that in neither variety is the patient likely to express the fear explicitly. In the one case he is not aware of it, and in the other he is ashamed to own to it. Much unnecessary suffering could be saved if medical men would more fully appreciate the mentality of these patients. It is the rare case of words being more important than deeds.

I am, Sir, yours faithfully,

MAURICE E. SHAW.

Wimpole-street, W., Feb. 10th, 1933.

ADENOMA OF THE PANCREAS

To the Editor of THE LANCET

SIR,—In your account of the meeting of the Association of Clinical Pathologists (p. 307) a case of adenoma of the pancreas causing hypoglycæmia, presented by my colleague Dr. Murray, is reported as having been in the Archway Hospital. In fact the patient was in St. Mary Islington Hospital; and I rectify the mistake as the case has already been fully recorded by Dr. W. G. Barnard in the *Journal of*

PANEL AND CONTRACT PRACTICE

Sickness Claims

THE sickness experience of the Hearts of Oak Benefit Society, as reported in the daily press, brings to light some interesting facts. During the last eight years, that is during the period of the most acute depression from unemployment, there has been a continuous yearly rise of sickness claims. When work was abundant claims were light, but in industrial (especially mining) areas there is now an immense increase in sickness. Apparently the actuarial calculation for the sickness of young people is not in accordance with the society's experience. Young people are claiming much more than they did; they have no jobs and nothing to do except to think about themselves, and there is a consequent increase in claims for mental and nervous depression. In the first week of January there was an increase of 100 per cent. in new claims, in the second week of 110 per cent., in the third of 130 per cent., and in the fourth of 200 per cent. It is suggested that these claims, approximately 10,000 a week, were almost entirely a result of influenza, and this made more serious by a low standard of physique and an exaggeration of under-nourishment, both backed up by mental depression. Even in happy times influenza is apt to leave depression behind, and an increase of nervous and mental breakdown is to be expected, brought on partly by influenza and partly by the absence of happiness and of employment, especially among young people who have failed to obtain employment since they left school. While certifiable insanity may show little variation, it is worthy of note that the number of out-patients attending the Maudsley Hospital jumped from 1608 in 1930 to 1993 in 1931. Figures for 1932 are not yet available. The effect of the prevalence of the influenza epidemic is evident from the number of prescriptions received by the pricing bureaux of insurance committees.

Effect of Removal from the Panel

The Minister of Health can only remove a doctor's name from the panel after an inquiry which has satisfied him that the continuance of the practitioner on the panel would be prejudicial to the efficiency of the service. His action is administrative after an inquiry committee has reported its findings, and from his decision there is no appeal to the courts. This procedure is apt to be confused in the lay mind with that of the General Medical Council which has power to erase a doctor's name from the Register if it is proved to the satisfaction of the Council that he has been guilty of infamous conduct in a professional sense. This is a far greater penalty than removal from the panel, for it prevents a doctor from acting as a medical practitioner at all. It does not, of course, take away his medical knowledge—he could diagnose and treat a case just as well before as after the decision—but he cannot give a medical certificate which would have any value legally, he cannot give a death certificate, and he cannot sue for his fees. If an insurance committee or a local medical committee or a panel committee reports to the Minister that the continuance of a practitioner on the panel would, in their opinion, be prejudicial to the service, he must (but if the report comes from other sources, he may) set up an inquiry committee consisting of a lawyer and two doctors who may go into anything in connexion with this doctor's practice. Due notice is given to the doctor of all points of inquiry, evidence is given on oath, barristers or solicitors are employed, and the rules of evidence are strictly adhered to. The committee reports to the Minister who decides on that report the penalty to be imposed—after consultation with the advisory committee. It may be a fine, in which case the doctor has the right to be heard on the question of its amount. It may be suspension of decision for a period, to give the doctor time to furnish evidence of subsequent good conduct. It may be permission to retire from the panel, on the written undertaking that he will not rejoin elsewhere without the Minister's consent. Or it may be immediate removal from the panel list. This decision does not prevent the doctor from carrying on with private work in practice, but the regulations definitively prevent him acting either as an assistant or as a deputy (including locum tenency) to another doctor's practice. It might be thought that, as the principal is responsible for the acts of his assistant or deputy, he could employ whomsoever he wished to do the work he could not do himself, but the regulation is quite clear on this matter. A doctor removed from the panel cannot act as locum tenens, assistant, or deputy to another panel doctor. He could, of course, have a partner who is on the panel, but he would not himself be able to treat any panel patients for or on behalf of that partner.

Inspection of Surgeries

Gloucester insurance committee has decided to revert to the practice of inspecting the surgeries and waiting-room accommodation of its insurance practitioners. There had, it seems, been a few complaints. The regulation is brief but important:

> A practitioner is required to provide proper and sufficient surgery and waiting-room accommodation, having regard to the circumstances of his practice.

No standard is laid down, but obviously such things as heating and seating must be taken into consideration, for it is not to the advantage of the service nor of the practitioner for insured persons to be overcrowded when attending for treatment nor that they should be expected to sit in badly ventilated and insufficiently heated rooms. On the other hand, it is not suggested they should have the use of the doctor's best room when they come in, as they often do, wearing their working clothes and muddy boots. Some time ago a discussion took place whether a couch should be provided in the consulting room. Was a couch accommodation or was it apparatus? The insurance committee has no authority over apparatus, but it has over accommodation; hence the matter was important. The doctor in this case said he never used a couch in his consulting room; any examination in the recumbent position was done at home in the patient's bedroom, which, he said, was more suitable for the purpose, especially in the case of women patients. In view, however, of emergency treatment that may at any time be required it can hardly nowadays be contended that a couch is not a necessity in the consulting room.

TINFOIL FOR HOSPITALS.—The tinfoil fund of the Ancient Order of Druids last year received over 100 tons of tinfoil, lead capsules, tooth-paste tubes, and other waste metals averaging £20 per ton in value which were sold for the benefit of hospitals. Since the fund was started in 1912 more than £20,000 has thus been realised.

There is here a definite suggestion that this doctor had one scale of treatment for the panel and another for the private patient. It is a tradition of our profession that, whether one is paid or whatever one is paid, we should do our best for the patient under the conditions in which we are working, and as a medical member of the referring subcommittee I should always in such a case vote in favour of a resolution for "investigation by reference." Further, as the representative of the Minister, I should do the same, for the doctor is under contract with him to give the same standard of treatment to his panel patients as he does to those patients for whom he is paid on an ad-hoc basis. I cannot feel that in this case an investigation by reference was "rashly ordered."

We may agree that any investigation as to our conduct is a source of worry however clear our conscience may be. But there is another side to be considered. These investigations are a great safeguard to the doctor concerned. Whenever "any sort of lie about a doctor" is once started it is well to have it nailed to the counter. Some anonymous publicity is not a very big thing to put against the advantage of printed evidence that the complaint had been inquired into and shown to be groundless. There must be many of us who know that misstatements have been circulating for years about some case of our own that we should like to have fully investigated in order to clear our reputation, and such lies are not always started by laymen. In this case "there was no evidence that this doctor had ever treated a panel patient differently from a private patient"; but the "sort of lie about a doctor to the clerk of the committee" was written by himself; and it is difficult to see how he could claim "some monetary compensation for worry and loss of time" even if funds were available and if there were any analogy in our legal procedure for such a payment.

Finally, in justice to our clerk, may I point out that claims for refund are not selectively referred by him to the medical benefit subcommittee as your opening sentences seem to imply; all of them pass to us ipso facto.—I am, Sir, yours faithfully,

T. B. LAYTON.

London Insurance Committee, Wilmington-square, W.C., Feb. 14th, 1933.

THE PATHOLOGY OF APPENDICITIS

To the Editor of THE LANCET

SIR,—In the leading article in your last issue, in which you reviewed the work and views of Prof. Aschoff, you were good enough to allude to the investigations by Dr. A. Paine and myself of some 20 years ago. I should like to add that in addition to the experimental work we investigated the pathology of early human appendicitis in specimens taken direct from the operating theatre and found that in them the early changes commenced in the submucosa and not on the surface of the mucous membrane, and as in the blood infection of rabbits the lymphoid tissue first became necrotic. We were working at this subject entirely from the aspect of rheumatism, but ten years before, Adrian had shown that appendicitis could occur in animals from blood infection and had also studied the same in man. By 1913 the German investigators had done much upon this problem.

There is no shadow of doubt in my mind that appendicitis can arise in this way, probably, as we experimentally demonstrated, and others had commented upon, from a source such as acute tonsillitis. I do not pretend to assert that appendicitis is always caused by infection from the blood stream, but to assert the opposite would be equally, even if not more, rash. On the face of it appendicitis following quickly upon an acute tonsillitis is more probably the result of a blood infection than a mysterious change of virulence in the microbic contents of the lumen of a previously healthy appendix, for the evidence in favour of this is good, reasonable, and scientific.

When an appendix has been damaged and an ulcer having formed has healed by scar formation with contraction, inspissated material beyond the stricture may, as we know, form a sterco1ith. Doubtless then the dangerous attack may now be dependent upon a local as well as a general factor. He is a bold pathologist who would deny the occurrence of appendicitis by a blood-borne infection.

I am, Sir, yours faithfully,

Harley-street, W., Feb. 13th, 1933. JOHN POYNTON.

"DIAGNOSTIC EXPLORAL SUCTION" OF THE NASAL SINUSES

To the Editor of THE LANCET

SIR,—The July, 1932, number of the *Journal of Mental Science* contained statistics of the findings in 880 cases of mental disorder whose nasal sinuses were investigated by the exploratory technique evolved by Dr. Patrick Watson-Williams. In these cases of psychosis from sinus disease it not infrequently happens that the indications in the nose of the presence of sinusitis are not typical or may even be absent; the psychotic state, thus resembling other toxæmic states arising from foci of sepsis, increases as the evidence of external focal discharge diminishes. Hence the importance of this special technique in the search for sources of toxæmia in psychotic patients cannot be over-estimated, especially in cases where there is an early history of symptoms referable to the upper respiratory tract, and in those cases where psychosis appears immediately after an attack—not infrequently mild—of what is regarded as influenza.

In his letter to you of Feb. 4th (p. 276) Dr. Watson-Williams submits for general adoption a more precise nomenclature for this technique in order that records of investigations in sinus disease can be put upon a uniform basis. That records should adequately indicate the exact mode of investigation has been recognised in such research in cases of mental disorder. The Board of Control in Part I. of its Eighteenth Annual Report for the year 1931 (pp. 108–109) indicates the importance of this matter thus:

> "To those who report that search for evidence of sinusitis or other foci of chronic infection has failed to reveal it as a relatively common condition, we venture to make the request that they will make quite sure that they are using the precise technique employed by those who report positive results and, if they do not use this technique, to make that fact clear."

Of the terms which Dr. Watson-Williams suggests, that of "suction-exploration" appears to me the most useful. I am, Sir, yours faithfully,

T. C. GRAVES.

Birmingham, Feb. 13th, 1933.

THE INDUSTRIAL DOCTOR.—The parenthetic clause in line 10 of the second paragraph of Dr. Castellain's letter last week, should have read "save for medical and surgical first-aid."

comprehensive monograph, 'The Oligochæta,' published by the Clarendon Press in 1930, and at once recognised as a standard work. In it he discussed, with much originality and breadth of view, the questions raised by the morphology, phylogeny, and geographical distribution of these animals. Among his too rare excursions into more general subjects may be noted a remarkable address on the History of the Cell Theory, delivered before the Linnean Society in November, 1931, in which he demolished the statement current in text-books 'that the cell theory was formulated by Schleiden and Schwann in 1839.'

"Much of Stephenson's wide knowledge and sound judgment," Dr. Calman adds, "was devoted to clarifying the work of younger zoologists whose researches he directed and whose papers he edited, and all of these will retain a memory of a wise counsellor and a singularly attractive personality."

ALFRED PARKIN, M.D. Durh., F.R.C.P. Lond., F.R.C.S. Eng.

PHYSICIAN TO THE ROYAL VICTORIA INFIRMARY, NEWCASTLE-ON-TYNE

WE regret to announce the death of Dr. Alfred Parkin, one of the leading physicians of the north of England, which occurred suddenly at his residence in Newcastle on Wednesday, Feb. 8th, in the 54th year of his age.

Alfred Parkin was the youngest son of the late Mr. George Parkin, of Gateshead. He was born in Wrekenton in 1879, and received his general education at the Royal Grammar School, Newcastle. He proceeded to the study of medicine at the Durham University College of Medicine, graduating in 1901 with first class honours, after a brillant scholastic career, during which he won the Tulloch scholarship in 1898 and the Charlton and Gibb scholarships in 1901. After studying in Berlin and Vienna he took the English conjoint qualifications in 1902, the F.R.C.S. Eng., and M.D. Durh. in 1904, and the M.R.C.P. Lond. in 1908; he was elected F.R.C.P. Lond. last year. He held the house appointments at the Newcastle Infirmary, being house surgeon to Prof. Rutherford Morrison, and house physician to Sir Thomas Oliver. During the time of his house physicianship the King Edward VII. bridge over the Tyne was in course of construction, and several cases of caisson disease were admitted to the wards. Stimulated by his chief, Sir Thomas Oliver, to whom he was much attached, he made a study of the clinical features and carried out some experimental work. This became the subject for his M.D. thesis, which was published in the *Northumberland and Durham Journal* for 1905, and subsequently in book form, and was a model of exact observation and recording.

DR. ALFRED PARKIN

Photograph by James Bacon

When his resident appointments at the infirmary terminated he acted as assistant for a short time to the late Dr. Mearns, of Gateshead, and then entered on a fruitful period as resident medical officer to the Newcastle Dispensary, then situated in Nelson-street. He always looked upon this period as supplying him with very valuable experience, and it was while visiting in the homes of the poor that he laid the foundation of that understanding of the sick which was so marked a characteristic with him. About this time he was inclined to a surgical career and for a short period acted as one of the surgical registrars at the Royal Infirmary. His interest in surgical pathology was very keen and he was an excellent demonstrator in that subject, but the technique of surgery did not much attract him, and the investigation of cases and problems of diagnosis appealed more to his philosophic turn of mind, so that he soon turned towards medicine as a career. And no man ever made a happier choice. His election as assistant physician to his old hospital in 1908 settled all questions of a vocation, and from henceforth he gradually became one of the best known and sought after consulting physicians in the north. In 1913 he was elected to the full staff of the infirmary, and at the time of his death he held the posts of honorary physician to that institution, consulting physician to the Gateshead Union Hospital, and lecturer in therapeutics to the Durham University College of Medicine, where he had previously served as assistant demonstrator in anatomy, physiology, and pathology. During the war, with the temporary commission of Major R.A.M.C., he was one of the officers in charge of the First Northern General Hospital, located at the Armstrong College.

As a physician Alfred Parkin was a notable success. For him the problem of the moment was everything and he had a remarkable power for concentration. In consequence the patients entrusted to his care all felt that confidence, which is engendered by undivided attention. He took note of everything in the circumstances of the sufferer and investigated the details and history of illness with punctilious care. His quiet impressive manner was a great asset: he was quite unconscious of this, but all who worked with him appreciated the fact. And much above his knowledge and skill, was his understanding of the sick and of all that illness means in a household. He was often the "doctor's doctor," than which no higher compliment can be paid. As a man of affairs he was more reticent than shy, but he never shirked his duty and his opinion on business questions was always highly valued by his colleagues.

Parkin was a great teacher and especially at the bedside. In ordinary hospital practice he found so much of importance that he was a little impatient of the search for the unusual, and it became his life's occupation to drive home to his students, who were devoted to him, the lessons of their everyday work. As a lecturer he was not so happy—rhetoric did not appeal to him, and he liked an association more intimate than the lecture theatre provided. It was probably for the same sort of reason that he never wrote much and that he did not greatly value the opportunities given by medical societies to express his views in any casual or desultory manner. It was characteristic of him to want to get to the bottom of everything, at whatever cost of time or trouble. This attribute explained his interest in medical history and expressed his desire to get at the beginnings

OBITUARY

ALFRED EICHHOLZ, C.B.E., M.D. Camb.

LATE CHIEF MEDICAL INSPECTOR, BOARD OF EDUCATION

Dr. Eichholz, whose death on Feb. 6th was announced in our last issue, was born at Manchester in 1869. His father was a cotton merchant who came over to this country from Hildesheim; his mother was Babet Praeger of Amsterdam. Eichholz went to Manchester Grammar School and from there to Emmanuel College, Cambridge, where in 1891 he took a first class with distinction in the Natural Science Tripos, and became a Fellow of his College two years later, lecturing from 1895–98 on natural science and demonstrating physiology in which he did some original work. He completed his clinical studies at St. Bartholomew's Hospital, qualifying M.D. Camb. in 1895 and M.D. three years later. Directly upon this he was appointed inspector of schools for West Lambeth, and the remainder of his life was devoted to the welfare of school-children. For he became in 1908 a medical officer of the Board of Education and in 1919 chief medical inspector to the Board; his retirement in 1930 was retirement only in name, for he then undertook for the Board and the Ministry of Health the inquiry into the social conditions of the deaf of which the report appeared shortly before his death. Dr. Eichholz early recognised the defects in the health of school-children which impaired their working capacity late on. He learnt the home conditions under which many of them lived and his position at the Board of Education told him what resources were available or might be made available to remedy the defects which he found. From this knowledge he was able to frame policies which would provide remedies or remove obstacles to their employment.

DR. EICHHOLZ

Photograph by Elliott and Fry

Medical inspection and treatment gave Eichholz unrivalled opportunities of coöperation with medical officers and administrators. During his 22 years of activity at the Board of Education he was frequently called on to give evidence before Government committees. He was a witness on the Employment of Children in 1902, on Physical Deterioration in 1903, and on the Feeble-minded in 1908. His interest in social conditions, joined with his medical knowledge made his survey of the conditions of munition workers fruitful of results, a service for which in 1919 he was made C.B.E. Eichholz possessed qualities which marked him out for a good inspector. It was not easy to shield from him weak spots in the armour, but he was always constructive and helpful in criticism. He had a deep philosophic, scientific, and educational background, but his knowledge and thought were always in relation to something yet deeper. They had for their setting human needs and strivings, and not merely these in general but as they came before him in the individual, especially the individual handicapped child. It is impossible to over-estimate what, in particular, the blind and deaf and dumb child, adolescent and adult, owed to him. He made himself acquainted with the special problems and difficulties, and his knowledge of every school for the blind and the deaf in the country was intimate, for they had grown up under his guidance. In matters of administration, education, and industrial training, his colleagues at the Board could rely upon him in full assurance for help and advice; he could always either point out a way for meeting the needs of a particular school or teacher or child, or would set to work to open out a way. He never rested until the best had been done that could be done.

And then his way of doing things was always gracious and courteous. That is the unfailing testimony of his colleagues, of teachers, of parents, and children. His graciousness and courteousness were no mere accident, a pleasant added trait among other traits; they sprang from a life whose roots went deep. He was sustained by and lived out the Jewish faith and Jewish ideals. All who knew him in everyday life felt how entirely fitting was the tribute paid by his close friend, the Rev. E. Levine, when he reminded those who stood round the coffin at the cemetery synagogue, that, like Moses of old when he cast the tree into the bitter waters of Marah and they became sweet, so did Eichholz in private life, on committees, in the office, or in the school, make bitter waters sweet. The memory of his long service for his country will live in many directions and in many quarters, but the uppermost remembrance in the minds of his friends and colleagues will be the spirit of kindness, self-effacement, and helpfulness which animated all he was and all he did.

Dr. Eichholz married, in 1895, Ruth, younger daughter of the late Very Rev. Hermann Adler, the Chief Rabbi, and had three sons.

THE LATE LIEUT.-COLONEL J. STEPHENSON

In a biographical sketch last week of Colonel Stephenson, brief mention was made of his work as a zoologist. Mr. W. T. Calman, D.Sc., F.R.S., keeper of zoology at the British Museum (Natural History), writes: "Stephenson was eminent both as a teacher of zoology and as an investigator. During his 14 years at Lahore he succeeded in inspiring his Indian students with something of his own enthusiasm for the subject, and several of them have since gained distinction by their researches in very diverse branches of Indian zoology. Later, in Edinburgh, he was a prominent member of the very active school of zoology directed by Prof. Ashworth, and took an important share both in teaching and in research. Since removing to London three years ago he had been a valued member of the unofficial staff at the Natural History Museum, and as zoological secretary of the Linnean Society, and editor of the *Fauna of British India*, he exerted a widening influence among the younger generation of zoologists.

"His own researches were mainly concerned with the oligochætes, the group comprising the earthworms and their immediate allies. On these he published a long series of memoirs leading up to a on this new epoch in housing—the epoch of no general subsidies—without making what provision they could to insure against a failure of the housing supply during the transition period. The Bill allowed some scope for himself, as the Minister of Health, to approve applications for subsidised houses which had already been put forward. In committee it would be his object to find a reasonable provision which would allow bona fide schemes which were advanced to a considerable degree to go through under the old subsidy regime. As to the maintenance of standards of building, the state of affairs when this Bill passed into law would be this: the local authorities would have full power, both under by-laws and under the Town Planning Act, to impose their own standards of housing in their localities. The Ministry of Health would also retain control by its authority to approve the guarantee for the building societies' proposals. But further than that, it was his intention to accept certain amendments, which were to be proposed at a later stage by Sir P. Harris, relating to the size and density of houses, which would have the effect of maintaining the present standards in that respect.

It was his intention to set up a committee charged with the task of reviewing the housing and slum clearance problem. He would propose to include in the inquiry of this committee any possible addition in the way of powers of re-conditioning, particularly power for the compulsory purchase of houses by local authorities, in order that they might be re-conditioned—a power which was the only important power which they did not possess under existing legislation. The inquiry should include the price at which such houses should be purchased. There ought also to be some investigation into alternative powers in default of the local authorities. Slum clearance was an urgent necessity, and if they could not get it done by one power it must be done by another. They would never deal with the slums efficiently until they concentrated the subsidy on the slums. With the knowledge and agreement of the Chancellor of the Exchequer he said that he would not exclude from the consideration of the committee that there should be some extension of financial assistance from the Exchequer to the method of dealing with slums by re-conditioning, as well as by clearance. It need not, however, go abroad among the local authorities that because the Government were considering any possible means of increasing the efficiency of their legislation that was any reason why the authorities should delay in putting into force the powers to deal with slums which they had at the present time.

The resolution was agreed to.

SCOTLAND

In the House of Commons on Thursday, Feb. 9th, Mr. SKELTON (Under Secretary of State for Scotland), in moving the second reading of the Housing (Financial Provisions) (Scotland) Bill, said that the Slum Clearance Act, 1930, would remain unaltered. The State subsidy of £2 10*s.* per person removed from a slum and the local subsidy of £4 10*s.*, or whatever more might be necessary to re-house the persons so removed, would also remain. But the general subsidy of £9 in towns and £12 10*s.* in rural districts, under the Wheatley Act of 1924, would come to an end. In place of the general subsidy there would be a subsidy of £3 both for town and country districts which was to be used for the specific purpose of the housing of the low-wage earners, who were at present living in overcrowded conditions. The Rural Housing Acts of 1926 and 1931, whereby rural houses were re-conditioned, would remain unaffected. The 1923 Act was swept away. The subsidy to private enterprise for letting purposes was brought to an end. Under the new scheme the State and the local authorities would combine to give a guarantee for building society loans, between the proportions of 70 and 90 per cent., to be used for the purpose of encouraging and financing private enterprise in building. The main problem to-day was not that of dealing with a rapidly-increasing population; it was a problem of the slums and the overcrowded areas. The problem of slum clearance was really one for public enterprise, and they might leave to private enterprise the work of building the houses required. The work of slum clearance went on unchecked. Between 1923 and Dec. 31st, 1932, 20,000 slum houses had been closed and over 19,000 houses had been built to replace them. At Jan. 1st, 1933, there were 7752 houses actually under construction and 2469 approved, but not yet begun. That was a very remarkable result in a time of financial difficulty. The £3 subsidy house was to be confined to low-wage earners who were overcrowded, but not living in slum conditions.

The Bill was read a second time.

Hospitals and Road Accidents

The London Passenger Transport Bill was considered on Report in the House of Commons on Monday, Feb. 13th.

Lieut.-Colonel HEADLAM, Parliamentary Secretary to the Ministry of Transport, moved to delete Clause 53. He said this amendment carried out a pledge which was given by the Government during the committee stage of the Bill. Sections 35 and 36 of the Road Traffic Act, 1930, imposed obligations to provide against liability in respect of third party risks, either by a policy of insurance or by underwriting, involving the giving of security as defined by Section 37 of the Road Traffic Act, and depositing the sum of £15,000 with the Accountant-General of the Supreme Court. The removal of Clause 53 from the Bill really put the Board in the same position as any other persons who owned motor vehicles. Under Section 36 of the Road Traffic Act, insurers were subject to a further liability to pay to a hospital which had given treatment to any person injured by their vehicles reasonable expenses up to the sum of £25. He hoped that the elimination of the clause would give satisfaction to hon. Members.

The amendment was agreed to.

Food Adulteration

ON Feb. 14th, in the House of Commons, Mr. R. J. RUSSELL asked leave to introduce a Bill to amend the Food and Drugs (Adulteration) Act, 1928, and to control the sale of cheese other than whole-milk cheese. He said the Bill proposed that the butter-fat in cheese should be standardised at from 40 to 55 per cent., a percentage which had been reduced by manufacturers to about 16 or 20 per cent. The Bill would secure that all cheese not made of whole-milk would be marked as "skimmed-milk" cheese.

Leave was granted to introduce the Bill, which was brought in and read a first time.

HOUSE OF COMMONS

THURSDAY, FEB. 9TH

Foreign Skimmed Milk

Mr. DREWE asked the Minister of Agriculture whether, in view of the position of the milk industry and the present glut of milk, he would be prepared to prohibit or restrict the entry of foreign machine-skimmed milk as an emergency measure pending the reorganisation of the milk industry.—Sir GEORGE BOWYER replied: My right hon. friend has no powers to take the action suggested. He would draw the attention of my hon. friend to the views of the Reorganisation Commission for Milk on the subject of imports of skimmed condensed milk as set out on pages 138 and 139 of the Commission's Report.

Pasteurisation of Milk

Captain PETER MACDONALD asked the Minister of Health whether his department had now reached any decision as to the value of and need for compulsory pasteurisation of milk and, if so, what his decision was.—Sir E. HILTON YOUNG replied: This is now under the consideration of a committee of the Economic Advisory Council, which is examining the question of disease among milch cattle. Pending their report I am not in a position to make any pronouncement on the subject.

of things. His little brochure on Ambrose Paré is an example of this, and he had previously shown this quality in his M.D. thesis.

"I like to think of Parkin," writes a friend and colleague, "in wrapt attention when his interest was aroused; he always seemed to hold a watching brief for common sense and logic, and his judicial mind usually led him to a conclusion with which most of us had to agree. In debate he was often satirical, but never without justification, and he never seemed to speak until goaded to be outspoken. A great capacity for friendliness was one of his most outstanding characteristics, and he was loyal and staunch through all vicissitudes. None loyal to his memory would wish it to be known how many times he befriended those in trouble, but there are many sad hearts at his passing, and many among his poorest dispensary and hospital patients. Parkin was very fond of children and his affection for them was reciprocated. He took no part in sport, but was very fond of motoring, and he loved the country and country affairs. It was a delight to accompany him to a country consultation; there was never a dull moment on such a journey, for he knew the north country well and he found great interest in all around him."

Dr. Parkin's death was an unexpected blow to a large circle of friends and patients. There is no doubt that he had always given of himself too freely, and that he was often a tired man, for while very chary of undertaking certain work he always concentrated closely on the job in hand, a fact which accounted for his infrequent appearance in public affairs and at learned societies. He seemed to be in good health on the day of his death; he took his ward class as usual in the morning, and one who attended it describes it as exceptionally large and the lecturer extremely happy in his teachings. In the afternoon he made a long car journey to attend a country consultation. He was taken ill on the way home, and died the same night from coronary thrombosis. He leaves no family, but is survived by a widow and by his mother, an old lady of 97, who was his constant care. He and his wife were devoted to one another, and great sympathy is felt for her. Dr. Alfred Parkin was the uncle of the late Dr. G. C. Parkin, who died in December last during a typhoid epidemic while working among his patients at Malton.

* * *

WILLIAM HENRY HARSANT, F.R.C.S. Eng., who died on Feb. 10th at Bristol in his eighty-third year, was born at Epsom and educated at the City of London School. Entering Guy's Hospital he qualified L.S.A. in 1873, and in the following year was gold medallist in surgery and house-surgeon at the hospital. He then went to Bristol as house-surgeon to the General Hospital, became lecturer on anatomy at the medical school, and secured the position of surgeon to the Royal Infirmary, his special interest being in the surgery of the thyroid and middle ear. An accidental infection led to the loss of his right index finger and the decision to abandon surgery for general practice in Clifton, where for many years he was one of the most popular and respected of family advisers. Mr. Harsant was a life-long member of the Bristol Medico-Chirurgical Society, filling all the offices up to the presidency and being for a time joint editor of its journal. His wife predeceased him and he is survived by one of their two daughters.

PARLIAMENTARY INTELLIGENCE

NOTES ON CURRENT TOPICS

New Bills Introduced

IN the House of Lords on Wednesday, Feb. 8th, the following Bills were presented and read a first time: Cancer Hospital (Free) Bill; Samaritan Free Hospital for Women Bill; and the Essex County Council Bill.

The Essex County Council Bill contains provisions for the licensing and control of establishments for massage and special treatment. Clause 54 provides that the provisions of this part of the Bill shall not apply to establishments for massage or special treatment carried on by a duly registered medical practitioner with respect to which there has been lodged with the Council a certificate, in a form to be approved by the Council, and signed by two duly registered medical practitioners practising or residing in the county, not being in partnership with such first-mentioned medical practitioner, or with each other, and not having any financial or other interest in such establishment, to the effect that the medical practitioner carrying on, or proposing to carry on, such establishment is a suitable person to carry on the same at premises used, or to be used, therefor. It is further provided that any such certificate shall not be valid (*a*) with respect to any person or premises other than the person or premises specified therein, or (*b*) for a period extending beyond Jan. 31st next following the date of the certificate.

The Bill also contains miscellaneous provisions with regard to the control of refuse dumps, the pollution of rivers and streams, town planning, and the registration and inspection of premises used for the manufacture of ice-cream.

Housing and Slum Clearance

ENGLAND AND WALES

The House of Commons on Tuesday, Feb. 7th, considered in Committee the financial resolution in connexion with the Housing (Financial Provisions) Bill. Sir D. HERBERT, Chairman of Committees, was in the chair.

Sir E. HILTON YOUNG (Minister of Health) in moving the resolution said it was the necessary preliminary to the Government's scheme for the enlistment of the building societies in an effort to provide housing for the working classes. The outline of the scheme was that a certain guarantee should be extended to the building societies in respect of advances made by them in excess of their normal advances for building. The liability would be distributed in this way: one-third of the excess would be guaranteed by the local authorities, one-third by the Exchequer, and one-third would remain with the building societies. In practice it would amount to this: the normal amount advanced by building societies was 70 per cent. of the value of a building; that would be raised under this scheme to 90 per cent., and the difference of 20 per cent. would be guaranteed in the manner he had described. It was not contended that they would be able by this scheme to build the very cheapest sort of house to let at the lowest rents to the least well-paid classes of wage-earners. But it was contended that already it was possible to provide small houses at such rents as would meet a large part of the demand for houses for the wage earners down to the class just above the very lowest and cheapest of all. In securing that they would have secured a great addition to the supply of houses from private enterprise. That was a big step in advance.

It would be unwise for the Government to embark

PUBLIC HEALTH SERVICES

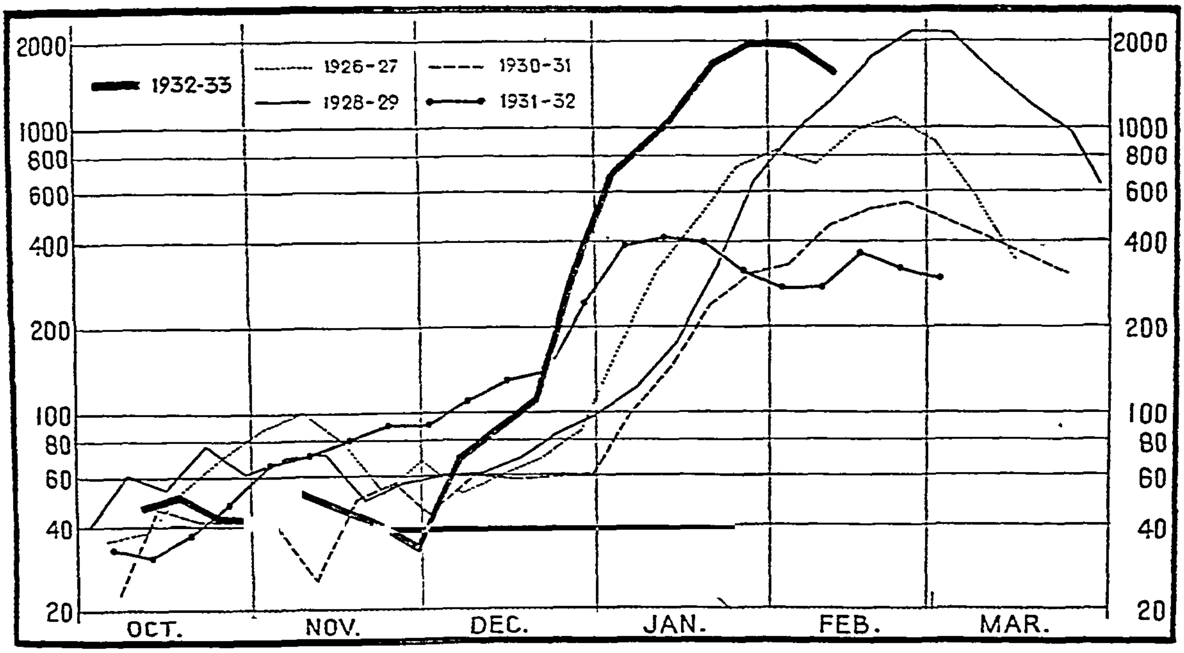

Chart showing the course of various influenza outbreaks in England and Wales. The numbers of deaths are charted as logarithms instead of actual figures, and it will be seen that this greatly exaggerates the earlier stages of the epidemics, and flattens the peaks. (Reproduced with alterations and additions from the League of Nations *Weekly Epidemiological Record* for Jan. 19th.)

Influenza

LAST week's figures show that the outbreak of influenza in this country is now abating. In the seven days ending Feb. 11th there were 1306 deaths in the 118 great towns of England and Wales, against 1934 and 1911 in the previous two weeks, while in London the total fell from 368 to 261. The accompanying chart shows the course of the epidemic in comparison with those of some other recent years. It will be seen that the peak has been reached more rapidly than in 1928-29, when the largest total of deaths in a single week was about the same.

TABLE I

—	118 great towns.	South-eastern area.	Greater London.	Northern area.	Midland area.	Eastern area.	South-western area.	Wales and Monmouthshire.
Jan. 7th	1·73	1·22	1·04	1·70	3·65	0·42	0·57	0·38

„ 21st	4·04	3·73	3·63	4·81	4·32	1·36	1·81	1·58
„ 28th	4·91	4·06	4·08	5·66	5·08	5·98	2·60	7·15
Feb. 4th	4·85	4·39	4·12	5 27	4·00	8·71	4·76	7·53

More detailed figures which are now available for the week ended Feb. 4th will be found in our usual analysis of the Registrar-General's weekly return, under the heading of Infectious Disease. Table I., which is reproduced from the return, gives influenzal death rates per 1000 per annum in the towns of the various areas, and shows that the eastern area and Wales were now bearing the brunt, after enjoying comparative immunity until a late stage. The rate for Greater London for the first time rose above the average of the 118 great towns. Table II gives the mortality in the four main age-groups.

TABLE II

Influenza in Glasgow.—A statement issued by Dr. A. S. M. Macgregor, M.O.H. for Glasgow, shows that the outbreak began there at the beginning of December and reached its height during the last fortnight of the month. The fall was rapid, although latterly it tended to taper off gradually and to merge into a period of increase of respiratory affections during the spell of cold weather. The general death-rate was at its highest (28·7 per 1000 per annum) during the week ended Dec. 24th, and the incidence of influenza fell far short of the experience of January, 1929, when the death-rate rose to 50 per 1000. The proportion of absentees from school was 15 per cent. on Dec. 23rd, compared with the ordinary figure of 5·5, the corresponding figures for teachers being 5 and 1·5 per cent. respectively. Except in one large general hospital, where the proportion off duty reached 10 per cent., the hospital staffs did not suffer as much as the outside population. The prevailing

Poor-law Children

Mr. LOVAT-FRASER asked the Minister of Health if he was aware that in April, 1931, there were over 100 children in the workhouses of Dorsetshire contrary to the regulations, and that there were still over 100 children there; and if he proposed to take any steps in the matter.—Sir E. HILTON YOUNG replied: The numbers stated are not in accordance with the information I possess. The return relating to Jan. 1st last is not yet available, but on Jan. 1st, 1931, the number was 68, and on Jan. 1st, 1932, was 44. Since then I have sanctioned the erection of two additional cottage homes to accommodate 30 children.

Radium Conference Report

Mr. LECKIE asked the Minister of Health what action he proposed to take to carry out the recommendation of the Radium Conference, whose report was published in January.—Sir E. HILTON YOUNG replied: The conference on massive radiation to which the hon. Member refers was not summoned by me, but by the president of the Royal College of Physicians and the president of the Royal College of Surgeons. It may, I think, safely be anticipated that the report of the conference will receive the attention of the Radium Commission and other bodies directly concerned with the therapeutic application of radium.

Public Health Law Consolidation

Mr. LIDDALL asked the Minister of Health when the Committee on Local Government and Public Health Law Consolidation, appointed Dec. 8th, 1930, would issue the promised interim report covering the consolidation of the law of local government.—Sir E. HILTON YOUNG replied: I understand that the committee hope to complete their interim report dealing with the law of local government not later than the end of the present month.

Female Vagrancy

Sir GIFFORD FOX asked the Minister of Health whether his returns from the provinces showed any increase in or any appreciable numbers of women or girl tramps.—Sir E. HILTON YOUNG replied: Such information as is available does not suggest that there has been any considerable increase in the number of women and girl casuals. They do not ordinarily account for more than 5 per cent. of the total number of tramps.

MONDAY, FEB. 13TH

All-India Medical Council Bill

Mr. JOHN asked the Secretary of State for India whether he had considered the resolution passed at the All-India Medical Council, held at Lucknow, and sent to him, requesting the Government not to proceed with the All-India Medical Council Bill until such time as the Federal legislature was duly constituted; and what action he proposed to take in the matter.—Sir S. HOARE replied: The resolution referred to by the hon. Member has not reached me.

TUESDAY, FEB. 14TH

Mental Condition of Accused Persons

Mr. MCGOVERN asked the Secretary of State for Scotland what were the reasons for dropping the prosecution of Colonel Frederick Watkins, Blair Atholl, Lenzie, who was arrested and charged with shoplifting from Messrs. Marks and Spencers' stores on Dec. 22nd, 1932.—Mr. NORMAND (Solicitor General for Scotland) replied: This officer was charged with shoplifting from the stores of Messrs. F. W. Woolworth, Ltd., Glasgow. The Lord Advocate ordered no further proceedings, in view of the accused's previous medical history, and a medical specialist's report as to his mental condition. The accused is now under treatment in a home.

Mr. MCGOVERN: Is it not a fact that the Lord Advocate instructed the Edinburgh agents of this man to secure such a certificate, and that on the production of such certificate he would order that no further steps should be taken in this case; and is this man now a paymaster in the Regular Army in the Scottish Command in Edinburgh?

Mr. NORMAND: With regard to the first part of the question, I think the position is that the only connexion that the Lord Advocate had with the doctor who gave the certificate was that the doctor was the usual doctor employed by the Crown in cases where the mental condition of an accused person is in question. I am unable to answer the second part of the question.

Mr. MCGOVERN asked if medical evidence for and against as to the mental condition of this man should have been produced in court to decide whether he was mentally unstable or not.

Mr. NORMAN said that the course taken in this case was perfectly normal. In minor cases of this kind it was within the discretion of the prosecutor to have an investigation made for himself and take what action seemed proper to him.

Mr. MCGOVERN asked the Secretary for Scotland the reasons for the failure to proceed with the prosecution of Mrs. Mary McBeth or Semple, of Newlands, Glasgow, who was charged with shoplifting from Messrs. Marks and Spencers, Ltd., on Dec. 8th, 1932; whether he was aware that she had been charged on two previous occasions, on Jan. 19th, 1914, from Messrs. Simpson and Sons' Stores, Jamaica-street, Glasgow, and in November, 1924; and what the sentence was on each occasion.—Mr. NORMAN replied: It is not the fact that the prosecution against the woman referred to did not proceed to trial. The case was in fact tried on Feb. 1st, 1933, before the Stipendiary Magistrate, Glasgow, who, in view of medical evidence upon the accused's mental condition, found her not guilty. She had previously been charged with similar offences. In February, 1914, she was put on probation for six months, and in November, 1924, she was ordered to find caution for her good behaviour, which was done.

Mr. MCGOVERN asked whether medical certificates were produced on behalf of this woman and the Stipendiary Magistrate found himself in a great difficulty in not accepting what had previously been accepted by the Lord Advocate; was this woman charged in 1914 with stealing an article valued at £43; did she plead that there was anything wrong with her mind, and did the police doctor certify her as being absolutely sane?

Mr. NORMAND: The Stipendiary Magistrate heard evidence and did not act upon any certificate. I am not able to answer the question as to the value of the article which she was accused of stealing in 1914. I do not think that on either of the previous occasions she pleaded insanity or mental weakness in connexion with the charges.

Mr. MAXTON: May we advise our constituents that under the present judicial regime in Scotland a medical certificate will always be taken as an excuse for theft?

Mr. NORMAND: No, Sir.

Mr. MCGOVERN gave notice that he would raise the matter again when the Lord Advocate returned, because, he said, there was a feeling in Scotland that the law was being "rigged" in this case.

Medical and Dental Services Report

Mr. LIDDALL asked the Secretary to the Treasury when the Committee on Medical and Dental Branches of the Defence Services, appointed May 19th, 1931, would present its report.—Mr. HOARE-BELISHA replied: I am informed by the chairman that this inquiry has now reached the stage at which the Committee may shortly consider a report.

GUERNSEY MENTAL HOSPITALS.—Dr. T. Saxty Good medical superintendent of Oxford County and City Mental Hospital, has reported upon the condition of the mental hospitals in the island of Guernsey. He describes the female institution, an annexe of the St. Peter Port Hospital, as gloomy and prison-like in appearance—it was, in fact, formerly an old house of correction. The room used as an infirmary is dark, dismal, and quite unsuitable, and the single rooms are "dark, cold, badly ventilated and lighted." There is no form of central heating, "the general effect is extremely depressing," and structurally the building is inadequate and unsuitable. None of the nurses are fully trained in mental nursing; there is too much solitary confinement; the patients are unoccupied and unclassified, and there are no amusements. In the male hospital, an annexe of the country hospital, the single rooms are lighted by small skylights, and the floors are of concrete. "The whole building has a prison-like appearance, and is quite unsuitable for treating mental illness." In the mental and general hospitals, the workhouses, and schools Dr. Good found a serious proportion of mental defectives. There is no out-patient department at any hospital in the island. Dr. Good recommends the appointment of a medical man experienced in the treatment of mental disorder to organise the main and auxiliary services for dealing with such disorders. He thinks that money spent upon improving the existing buildings would be largely wasted, and suggests a new building in the grounds of the country hospital, and the collection there of the whole of the hospital services, leaving only a small unit in St. Peter Port to deal with accidents. The asylums committee has recommended the States to appoint "for at least one year" a medical officer as proposed by Dr. Good.

Royal College of Physicians of Edinburgh

At a quarterly meeting of the College, held on Feb. 7th, with Dr. Robert Thin, the president, in the chair, Dr. Ion Simson Hall (Edinburgh) was introduced and took his seat as a Fellow of the College. Dr. Robert Lees (Edinburgh), Dr. Charles Mackay Seward (Exeter), and Dr. Ian George Wilson Hill (Edinburgh) were elected to the Fellowship.

London School of Hygiene and Tropical Medicine

The next series of eight lectures and demonstrations on tropical hygiene, which are intended for men and women outside the medical profession proceeding to the tropics, will be given by Lieut.-Colonel G. E. F. Stammers from March 6th to 15th. The synopsis may be had from the secretary of the school, Keppel-street, Gower-street, W.C.1.

Royal Statistical Society

A meeting of this society will be held on Tuesday, Feb. 21st, at 5.15 P.M., in the hall of the Royal Society of Arts, John-street, Adelphi, London, W.C., when Mr. A. Bradford Hill, D.Sc., will read a paper on Some Aspects of the Mortality from Whooping-cough.

Medico-Legal Society

An ordinary meeting of this society will be held at 11, Chandos-street, Cavendish-square, W. 1, on Thursday, Feb. 23rd, at 8.30 P.M., when a paper will be read by Dr. S. C. Dyke on The Human Blood-Groups, followed by a discussion which should attract considerable attention, seeing the significance which now has to be attached to findings along this line. Members may introduce guests to the meeting upon production of the member's private card.

Central Association for Mental Welfare

The association has again rented the Green Lady Hostel, Littlehampton, for the use of local authorities, institutions, and others as a holiday home for mental defectives. The hostel will be available for two periods: from March 31st to May 26th, and from Sept. 1st to Oct. 27th. Applications for the first period should be sent not later than Feb. 27th to the secretary of the association, 24, Buckingham Palace-road, London, S.W.1, from whom further information may be had.

Fellowship of Medicine and Post-Graduate Medical Association

The next lecture in the series on practical problems in medicine and surgery will take place on Tuesday, March 28th, at 11, Chandos-street, Cavendish-square, London, W., at 4 P.M., when Mr. J. P. Lockhart-Mummery will lecture on the Causes and Treatment of Incontinent Anus. There will be a week-end course of practical demonstrations in general medicine and surgery at the New General Hospital, Southend-on-Sea, on Saturday, March 4th, and Sunday, March 5th. The course will include ward rounds, lecture-demonstrations, demonstration of X ray films, and a discussion on Infection by the Staphylococcus. Further particulars may be had from the secretary of the Fellowship at 1, Wimpole-street, London, W.1.

Treatment of Industrial Rheumatism

In a lecture given at the Royal Institute of Public Health on Feb. 8th, Dr. W. S. C. Copeman said that chronic rheumatism costs this country £17,000,000 per annum, yet the only *official* methods of combating it at present are by the payment of weekly allowances whilst the patient is not at work, and by analgesic drugs. Most of the schemes put forward for dealing with it entailed the *de*centralisation of treatment centres. Dr. Copeman felt this method to be wasteful and likely to be inefficient. In any practical scheme diagnosis must in the first instance be in the hands of the insurance practitioner, or failing this, by "rheumatic advisory centres," which may be run apart from treatment clinics in all thickly populated and industrial parts of towns. If special (physical) treatment should be required, the patients are referred from these centres to a central clinic. Treatment at these "town clinics" must be supervised by experts, and must be given after working hours. If treatment in bed is required, or more than two months' treatment, cases should be sent on to a spa or provincial general hospital. Afterwards they must be referred directly back to their own doctor and "followed up" from the centre.

Sir Edward Stewart, M.D., the chairman, said that the British Red Cross Society were considering the adoption of the scheme outlined by Dr. Copeman, since it appeared necessary that any scheme which might later be put into operation in this country should be on a national scale. If the problem were left in the hands of local authorities there would be overlapping between the various areas.

WE regret to announce the death on Feb. 12th, in his 70th year, of Dr. T. B. Hyslop, sometime medical superintendent of the Bethlem Royal Hospital.

Hunterian Society

Sir Crisp English will deliver the Hunterian oration at the Mansion House, London, E.C., at 9 P.M., on Monday, Feb. 27th. The subject of the oration will be the Language of Facts.

Malmesbury Hospital

Last year 353 in-patients were admitted to the Malmesbury and District Hospital and Maternity Home, 40 of whom were maternity cases. The average stay was 21·5 days, and the average weekly cost of maintenance £2 11*s.* 2*d.*

Birmingham Hospitals Contributory Association

The income last year was £272,000, an increase, notwithstanding trade depression, of £70,000. In the five years since the Hospital Saturday Fund was linked with the Contributory Association rather more than a million has been raised. The contributors number 445,000.

Liverpool's Hospital "Flying Squad"

The Merseyside Hospitals' Council is endeavouring to bring up to 250 the "flying squad" of motorists who volunteer to take blood donors to hospital and relatives to patients dangerously ill during the hours of the night when public transport is not available. The corps already numbers 180, many of whom are young women, but the volunteers' duties are increasing so rapidly that a considerable augmentation is necessary. Each member takes one month's duty at a time.

Anti-cancer Serum

The central public health committee of the London County Council has granted permission to Dr. T. Lumsden, director of the cancer research laboratory at the London Hospital, to arrange for the treatment with anti-cancer serum of patients in the Council's hospital who may assent to such treatment, provided the work is carried on in each case under the supervision and control of the medical superintendent of the hospital concerned.

Volunteer Nurse Patrols

A corps of women volunteer nurses is being trained at Glasgow to patrol the main roads in the west of Scotland to give aid to persons injured in accidents. The nurses, who will become a unit of the St. George's Ambulance Association, will tend the injured on their way to hospital and supplement the ambulance corps in first-aid service; they will wear a uniform similar to that of the Voluntary Aid Detachment. It is hoped eventually that the service will cover the whole of Scotland.

The Institute of Medical Psychology

A post-graduate course in psychotherapeutic theory and method has been arranged by this institute. The work of the course is divided into two groups (each limited to six in number); members of the first group are asked to give three hours twice a week, while members of the secondary group are expected to devote 12 hours weekly to the work of the course and to attend on three days. The introductory part of the work of the first group may be attended by medical practitioners as an isolated course of lectures, which will be given at 4.45 P.M. and 5.45 P.M. on Fridays and Tuesdays from March 10th to April 11th. Applications and inquiries should be sent to the honorary lecture secretary, at the institute, 6, Torrington-place, London, W.C.1.

Aberdeen Hospitals

Last year was marked by a further extension of the work of the radium department of Aberdeen Royal Infirmary, 557 treatments by radium and radon having been given as compared with 430 in 1931. In consequence of the insufficient supply of radium a further loan of 200 mg. was obtained and converted into radon, as it had been found that the treatment of suitable cases by this agency was the more economical. There were 6780 in-patients, an increase of over 500, and 26,521 out-patients, an increase of nearly 1000. The average cost per occupied bed was £88 10*s.* 10*d.* as compared with £93 0*s.* 1*d.* in 1931; the average cost of each in-patient was £4 17*s.*, a fall of 11*s.* 7*d.* Motor accident cases numbered 143; they cost £800, in respect of which £203 has, so far, been recovered. The Aberdeen Royal Mental Hospital is to be reconstructed and enlarged at a cost of £100,000, instead of £70,000 as originally contemplated. Since only £25,000 is available, the remaining £75,000 will have to be borrowed on the basis of repayment over a period of 30 years.

type of illness was of sharp onset and short duration, ushered in with shivering and fever followed by headache and joint pains, and lasting two or three days. Often the acute symptoms were followed by persistent cough and debility. The gastric type was not in evidence. The outbreak apparently caused an increased incidence of acute lobar pneumonia at a time when this does not usually prevail to anything like the same extent. Of 49 cases of pneumonia (30 lobar, 10 broncho-pneumonia, and 9 "influenzal") admitted to one of the hospital wards between Dec. 15th and Jan. 17th, 17 proved fatal, giving a mortality-rate of 35 per cent. against a pre-influenzal rate of about 15 per cent. in the same ward. Dr. Ian Christie, at Knightswood Fever Hospital, found 53 per cent. of type II. infections compared with an average of 36 per cent. for the city during the past three years.

INFECTIOUS DISEASE

IN ENGLAND AND WALES DURING THE WEEK ENDED FEB. 4TH, 1933

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 18 (last week 14); scarlet fever, 1757; diphtheria, 678; enteric fever, 9; acute pneumonia (primary or influenzal), 5151 (last three weeks 3456, 3781, and 4821); puerperal fever, 37; puerperal pyrexia, 154; cerebro-spinal fever, 90; acute poliomyelitis, 11; acute polio-encephalitis, 1; encephalitis lethargica, 15; dysentery, 24; ophthalmia neonatorum, 91. No case of cholera, plague, or typhus fever was notified during the week.

The number of cases in the Infectious Hospitals of the London County Council on Feb. 7th–8th was as follows: Small-pox, 56 under treatment, 4 under observation (last week 44 and 5 respectively); scarlet fever, 1611; diphtheria, 1597; enteric fever, 8; measles, 271; whooping-cough, 670; puerperal fever, 23 (plus 11 babies); encephalitis lethargica, 230; poliomyelitis, 1; other diseases, 321. At St. Margaret's Hospital there were 15 babies (plus 9 mothers) with ophthalmia neonatorum.

The notifications of cerebro-spinal fever have been rising steadily for the last few weeks, the figures being 38, 47, 61, 66, and 90. They are distributed this week among 23 counties and 64 sanitary authorities, the largest numbers being in *Durham* 6 (Sunderland 3, West Hartlepool 1, Easington R.D. 2), *Lancaster* 8 (Liverpool 2, Manchester 2, St. Helens 2, Wigan 1, Rawtenstall 1), *London* 13 (Bethnal Green 1, Hackney 1, Hammersmith 1, Hampstead 1, Kensington 1, Poplar 1, St. Pancras 1, Shoreditch 1, Southwark 1, Stepney 2, Westminster 1, Woolwich 1), *Yorks West Riding* 26 (Barnsley 1, Bradford 2, Doncaster 3, Leeds 3, Sheffield 7, Adwick-le-Street U.D. 1, Conisbrough U.D. 2, Normanton U.D. 2, Royston U.D. 1, Shipley U.D. 1, Stocks Bridge U.D. 1, Doncaster R.D. 1, Rotherham R.D. 1).

Deaths.—In 118 great towns, including London, there was no death from small-pox or enteric fever, 19 (0) from measles, 5 (0) from scarlet fever, 81 (14) from whooping-cough, 40 (4) from diphtheria, 42 (10) from diarrhœa and enteritis under 2 years, and 1911 (368) from influenza. The figures in parentheses are those for London itself.

The towns which reported the largest number of deaths from influenza were as follows, last week's figures being given in parentheses: Manchester 87 (100), Sheffield 63 (85), Bristol 62 (65), Hull 49 (27), Liverpool 49 (49), Bradford 38 (18), West Ham 36 (24), Cardiff 36 (36), Leicester 35 (37), Stoke-on-Trent 34 (72), Leeds 31 (56), Oldham 29 (22), Salford 29 (20), Norwich 26 (17), Cambridge 25 (12), Swansea 25 (28), Nottingham 23 (37), Wigan 22 (20), Bolton 21 (43), Preston 21 (12), Birmingham 21 (24), Plymouth 21 (6).

Six fatal cases of measles were reported from Liverpool, 2 from Hull. Deaths from whooping-cough were widely distributed, 6 being reported from St. Helens, 5 from West Ham, 4 from Darlington; each 3 from Leeds, Sheffield, and Stoke-on-Trent. Diphtheria claimed 5 victims at Liverpool.

The number of stillbirths notified during the week was 273 (corresponding to a rate of 42 per 1000 total births), including 35 in London.

MEDICAL NEWS

University of Cambridge

On Feb. 11th the following degrees were conferred:—

M.D.—*A. D. Charters, J. R. Armstrong, S. W. Savage, and J. L. Newman.
M.B. and B.Chir.—R. S. C. McDade and S. S. Jaikaran.
M.B.—G. H. A. Graetz.
B.Chir.—*R. L. Osmaston and K. M. A. Perry.
* by proxy.

Royal College of Surgeons of England

At a meeting of the council held on Feb. 9th, with Sir Holburt Waring, the president, in the chair, diplomas of membership were conferred on 131 of the 134 candidates whose names were given in our issue of Feb. 4th as recipients of the L.R.C.P. (with the exception of B. T. W. Harvey, H. J. M. Robinson, and H. G. Ungley).

Resolutions of condolence were passed on the death of Sir Percy Sargent, vice-president of the College, and of Sir Frederic Hallett, formerly secretary of the examining board in England and the Imperial Cancer Research Fund. Mr. G. E. Gask, professor of surgery in the University of London, was elected a vice-president in place of Sir Percy Sargent.

The president reported the appointment of Mr. A. H. Burgess, professor of clinical surgery in the University of Manchester, as Bradshaw lecturer, and of Mr. L. W. G. Malcolm, conservator of the Wellcome Historical Medical Museum as Thomas Vicary lecturer for the ensuing year. Mr. Victor Bonney was re-elected the representative of the College on the Central Midwives Board, and Sir Cuthbert Wallace was elected a member of the executive committee of the Imperial Cancer Research Fund.

The president reported that an election of five Fellows into the council would take place on Thursday, July 6th, at 11 A.M., in the vacancies occasioned by the retirement in rotation of Lord Moynihan, Sir John Lynn-Thomas, Mr. Burgess, and Mr. V. Warren Low, and by the death of Sir Percy Sargent; that notice of the election would be given to the Fellows by advertisement and by circular on March 10th; that March 20th would be the last day for the nomination of candidates; and that a voting paper would be sent on April 4th to every Fellow whose address was registered at the College.

University of London

The University Extension and Tutorial Classes Council, in coöperation with the Central Association for Mental Welfare, has arranged a course, from Monday, May 8th, to Saturday, May 20th, on mental deficiency; it is specially designed for medical practitioners who are definitely concerned with the care of subnormal or abnormal persons. The course is divided into two parts, and part I. (May 8th to May 13th) may be taken separately if desired; part II. (May 13th to May 20th) may only be taken separately by those who have in previous years attended part I. The lectures will be given daily from 10 A.M. to 12.30 P.M. at the University, South Kensington, and the lecturers will include Dr. A. F. Tredgold, Dr. F. C. Shrubsall, Prof. Cyril Burt, Dr. William Moodie, and Dr. Emanuel Miller. Clinical work will also be arranged for each student. Further particulars may be had from Miss Evelyn Fox at the University Extension Department, University of London, South Kensington, S.W.7, to whom applications should be sent before April 18th.

British Post-Graduate Medical School

Sir Austen Chamberlain has accepted nomination by the Minister of Health to be a governor of this school, and the governors have appointed him chairman of the governing body in succession to Lord Chelmsford, who resigned on his election to be warden of All Souls College, Oxford.

Presentation to a Medical Man

Upon his retirement from the position of senior honorary surgeon of Saffron Walden Hospital, with which he has been connected for more than 40 years, Dr. H. C. Bartlett has been presented with a silver salver. In acknowledging the gift Dr. Bartlett said he believed that, with one exception, he was the last medical student to be apprenticed. The exception was Dr. Walter Gifford Nash, who has recently retired from the senior surgeoncy of Bedford Hospital. He said that his work "was to dispense, roll bandages, take out teeth, walk round the wards, visit the sick, answer the night bell, take down the shutters in the morning and put them up at night, go to church twice on Sunday, wear a tail coat and bowler hat, and to do everything possible to help the man with whom he was apprenticed."

NOTES, COMMENTS, AND ABSTRACTS

TESTS FOR MOTORISTS

It is estimated that in the 14 years since the war 1,800,000 men, women, and children have been injured or killed on the roads of Great Britain. The treatment of the injured is believed to cost our hospitals nearly £300,000 a year. It is said that over 98 per cent. of these traffic accidents are avoidable. What would the public think if an epidemic took a similar toll of life and if it were shown that a similarly high proportion of cases were preventable? Unable to share the general attitude of fatalism in these matters, the Pedestrians' Association comes forward with a pamphlet explaining, Why Britain should have Motor Driving Tests. The Royal Commission, on whose report the Road Traffic Act of 1930 was based, decided against tests. The Act itself requires no tests of intending motorists; it merely requires applicants for licences to make a declaration. The prescribed form of declaration undoubtedly eliminates a proportion of drivers who are physically unfit or disabled. Would not a proper test eliminate a larger number? Would it not therefore make the roads safer—a result which the Road Traffic Act has failed to achieve?

There are four arguments against tests. The beginner, it is said, is not a dangerous driver, because he is too frightened to take risks. The reckless driver, who is the chief danger, is not eliminated by tests. Tests if perfunctory are valueless; if thorough they are impracticable. The cost of tests would far outweigh the value. The Pedestrians' Association, in controverting these four arguments, hints that a fifth has influence with the motor trade—namely, a fear that if tests mean fewer drivers, there will be some decline of sales. Such an argument could hardly be seriously stated. Bad as trade is, it has no right to a stimulus which will put a few more people into the cemeteries and hospitals as well as into the factories. The Pedestrians' Association tells us that Great Britain has the highest density of motor vehicles per mile of road of all the countries in the world, and that therefore the highest standard of driving skill is required. It states that we have the worst accident record in the world (if account be taken of the number of cars and population), and that ours is the only civilised country (with the exception of Belgium) which has no tests. This last statement perhaps needs some small qualification. Many towns in England have obtained powers by Local Act for imposing "such reasonable tests as they may think fit" upon persons seeking a licence to drive a hackney carriage in the district. If this is desirable in the case of taxi-drivers, it may also be desirable for lorry-drivers, private motorists, and motor-cyclists. But if the enactment of compulsory tests for all drivers is not practical politics, possibly a beginning can be made with some voluntary system. It should not be beyond the powers of the various motoring associations to devise some criteria of physical fitness and technical competence and to apply them to such members as volunteer to be examined. Would not insurance companies be disposed to offer better terms to examinees who emerged with a first-class diploma? The Pedestrians' Association pamphlet mentions some interesting details of psychological tests evolved by the National Institute of Industrial Psychology.

Tests of course are not put forward as a panacea, but as an essential part of a comprehensive policy to lessen the avoidable accidents which multiply death and suffering. Controversy between pedestrians as such and motorists as such is misleading. All motorists are sometimes pedestrians and many pedestrians are sometimes motorists. But the Pedestrians' Association does well to draw attention to any possible remedy for the appalling loss of life on the roads.

QUININE AND ITS SUCCESSORS

To the Editor of THE LANCET

SIR,—May we correct one or two points in your leading article of Jan. 28th (p. 206) from which misapprehension seems to have arisen. When it is stated that nine-tenths of the world's quinine is made in Java and Sumatra, and one-tenth in India, the reference is obviously to the amount of cinchona bark grown. It is true that the quinine factory at Bandoeng, Java, manufactures large quantities of the product, but most of that sold to-day is made in Holland, Great Britain, Germany, France, Switzerland, and the U.S.A. The world consumption of quinine being somewhere in the region of 500,000 kg. in 1931, it is difficult to see how the figure of 60,000 kg. for the imports of all countries was obtained.

We are, Sir, yours faithfully,

HOWARDS AND SONS, LTD.
(H. LLOYD HOWARD, Director.)

Ilford, Jan. 31st, 1933.

*** The League of Nations pamphlet deals with "quinine or secondary alkaloids of cinchona," since the information which has been received has not ordinarily distinguished between the two. The difficulties encountered in its compilation are described thus: "The figure for imports seems to be accurately known in the case of quinine imported by Governments themselves; but the amount of quinine imported commercially is much less certain, because some of it may be reimported, or some of the goods declared as quinine are not quinine. In these cases the figure for imports is exaggerated." The figure of 60,000 kg. quoted in the article refers to quinine imported by Governments. The table from which it is taken gives, however, two figures, "total" and "corrected total." Under "corrected total" is apparently given the average amount imported over a period, usually over ten years; it is stated to be 59,809 kg. Under "total" appears the quantity imported during the last year for which figures have been received; in 1931 it reached 156,280 kg. The corrected total was used in our leading article.—ED. L.

DETERIORATION IN THE TROPICS

OUR last issue contained an annotation and a report of a discussion on mental and physical deterioration of Europeans in the tropics. Dr. D. V. Latham, in the January issue of the *East African Medical Journal*, describes the disadvantages of living, not only in the tropics, but at a high altitude. European residents in the East African highlands live at levels from 4500 feet upwards. With increasing altitude there is a falling incidence of tropical diseases, but psychological derangements, cardiovascular disease, and lung affections become commoner. The region most densely populated by Europeans lies actually on the Equator, and Dr. Latham believes that the combination of altitude and tropical sun is an important factor in modifying physiology and pathology. Mountain sickness may arise if the energy output is excessive, and the prognosis in pneumonia is distinctly less favourable than at lower altitudes because the anoxæmia induced is more marked. The effect on the mental faculties of life at high altitudes, he finds, is comparable to that of alcohol: some people become morose, others quarrelsome; cautious men may become reckless and reliable men irresponsible. He infers that the mind suffers more readily from fatigue in a reduced oxygen pressure, and irritability and lack of self-control appear more easily. Children suffer physically from a diet sterilised to excess, and morally from the devotion of their African attendants. Dr. Latham concludes by saying that "to my mind it is doubtful if a community will ever be able to overcome the added trials of the sun and altitude in a country where

Pay-beds at the Cancer Hospital, Fulham

The governors of this free hospital recently decided to introduce a Bill in Parliament to enable them to make charges to patients desirous of special accommodation.

Cardiff Royal Infirmary

Last year 5654 in-patients and 36,868 out-patients were treated at this hospital at a total cost of £61,694, an average of £9 1*s.* per in-patient and 5*s.* 10*d.* per out-patient. The average cost per occupied bed was £140 4*s.* During the year £3778 was collected in sixpences.

Sussex Provident Scheme

Under this scheme during 1932 over £20,000 was paid to hospitals and cooperating institutions and organisations which only received £332 in 1021. The scheme was started in 1920 and, as these figures show, has been very successful; during the 12 years £110,627 have been contributed. Last year the Royal Sussex County Hospital received £7180 for services rendered to members; the Royal Alexandra Hospital for Sick Children, £2108; New Sussex Hospital, £1939; Hove Hospital, £1102; Haywards Heath Hospital, £1051; and Brighton Corporation, £1030.

Medical Diary

SOCIETIES

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

Tuesday, Feb. 21st.—5.30 P.M., General Meeting of Fellows. 8.30 P.M., Patholo[illegible] Bland-Sutton Institute of [illegible] [illegible]strations [illegible]oids in Pulmonary Phagocytes. [illegible] Incidence and Total Incidence of Cancer in England and Holland. Prof. J. McIntosh: An Unusual Source of Tetanus Infection. Mr. J. W. Cook and Prof. E. C. Dodds: Biological Activity of Synthetic Org[illegible] to Œstrus. D[illegible] Observations [illegible] Mr. D. H. P[illegible] Portal Vein. [illegible] mental Hypertension. Dr. L. W. Proger: Apparatus for Cinema Microphotography. Mr. C. J. Britton: Experimental Reticulocytosis and Punctate Basophilia. Mr. E. G. Muir: *The Pathology of Prostatic Enlargement.* Dr. C. C. Bryson: The Histological Grading of Intrabuccal Carcinoma. Dr. A. C. Counsell: Pathological Specimens.

Wednesday.—5 P.M., Comparative Medicine and Therapeutics and Pharmacology. Discussion: Plant Poisoning in Man and Animals. Speakers: Mr. W. Horner Andrews, Sir William Willcox, Mr. J. A. Nicholson, Dr. G. Clough, and Dr. P. Haas.

Thursday.—8.30 P.M., Urology. Paper. Mr. J. Swift Joly: Bilateral Renal Calculi.

Friday.—5.30 P.M., Disease in Children. (Cases at 4.30 P.M.). *Cases will be shown.* 8 P.M., *Epidemiology and State Medicine.* Paper. Dr. G. C. M. M'Gonigle (Stockton-on-Tees): Some Results of the Removal of a Slum Population to Modern Dwellings.

MEDICAL SOCIETY OF LONDON, 11, Chandos-street, Cavendish-square, W.

Monday, Feb. 20th.—9 P.M., Mr. V. Z. Cope: Pathology of Acute Abdominal Disease (1st Lettsomian lecture).

CHELSEA CLINICAL SOCIETY.

Tuesday, Feb. 21st.—8.30 P.M. (at the Hotel Rembrandt, Thurloe-place, S.W.), Mr. Harold G. Taylor will open a discussion on Contraception. (Preceded by dinner at 7.30 P.M.)

MEDICO-LEGAL SOCIETY.

Thursday, Feb. 23rd.—8.30 P.M. (at 11, Chandos-street, Cavendish-square, W.), Dr. S. C. Dyke: The Human Blood Groups. To be followed by a Discussion.

ST. JOHN'S HOSPITAL DERMATOLOGICAL SOCIETY.

Wednesday, Feb. 22nd.—5 P.M. (at 49, Leicester-square, W.C.), Dr. H. Gordon: Arsenical Jaundice.

ROYAL MEDICO-PSYCHOLOGICAL ASSOCIATION.

Wednesday, Feb. 22nd.—2.30 P.M. (at 11, Chandos-street, [illegible] D. R. MacCalman: [illegible] Application.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

ROYAL *COLLEGE OF PHYSICIANS, Pall Mall East, S.W.*

Thursday, Feb. 23rd.—5 P.M., Dr. R. Cruickshank: Pneumococcal Infections (1st Milroy lecture).

ROYAL COLLEGE OF SURGEONS, Lincoln's Inn-fields, W.C.

Monday, Feb. 20th.—5 P.M., Mr. Laurence O'Shaughnessy: Thoracic Surgery. (Hunterian lecture.)

Wednesday.—5 P.M., Mr. G. A. Mason: Surgical Significance of the Vitelline Duct. (Hunterian lecture.)

Friday.—5 P.M., Mr. E. R. Flint: Pre-operative Procedure. (Hunterian lecture.)

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole street, W.

Monday, Feb. 20th to Saturday, Feb. 25th.—Royal Free Hospital, Gray's Inn-road. Fri., Antenatal demonstration by Dame Louise McIlroy at 5 P.M.—St. John's Hospital, Leicester-square, W.C. Post-graduate Course in Dermatology. Clinical instruction daily at 2 P.M. and 6 P.M. Lectures at 5 P.M. on Tues. and Thurs.—National Temperance Hospital, Hampstead-road, N.W. Evening M.R.C.P. Course, Mondays and Fridays at 8 P.M.—Prince of Wales's Hospital, Tottenham, N. Post-graduate Course in Medicine, Surgery and the Specialties. All day.—Hospital for Consumption, Brompton, S.W. Post-graduate Course in Practical Pathology dealing with Laboratory Methods and the Interpretation of Results, Mons. and Thurs., 11.30 A.M. to 1 P.M.—Fellowship of Medicine, 1, Wimpole-street, W. The Interpretation of Pyelograms. Mon., Wed., and Fri., 8 P.M.—*Courses open only to Members and Associates of the Fellowship of Medicine.*

ST. MARK'S HOSPITAL, City-road, E.C.

Thursday, Feb. 23rd.—4 P.M., Dr. J. K. Hasler: Anæsthesia in Rectal Surgery.

CENTRAL LONDON THROAT, NOSE, AND EAR HOSPITAL, Gray's Inn-road, W.C.

Friday, Feb. 24th.—4 P.M., Mr. A. Lowndes Yates: Diseases of the Ear which lead to Deafness.

ST. PETER'S HOSPITAL FOR STONE, Henrietta-street, W.C.

Wednesday, Feb. 22nd.—3 P.M., Mr. J. G. Sandrey. Congenital Abnormalities of the Upper Lip.

KING'S COLLEGE HOSPITAL MEDICAL SCHOOL, Denmark-hill, S.E.

Thursday, Feb. 23rd.—9 P.M., Dr. E. ff. Creed: Recent Work on Some Blood Diseases.

HOSPITAL FOR EPILEPSY AND PARALYSIS, Maida Vale, W.

Thursday, Feb. 23rd.—3 P.M., Dr. Wilfred Harris will demonstrate.

NATIONAL HOSPITAL, Queen-square, W.C.

Monday, Feb. 20th.—2 P.M., Dr. Riddoch: Out-patient Clinic. 3.30 P.M., Dr. Hinds Howell: Vascular Disease of the Nervous System.

Tuesday.—2 P.M., Dr. Walshe: Out-patient Clinic. 3.30 P.M., Dr. Grainger Stewart: Spinal Tumours and Syringomyelia.

Wednesday.—2 P.M., Dr. Martin: Out-patient Clinic 3.30 P.M., Dr. James Collier: Clinical Demonstration

Thursday.—2 P.M., Dr. Kinnier Wilson: Out-patient Clinic. 3.30 P.M., Dr. Walshe: Cerebral Tumours.

Friday.—2 P.M., Dr. Adie: Out-patient Clinic. 3 30 P.M., Dr. James Collier: Virus Diseases of the Nervous System.

LONDON JEWISH HOSPITAL, Stepney Green, E.

Thursday, Feb. 23rd.—4 P.M., Dr. Geoffrey Konstam: Anæmias Due to Defective Maturation of Red Blood Cells.

UNIVERSITY COLLEGE, Gower-street, W.C.

Wednesday, Feb. 22nd.—4.15 P.M., Dr. J. S. Prendergast: Renaissance Medicine.

LONDON SCHOOL OF DERMATOLOGY, St. John's Hospital, 49, Leicester-square, W.C.

Tuesday, Feb. 21st.—5 P.M., Dr. J. A. Drake: Leprosy.

Thursday.—5 P.M., Dr. A. Burrows: Leukæmia Cutis, Mycosis Fungoides.

ROYAL INSTITUTE OF PUBLIC HEALTH.

Wednesday, Feb. 22nd.—11.30 A.M., Demonstration at the British Red Cross Society Clinic for Rheumatic Diseases, Peto-place, Regent's Park, N.W.

SOUTH-WEST LONDON POST-GRADUATE ASSOCIATION, St. James's Hospital, Ouseley-road, Balham, S.W.

Wednesday, Feb. 22nd.—4 P.M., Mr. E. Lindsay: Painful Feet.

CHADWICK TRUST.

Tuesday, Feb. 21st.—5 P.M. (at the Royal Society of Tropical Medicine, 26, Portland-place, W.), Dr. Matthew B. Ray: The Hippocratic Tradition.

MANCHESTER ROYAL INFIRMARY.

Tuesday, Feb. 21st.—4.15 P.M., Dr. E. W. Twining: The Value of X Rays in Cardiac Conditions.

Friday.—4.15 P.M., Prof. F. E. Tylecote: Demonstration of Medical Cases.

ST. MARY'S HOSPITALS, Manchester.

Friday, Feb. 24th.—4.15 P.M., Post-graduate Lecture (at the Whitworth-street West Hospital), Dr. Ward: Problems of Infant Feeding.

GLASGOW POST-GRADUATE LECTURES.

Tuesday, Feb. 21st.—3.30 P.M. (in the Faculty Hall, St Vincent-street), Dr. Nora I. Wattie: Gonorrhœal Infection in Women.

Wednesday.—4.15 P.M. (at the Ear, Nose and Throat Hospital), Dr. W. S. Syme: Ear, Nose and Throat Cases.

INDEX TO "THE LANCET," VOL. II., 1932

The Index and Title-page to Vol. II., 1932, which was completed with the issue of Dec. 31st, is now ready. A copy will be sent gratis to subscribers on receipt of a post-card addressed to the Manager of The Lancet, 7, Adam-street, Adelphi, London, W.C.2. Subscribers who have not already indicated their desire to receive Indexes regularly as published should do so now.

ADDRESSES AND ORIGINAL ARTICLES

PHTHISIS PULMONALIS DUE TO THE BOVINE TYPE OF TUBERCLE BACILLUS

AN ACCOUNT OF TEN NEW SCOTTISH CASES

By A. Stanley Griffith, M.D.Vict., Ph.D. Camb.
MEMBER OF THE SCIENTIFIC STAFF, MEDICAL RESEARCH COUNCIL
AND
W. T. Munro, M.D. St.And., F.R.C.P. Edin.
MEDICAL SUPERINTENDENT, GLENLOMOND SANATORIUM

Until within the last ten years the bovine tubercle bacillus, although of frequent occurrence in the non-pulmonary forms of human tuberculosis, had rarely been found in cases of ulcerative pulmonary tuberculosis (phthisis pulmonalis). At the Washington Congress in 1908 Koch, in support of his view that the bovine was less virulent for man than the human tubercle bacillus, maintained that the former type of bacillus had never been definitely demonstrated in a case of phthisis. At that date, however, relatively few cases of this form of the disease had been examined bacteriologically, and, in order to fill this gap, on the initiative of Koch, workers in many different countries undertook the typing of cultures of tubercle bacilli obtained from the sputum of phthisical persons. The results of these early investigations were reviewed by one of us in 1914 and 1932, and are here briefly summarised. Of 926 cases reported by foreign investigators three only yielded bovine bacilli, and in two of these three the bovine bacilli were shown to be associated with bacilli of human type, the latter preponderating, while in the third case (de Jong-Stuurmann) the eugonic character of the culture indicated that in this instance also tubercle bacilli of both types were coexistent in the sputum of the patient.

In Great Britain, on the other hand, Griffith,[1] working for the Royal Commission on Tuberculosis, found among 29 phthisical persons in England two adult males, aged 21 and 31 years respectively, who were expectorating tubercle bacilli of the bovine type only with the sputum. On extending his inquiries to Scotland he [2] discovered in 1913, among 73 cases—45 from Edinburgh and 28 from Glasgow and Lanark—the first Scottish case, a girl of 16½, from Edinburgh. In these three cases the bovine bacilli were obtained repeatedly from the sputum, and no other type was present. Thus it was shown beyond reasonable doubt that the bovine tubercle bacillus can cause typical phthisis pulmonalis. In 1916 Wang [3] reported, among 29 examined, another case from Edinburgh, but in this instance only one examination could be made.

No further case came to light in Great Britain until 1924, when Tulloch, Munro, Ross, and Cumming [4] reported that two of the 100 strains which they had obtained from the sputum of 100 phthisical persons in Glenlomond Sanatorium were culturally of the bovine type and virulent for rabbits, though not so highly virulent as standard bovine bacilli. Since that date cultures of tubercle bacilli have been raised by Munro from the sputum of every phthisical person admitted to Glenlomond Sanatorium, with the remarkable result that down to the middle of 1932, out of 445 cases examined, bovine tubercle bacilli were found by him in no fewer than 18 cases, in one instance associated with human bacilli. In addition Munro found bovine bacilli in the sputum of a case of phthisis from the county of Roxburgh. During the period from 1916 onwards one of us (A. S. G.) continued intermittently to investigate cases in England, and in the last two years has examined, through the courtesy of Sir Pendrill Varrier-Jones, the bacilli from every new case of phthisis admitted to Papworth Settlement. These recent English investigations have resulted in the discovery of two further cases with bovine bacilli in the sputum. Both of these patients are males and have lived in Cambridgeshire all their lives. One is a farm labourer 59 years of age, and the other is a youth of 22, the son of a farmer. The number of cases from Papworth examined during the years 1929–32 is 430, making, with those previously reported from London, a total for south-east England of 657. Of these four only, two from Brompton Hospital and two from Cambridgeshire, have yielded bovine bacilli (a full account of the second Cambridgeshire case, Case 25, has not yet been published).

Until very recently no systematic investigations of the types of tubercle bacilli in phthisis in the northern counties of England have been undertaken. This want has been supplied by the important work of Cumming and Foster,[5] of Grassington Sanatorium, Yorkshire, briefly referred to at the centenary meeting of the British Medical Association, and published more fully in the current number of the *Journal of Pathology and Bacteriology*. These authors report that during the period from January, 1931, to September, 1932, they have obtained cultures of tubercle bacilli from the sputum of 339 phthisical persons from the north of England, and that of this number 12 had bovine tubercle bacilli in the sputum. In one instance both human and bovine bacilli were obtained from the sputum, and subsequent bacteriological examination of autopsy material showed that tubercle bacilli of both types were present together in the lung and bronchial mesenteric and cervical glands. In addition to the northern cases, Cumming and Foster examined 52 cases of pulmonary tuberculosis in children under 16 years of age from south-east England and found bovine tubercle bacilli in two instances.

Since our last joint report on this subject in 1932 [6] we have continued to investigate the frequency of bovine infections in phthisis in Scotland and have widened our collecting area to include the districts served by East Fortune Sanatorium in the east of Scotland and Lochmaben Sanatorium in the south of Scotland. As in each of these institutions we have already found several cases of phthisis with bovine bacilli in the sputum, as well as additional cases from Glenlomond, we think it desirable, in view of the findings of Cumming and Foster, to publish without delay the cases we have so far confirmed, with the object of calling special attention to the number and wide distribution in this country of cases of phthisis of bovine origin. Although there is now general recognition of the fact that bovine bacilli frequently cause the non-pulmonary forms of tuberculosis in children, the possibility of these bacilli causing phthisis in adolescent or adult age after an infection in childhood has been regarded hitherto as very remote. Evidence is accumulating that, on the contrary, pulmonary phthisis due to bovine tubercle bacilli is often, perhaps usually, a late manifestation of an infection of alimentary origin acquired in childhood.

Results of Further Investigations

From June, 1931, to the end of 1932 we have obtained cultures of tubercle bacilli from the sputum communications are rapidly improving and the strain of competitive life is daily approaching that found in more temperate climates."

A DIARY OF HEALTH HINTS

Dr. Shrubsall has found a thought on health for every day of the year and embodied the result in a neat little book, one thought to a page, with the appropriate date at the top.[1] An irresistible impulse to treat it as a birthday book will probably prevent the reader from taking it seriously at the outset; this is a pity because most people find one health thought a day quite enough to assimilate, if not too much, and it is convenient and helpful to have a page of sensible information ready to our hands for daily use. Probably the advice given will rarely prove to be applicable to the special trials of each day, but provision has been made to overcome this difficulty; if one wakes convinced that he has cancer on June 24th, only to find that the day's health reminder deals with the dangers of cross-country running, he can turn at once to the index to learn that his present phobia was discussed on Jan. 7th. Sir Arthur Newsholme, in his foreword, points out that references to diet and daily physiological duties recur frequently, and that repetition of advice upon these subjects from various angles is most valuable. More than one date is given up to a note on the increase of street accidents, and Dr. Shrubsall will have performed a service to the community if he can help us to exercise discretion and good sense in our dealings with traffic. He repeatedly advises his readers, when in doubt, to refer their problems to the doctor, but believes that if his suggestions on hygiene are followed the services of a doctor will be required less, rather than more, frequently. Advice is given in straightforward language and on a pleasantly personal note; his devotion to inverted commas, however, makes reading an optical hurdle-race.

Births, Marriages, and Deaths

BIRTHS

FORD.—On Feb. 8th, at The Goffs, Eastbourne, the wife of Dr. J. Norman C. Ford, of a daughter.

HUBERT.—On Feb. 2nd, at Oakley-street, Chelsea, the wife of Dr. W. H. de B. Hubert, of a daughter.

JOSCELYNE.—On Feb. 6th, the wife of Patrick Joscelyne, M.B., of Longmead-avenue, Bishopston, Bristol, of a daughter.

SCORER.—On Feb. 12th, at Dellfield, Hempstead-road, Watford, the wife of Dr. Scorer, of a son.

SELBY.—On Feb. 4th, at "Midway," Neston, Wirral, Cheshire, the wife of Robert Selby, F.R.C.S.E., of a daughter.

WAKELEY.—On Jan. 31st, the wife of Cecil P. G. Wakeley, F.R.C.S., of a son.

WELLS.—On Feb. 1st, at Havenfield, Great Missenden, the wife of Dr. Arthur Q. Wells, of a son.

MARRIAGES

KERSLEY—YEOMANS.—On Feb. 1st, at Woolbeding Church, Midhurst, George Durant Kersley, M.R.C.P., to Mary Ada Roper Yeomans, of Midhurst, Sussex.

DEATHS

BALDWIN.—On Feb. 6th, at his residence, The Green, Lockwood, Huddersfield, Henry (Harry) Clifford Baldwin, M.R.C.S., L.R.C.P. Lond.

CLARKE.—On Feb. 12th, at Bolingbroke-grove, S.W., Dr. Thomas Clarke (late of Pewsey, Wilts), *aged* 80.

CUSCADEN.—On Feb. [illegible] eneral Sir George Cusca[illegible] ralian Army Medical Se[illegible]

HARSANT.—On Feb. 10th, at Tower House, Clifton Down-road, Bristol, William Henry Harsant, F.R.C.S., in his 83rd year.

KUNHARDT.—On Feb. 9th, suddenly, at his home, Gorse Hill, Totland Bay, Lieut.-Colonel John Kunhardt, I.M.S. (retd.).

MILLER.—At "Elm House," Hawick, on Jan. 10th, 1933, William Miller, M.B., Ch.B., M.R.C.P. Edin., younger son of Mr. and Mrs. William Miller, 5, Park-place, Dunfermline.

PARKIN.—On Wednesday, Feb. 8th, 1933, suddenly, at The Cedars, Osborne-road, Newcastle-upon-Tyne, Alfred Parkin, M.D., F.R.C.P., F.R.C.S., beloved husband of Elizabeth Parkin. Service at Jesmond Wesleyan Church, Clayton-road, Saturday, 11.20 A.M. Interment Jesmond Old Cemetery, 12 noon.

WALL.—On Feb. 8th, at Herne Hill, Vivian Francis Wall, M.R.C.S., L.R.C.P.

WOOD.—On Feb. 6th, at Bexhill, after a long illness, George Benington Wood, M.B., C.M., of Little Coopers, Eversley, Hants, and formerly o. Sandown, I.O.W., aged 72.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

PHTHISIS PULMONALIS DUE TO THE BOVINE TYPE OF TUBERCLE BACILLUS

AN ACCOUNT OF TEN NEW SCOTTISH CASES

By A. Stanley Griffith, M.D.Vict., Ph.D. Camb.
MEMBER OF THE SCIENTIFIC STAFF, MEDICAL RESEARCH COUNCIL
AND
W. T. Munro, M.D. St.And., F.R.C.P. Edin.
MEDICAL SUPERINTENDENT, GLENLOMOND SANATORIUM

Until within the last ten years the bovine tubercle bacillus, although of frequent occurrence in the non-pulmonary forms of human tuberculosis, had rarely been found in cases of ulcerative pulmonary tuberculosis (phthisis pulmonalis). At the Washington Congress in 1908 Koch, in support of his view that the bovine was less virulent for man than the human tubercle bacillus, maintained that the former type of bacillus had never been definitely demonstrated in a case of phthisis. At that date, however, relatively few cases of this form of the disease had been examined bacteriologically, and, in order to fill this gap, on the initiative of Koch, workers in many different countries undertook the typing of cultures of tubercle bacilli obtained from the sputum of phthisical persons. The results of these early investigations were reviewed by one of us in 1914 and 1932, and are here briefly summarised. Of 926 cases reported by foreign investigators three only yielded bovine bacilli, and in two of these three the bovine bacilli were shown to be associated with bacilli of human type, the latter preponderating, while in the third case (de Jong-Stuurmann) the eugonic character of the culture indicated that in this instance also tubercle bacilli of both types were coexistent in the sputum of the patient.

In Great Britain, on the other hand, Griffith,[1] working for the Royal Commission on Tuberculosis, found among 29 phthisical persons in England two adult males, aged 21 and 31 years respectively, who were expectorating tubercle bacilli of the bovine type only with the sputum. On extending his inquiries to Scotland he [2] discovered in 1913, among 73 cases—45 from Edinburgh and 28 from Glasgow and Lanark—the first Scottish case, a girl of 16½, from Edinburgh. In these three cases the bovine bacilli were obtained repeatedly from the sputum, and no other type was present. Thus it was shown beyond reasonable doubt that the bovine tubercle bacillus can cause typical phthisis pulmonalis. In 1916 Wang [3] reported, among 29 examined, another case from Edinburgh, but in this instance only one examination could be made.

No further case came to light in Great Britain until 1924, when Tulloch, Munro, Ross, and Cumming [4] reported that two of the 100 strains which they had obtained from the sputum of 100 phthisical persons in Glenlomond Sanatorium were culturally of the bovine type and virulent for rabbits, though not so highly virulent as standard bovine bacilli. Since that date cultures of tubercle bacilli have been raised by Munro from the sputum of every phthisical person admitted to Glenlomond Sanatorium, with the remarkable result that down to the middle of 1932, out of 445 cases examined, bovine tubercle bacilli were found by him in no fewer than 18 cases, in one instance associated with human bacilli. In addition Munro found bovine bacilli in the sputum of a case of phthisis from the county of Roxburgh. During the period from 1916 onwards one of us (A. S. G.) continued intermittently to investigate cases in England, and in the last two years has examined, through the courtesy of Sir Pendrill Varrier-Jones, the bacilli from every new case of phthisis admitted to Papworth Settlement. These recent English investigations have resulted in the discovery of two further cases with bovine bacilli in the sputum. Both of these patients are males and have lived in Cambridgeshire all their lives. One is a farm labourer 59 years of age, and the other is a youth of 22, the son of a farmer. The number of cases from Papworth examined during the years 1929–32 is 430, making, with those previously reported from London, a total for south-east England of 657. Of these four only, two from Brompton Hospital and two from Cambridgeshire, have yielded bovine bacilli (a full account of the second Cambridgeshire case, Case 25, has not yet been published).

Until very recently no systematic investigations of the types of tubercle bacilli in phthisis in the northern counties of England have been undertaken. This want has been supplied by the important work of Cumming and Foster,[5] of Grassington Sanatorium, Yorkshire, briefly referred to at the centenary meeting of the British Medical Association, and published more fully in the current number of the *Journal of Pathology and Bacteriology*. These authors report that during the period from January, 1931, to September, 1932, they have obtained cultures of tubercle bacilli from the sputum of 339 phthisical persons from the north of England, and that of this number 12 had bovine tubercle bacilli in the sputum. In one instance both human and bovine bacilli were obtained from the sputum, and subsequent bacteriological examination of autopsy material showed that tubercle bacilli of both types were present together in the lung and bronchial mesenteric and cervical glands. In addition to the northern cases, Cumming and Foster examined 52 cases of pulmonary tuberculosis in children under 16 years of age from south-east England and found bovine tubercle bacilli in two instances.

Since our last joint report on this subject in 1932 [6] we have continued to investigate the frequency of bovine infections in phthisis in Scotland and have widened our collecting area to include the districts served by East Fortune Sanatorium in the east of Scotland and Lochmaben Sanatorium in the south of Scotland. As in each of these institutions we have already found several cases of phthisis with bovine bacilli in the sputum, as well as additional cases from Glenlomond, we think it desirable, in view of the findings of Cumming and Foster, to publish without delay the cases we have so far confirmed, with the object of calling special attention to the number and wide distribution in this country of cases of phthisis of bovine origin. Although there is now general recognition of the fact that bovine bacilli frequently cause the non-pulmonary forms of tuberculosis in children, the possibility of these bacilli causing phthisis in adolescent or adult age after an infection in childhood has been regarded hitherto as very remote. Evidence is accumulating that, on the contrary, pulmonary phthisis due to bovine tubercle bacilli is often, perhaps usually, a late manifestation of an infection of alimentary origin acquired in childhood.

Results of Further Investigations

From June, 1931, to the end of 1932 we have obtained cultures of tubercle bacilli from the sputum communications are rapidly improving and the strain of competitive life is daily approaching that found in more temperate climates."

A DIARY OF HEALTH HINTS

Dr. Shrubsall has found a thought on health for every day of the year and embodied the result in a neat little book, one thought to a page, with the appropriate date at the top.[1] An irresistible impulse to treat it as a birthday book will probably prevent the reader from taking it seriously at the outset; this is a pity because most people find one health thought a day quite enough to assimilate, if not too much, and it is convenient and helpful to have a page of sensible information ready to our hands for daily use. Probably the advice given will rarely prove to be applicable to the special trials of each day, but provision has been made to overcome this difficulty; if one wakes convinced that he has cancer on June 24th, only to find that the day's health reminder deals with the dangers of cross-country running, he can turn at once to the index to learn that his present phobia was discussed on Jan. 7th. Sir Arthur Newsholme, in his foreword, points out that references to diet and daily physiological duties recur frequently, and that repetition of advice upon these subjects from various angles is most valuable. More than one date is given up to a note on the increase of street accidents, and Dr. Shrubsall will have performed a service to the community if he can help us to exercise discretion and good sense in our dealings with traffic. He repeatedly advises his readers, when in doubt, to refer their problems to the doctor, but believes that if his suggestions on hygiene are followed the services of a doctor will be required less, rather than more, frequently. Advice is given in straightforward language and on a pleasantly personal note; his devotion to inverted commas, however, makes reading an optical hurdle-race.

Liverpool Sta [illegible] £100.

Liverpool, Women's Hospital, Catherine-street.—H.S. At rate of £100.

London Homœopathic Hospital, Great Ormond-street and Queen-square, W.C.—Asst. Physician.

Manchester Babies' Hospital, Burnage-lane, Levenshulme.—Jun. Res. M.O. At rate of £50.

Manchester, Crumpsall Hospital and Institution.—Med. Supt. £1200.

National Hospital for Diseases of Heart, Marylebone, N.W.—Res. M.O. At rate of £150.

[illegible] *ospital, Hampstead-road, N.W.*—Hon.

[illegible] *Victoria Infirmary.*—Jun. Surg. Reg. £150.

Northwood, Mount Vernon Hospital.—H.S. At rate of £150.

Nottingham General Hospital.—H.S. At rate of £150.

Oswestry, Shropshire Orthopædic Hospital and Agnes Hunt Surgical Home.—H.S. At rate of £200.

Paddington Metropolitan Borough.—Visiting M.O. One and a half guineas per attendance.

Plymouth City General Hospital.—Med. Supt. £1000.

Preston, Sharoe-green Hospital.—Res. Asst. M.O. At rate of £150.

Prince of Wales's General Hospital, N.—Res. Sen. and Jun. H.P.'s and H.S.'s. At rate of £120 and £90 respectively.

Princess Elizabeth of York Hospital for Children, Shadwell, E.—H.S. At rate of £125.

Queen Charlotte's Maternity Hospital, Marylebone-road, N.W.—Dist. Res. M.O. Also Asst. Res. M.O. Each at rate of £80.

Queen's Hospital for Children, Hackney-road, E.—H.P. and Cas. O. Each at rate of £100.

Royal Free Hospital, Gray's Inn-road, W.C.—Chief Clin. Asst. for Ophthalmic Dept.

St. John's Hospital for Diseases of the Skin, 49, Leicester-square, W.C.—Out-patient and In-patient Med. Regs. Each £50.

St. Mary's Hospital, W.—Director of V.D. Clinic. £400.

St. Mary's Hospital for Women and Children, Plaistow, E.—Hon. Ophth. S.

St. Thomas's Hospital.—Res. Anæsthetist.

Shrewsbury, Royal Salop Infirmary.—Res. Surg. O. £250.

Weston-super-Mare General Hospital.—Res. H.S. £150.

Windsor, King Edward VII. Hospital.—Res. M.O. £200.

The Chief Inspector of Factories announces a vacant appointment for a Certifying Factory Surgeon at Huddersfield (East York).

Births, Marriages, and Deaths

BIRTHS

FORD.—On Feb. 8th, at The Goffs, Eastbourne, the wife of Dr. J. Norman C. Ford, of a daughter.

HUBERT.—On Feb. 2nd, at Oakley-street, Chelsea, the wife of Dr. W. H. de B. Hubert, of a daughter.

JOSCELYNE.—On Feb. 6th, the wife of Patrick Joscelyne, M.B., of Longmead-avenue, Bishopston, Bristol, of a daughter.

SCORER.—On Feb. 12th, at Dellfield, Hempstead-road, Watford, the wife of Dr. Scorer, of a son.

SELBY.—On Feb. 4th, at "Midway," Neston, Wirral, Cheshire, the wife of Robert Selby, F.R.C.S.E., of a daughter.

WAKELEY.—On Jan. 31st, the wife of Cecil P. G. Wakeley, F.R.C.S., of a son.

WELLS.—On Feb. 1st, at Havenfield, Great Missenden, the wife of Dr. Arthur Q. Wells, of a son.

MARRIAGES

KERSLEY—YEOMANS.—On Feb. 1st, at Woolbeding Church Midhurst, George Durant Kersley, M.R.C.P., to Mary Ada Roper Yeomans, of Midhurst, Sussex.

DEATHS

BALDWIN.—On Feb. 6th, at his residence, The Green, Lockwood, Huddersfield, Henry (Harry) Clifford Baldwin, M.R.C.S., L.R.C.P. Lond.

CLARKE.—On Feb. 12th, at Bolingbroke-grove, S.W., Dr. Thomas Clarke (late of Pewsey, Wilts), aged 80.

CUSCADEN.—On Feb. [illegible] -General
Sir George Cusca[illegible] [illegible]stralian
Army Medical Se[illegible]

HARSANT.—On Feb. 10th, at Tower House, Clifton Down-road, Bristol, William Henry Harsant, F.R.C.S., in his 83rd year.

KUNHARDT.—On Feb. 9th, suddenly, at his home, Gorse Hill, Totland Bay, Lieut.-Colonel John Kunhardt, I.M.S. (retd.).

MILLER.—At "Elm House," Hawick, on Jan. 10th, 1933, William Miller, M.B., Ch.B., M.R.C.P. Edin., younger son of Mr. and Mrs. William Miller, 5, Park-place, Dunfermline.

PARKIN.—On Wednesday [illegible] at The
Cedars, Osborne-road, [illegible] Parkin,
M.D., F.R.C.P., F.R.[illegible] [illegible]lizabeth
Parkin. Service at Jes[illegible] [illegible]on-road,
Saturday, 11.20 A.M. [illegible] [illegible]metery,
12 noon.

WALL.—On Feb. 8th, at Herne Hill, Vivian Francis Wall, M.R.C.S., L.R.C.P.

WOOD.—On Feb. 6th, at Bexhill, after a long illness, George Benington Wood, M.B., C.M., of Little Coopers, Eversley, Hants, and formerly o. Sandown, I.O.W., aged 72.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

---

[1] Things to be Desired, or Daily Health Reminders. By W. W. Shrubsall, D.P.H. With a foreword by Sir Arthur Newsholme, K.C.B., M.D., F.R.C.P. London: John Bale, Sons and Danielsson, Ltd. 1932. Pp. 370. 5s.

Physical signs indicated disease of whole left lung with softening in progress about central area: fibrosis of right lung with restricted disease of apex of upper lobe which showed evidence of a small cavity and a fine subclavicular infiltration. The X ray examination showed on left side a large area of dense perihilar consolidation with a spread of a lighter nature towards periphery. Dr. Cameron stated that this particular picture of dense perihilar disease is not common in lung tuberculosis. In November, 1931, a left artificial pneumothorax gave a small partial collapse. In February, 1932, the patient was afebrile with normal pulse, cough practically absent, and sputum scanty but still containing tubercle bacilli; left lung fibrosing and pulling heart over.

Cultures of tubercle bacilli were obtained directly from the sputum in December, 1931, and January, 1932. Both strains were dysgonic and highly virulent for rabbits inoculated subcutaneously.

CASE 29.—Female, aged 33, farm-worker, admitted to *Lochmaben on March* 1st, 1932.

She was born on a farm in Kirkbride, Cumberland, and did all sorts of work, including milking the cows and making butter. She had no illness until ten years ago, when she had spasms of abdominal pain and according to her doctor was threatened with appendicitis. She lost 1 st. in weight which she did not regain. She began to cough in January, 1932, and about that time contracted a very bad cold which pulled her down. She came to her sister in Scotland for a change and was there recognised as a case of pulmonary tuberculosis. On the farm a cow with tuberculosis of the udder was destroyed a year ago. Mother died three years ago of heart trouble; father, one brother, and two sisters alive and well.

On admission the patient looked pale and thin, and there was slight systemic disturbance. X ray examination showed pleural effusion of lower third on left side with much pleural thickening above, obscuring lung. On right side infiltration about the root spreading up to upper lobe, with suggestion of breaking down about middle of lung, and also nodular spread into lower lobe.

Cultures of tubercle bacilli were obtained directly from the sputum in May and June, 1932. Both strains were typically bovine in cultural characters and in virulence for the rabbit.

Autopsy.—The woman died on Nov. 24th, 1932. At the autopsy Dr. Elder found no signs of tuberculosis in the abdominal organs or glands. The mesenteric glands were examined at Cambridge and were free from lesions. The appendix was fibrosed and bound down by adhesions to the brim of the pelvis. There were no enlarged glands in the ileocæcal region or in the neck.

The right pleural cavity was free from disease. On the left side the pleural membranes were thickened and adherent in the lower two-thirds. The base of the left lung was firmly adherent to the diaphragm at its outer margin and between the diaphragm and the lung there was a thin layer of thick pus. At the base of the lung five subpleural nodules were seen; they were almond-shaped and approximately 2 × 1 × ½ in. Lungs: from the root of the right lung fibrocaseous disease extended outwards affecting about two-thirds of the organ. The spread was fairly uniform in all directions and did not reach the periphery at any point. There were numerous cavities: the larger (about ½ in. diameter) were at the root and the excavations and caseous parts diminished in size from the root outwards. A similar condition was found in the left lung but the spread was not so uniform; it did not extend so high up but it reached the periphery and the base where the nodules previously mentioned were found. There was more cavitation in this lung.

The bronchial glands were examined at Cambridge. They were coal black. The prætracheo-bronchials showed no lesions. The intertracheo-bronchial on the right side was enlarged 3·5 cm. in length and 1·5 cm. in diameter, capsule thickened, and half or more of its substance was caseated. The corresponding gland on the left side contained a caseous nodule the size of a hempseed. Further along this bronchus, within the hilus, there was a pea-sized partly caseous gland and another just beyond showed a narrow part of the cortex opaque.

The definitely intrapulmonary glands on both sides were intensely anthracotic but showed no tuberculous lesions.

CASE 30.—Female, aged 27, domestic servant, born in Dumfriesshire. Admitted to Lochmaben in March, 1932.

No illnesses in childhood, at 19 years "rheumatic fever" and still suffers from pains in the joints, but there is no cardiac damage and quite recently she had a rash on the legs and arms lasting three days. Two years ago had an attack of influenza and lost weight which has not been regained. For the last two to four years she has not felt fit. She has always been fond of milk.

The X ray examination showed on right side well-marked root-spread along interlobar pleura with infiltration into upper and lower lobes and some evidence of breaking down in lower part of upper lobe; on left side increased root shadow with little or no evidence of infiltration.

Cultures of tubercle bacilli were obtained directly from the sputum in May and June, 1932. Both strains were dysgonic, and produced progressive general tuberculosis in rabbits. One strain caused general tuberculosis in a goat after subcutaneous inoculation, the animal dying in 58 days.

CASE 31.—Female, aged 28 years, domestic servant Admitted to East Fortune in February, 1929.

She was born in Midlothian, was fond of milk, and had enlarged glands in the neck in early childhood. On admission there were clusters of enlarged glands like small beans in the lower third of the left posterior triangle and in the left axilla; she had a cough and her sputum contained tubercle bacilli. X ray examination showed definite infiltrating tuberculosis of left upper lobe with thickening along upper part of root spreading out along septum: also evidence of infiltration into right lower lobe. Radiogram of spine showed doubtful compression of two lower dorsal bodies but no evidence of active spine disease. Laryngoscopic examination showed extensive infiltration of both vocal cords.

She improved very much and was discharged at her own request in November, 1929, having gained 7 lb. in weight (8 st. 8½ lb.): the sputum was negative. Three months later she began work as domestic servant and worked for 15 months. In April, 1931, her sputum was blood-stained and she gave up work on account of breathlessness. She became progressively more dyspnœic and was readmitted on May 28th, 1932; the sputum was laden with tubercle bacilli, mainly short.

X ray examination showed whole left lung involved in dense disease with extensive thick-walled cavities in left upper lobe; lighter infiltration of good definition in right upper lobe; calcified glands in neck. She slowly went downhill, and on Oct. 7th, 1932, asked to be allowed to go home, where she died a week later.

Cultures of tubercle bacilli were obtained directly from the sputum in June and September, 1932. Both strains were dysgonic and produced severe and rapidly fatal progressive general tuberculosis in rabbits inoculated subcutaneously.

CASE 32.—Female, aged 21, housewife. Home address, Cardenden. Admitted to Glenlomond in October, 1931.

She had no illnesses in childhood and from 14 years of age for six years worked on a farm as a milker and outworker. She drank a good deal of milk and she stated that during the last three years of her employment there was a cow which was a "piner" and was killed on the farm. She married at the age of 19 and has a child of 16 months. Her illness began in August, 1931, with a bad cold, and cough with a little sputum developed later. She began to get hoarse in September.

On admission X ray examination showed left lung infiltrated with signs of cavities in upper lobe. Small glands were felt in the posterior triangles. In December, 1931, artificial pneumothorax was done, giving a complete ribbon collapse of lung. Subsequently she improved continuously, cough and sputum subsided, and on May 28th, 1932, she was discharged, her general condition being very good.

A culture of tubercle bacilli obtained directly from the sputum in 1931 was dysgonic and virulent for rabbits.

CASE 33.—Female, aged 11.

She was breast-fed for three to four months, and then was brought up on Nestlé's condensed milk and oat flour until the age of 13 months. Subsequently she was given raw cow's milk. Enlarged glands in the neck were first noticed when she was 20 months old. The child was first admitted to Glenlomond Sanatorium in September, 1928, when she was 7 years old. Four months previously enlarged glands had been excised from the right side of the neck and the of 222 cases of phthisis pulmonalis, of which 70 were from Glenlomond, 88 from East Fortune, and 64 from Lochmaben Sanatorium. We are greatly indebted to Dr. C. Cameron, medical superintendent of East Fortune, and to Dr. G. W. Elder, medical superintendent of Lochmaben Sanatorium, for supplying us with specimens of sputum and for allowing us to consult the clinical records of the cases and personally to examine several of the patients.

The strains obtained from 212 of the cases exhibited the characters of tubercle bacilli of the human type, 209 of the strains belonging to the eugonic human and 3 to the dysgonic human variety. The latter were tested on the rabbit and proved slightly virulent for this species.

The strains, 20 in number, from the remaining ten cases were identical in cultural characters with bovine bacilli. All these strains were tested on the rabbit by subcutaneous, and in some instances also by intravenous, inoculation and produced in one or more animals rapidly fatal general tuberculosis indistinguishable from that which follows inoculation of standard bovine tubercle bacilli. One strain was tested on the goat and proved fully virulent for this species also.

Of the ten cases of bovine phthisis two were from Glenlomond, four from East Fortune, and four from Lochmaben Sanatorium.

Three have died and autopsies were made on two. In one instance (No. 27) the patient died before the type of infecting bacillus had been determined, and only a partial autopsy was made. The channel of the infection therefore was not determined. The occurrence in the case however of enlarged glands before the onset of phthisis indicated that the channel of infection was probably the alimentary canal.

At the second autopsy (Case 29) no tuberculous lesions were found in the neck glands or in the abdominal organs or lymph glands. The tuberculous disease was apparently confined to the thoracic cavity. There had been clinical indications of a cerebral tuberculoma in the left frontal lobe, but this could not be confirmed as permission to examine the brain was not granted. The intertracheobronchial glands, particularly the right, showed caseation, but there was no lesion in the lung which could be regarded as primary, the distribution of the pulmonary lesions suggesting rather a root-spread type of disease.

Though the anatomical evidence as to the portal of entry of the bacilli was inconclusive, it should be noted that this is the first autopsy on a case of bovine phthisis in which there were no signs of disease in the glands of the alimentary tract older than the pulmonary lesions. As the woman was a farm-worker and came as milker into close contact with cows this may be an example of infection with bovine bacilli through the respiratory tract, the vehicle of infection being, as suggested by Bruno Lange, dust from the hides of cows or arising in the shippons, or droplets sprayed by a cow suffering from tuberculosis of the lungs.

More autopsies on cow-contact cases and cases in which clinically there was no evidence of alimentary infection are clearly desirable and will be necessary to settle the question whether human phthisis pulmonalis can be produced by air-borne bovine bacilli.

Case Records

The clinical particulars of each of the ten bovine cases and the results of the bacteriological investigations of the strains isolated may be summarised as follows.

Case 26.—Female, aged 32, domestic servant. Home address, Kirkpatrick Durham, Kirkcudbright, admitted to Lochmaben in August, 1931.

Patient was healthy as a child, except for measles at 5, and never complained until after she was 16 years old. From 16 to 21 she had amenorrhœa and was easily tired. She married at 27 and has two children 6 and 5 years old. She was notified as a case of phthisis pulmonalis after the first child and lost her voice about a year ago. She liked milk and had been in the habit of drinking it raw, but she has not had enlarged cervical glands or symptoms of abdominal tuberculosis. Her father, a gardener, died five years ago at the age of 60; he had a cough for several years, diagnosed by his doctor as bronchial catarrh. One sister, aged 24, one brother, aged 21, and one sister, aged 29 years, died of "acute tuberculosis" in December, 1914, December, 1918, and April, 1930, respectively. Three sisters are alive. The mother died a year ago at age of 70.

In July, 1932, her condition was as follows: very thin, pale, breathless, not febrile, pulse about 100, speaks in a hoarse whisper. The X ray examination showed on left side, extensive infiltration with appearance of much breakdown in upper lobe, pleura thickened, and heart pulled over; on right side, shadow increased at root, spreading out into upper lobe, which was infiltrated and showed some evidence of breaking down. Dr. Elder thinks that it is undoubtedly an infection spreading from the roots.

Cultures of tubercle bacilli were obtained directly from the sputum in December, 1931, and in January and May, 1932. The three strains were dysgonic. Each strain was tested subcutaneously on the rabbit. The three rabbits died in 78, 100, and 53 days respectively of typical severe generalised tuberculosis.

Case 27.—Female, aged 35, housewife, admitted to East Fortune in June, 1931. Home address, Middlemaens, Pencaitland, East Lothian.

Two years ago she had enlarged cervical glands which discharged. In December, 1930, she had a bad influenzal cold and cough was severe for some time, but she was able to do her housework. In February and March, 1931, she felt better, but at the end of March she had another attack of "influenza." From that time she became thinner and weaker and cough has been persistent and severe with copious sputum. On admission firm glands were palpable in both posterior triangles and supraclavicular areas, and there was a scar from a glandular abscess which healed two years ago. The lung signs were those of extensive fibrotic disease of the left lung consolidatory in nature with areas of activity in the upper lobe; there was less dense but also active disease of the upper half of the right lung. Dr. C. Cameron thought the disease had been in existence at least two years. A radiogram showed upper third of left lung honeycombed with cavities and many cavities in the upper and middle lobes of the right lung and infiltration of lower lobe. She died in February, 1932. Unfortunately the type of infecting bacillus had not then been ascertained and only a partial necropsy was made. Both lungs were densely adherent, the upper lobe of the left being completely excavated and containing pus; the lower lobe was densely fibroid and contained multiple cavities; there was fibroid disease with multiple cavities in upper half of right lung.

A culture of tubercle bacilli was obtained directly from the sputum in January. The strain was dysgonic and virulent for rabbits.

Case 28.—Female, aged 25, housewife. Home address, Linlithgow, West Lothian. Admitted to East Fortune in October, 1931.

She had pneumonia between 6 and 12 years of age and "influenza" at 13 or 14. In 1926 her appendix was removed, but no mention in records of abdominal tubercle. She then remained well until January, 1930, when she took what she described as a chill followed by loss of appetite, loss of weight, and general weakness. Her history afterwards was the usual oscillating one, sometimes fairly well and sometimes ill with fever, headache, and general malaise, and at intervals pleural pain. There is no family history of tuberculosis. She has one boy aged 3 who is well.

On admission her general condition was poor; fairly severe cough; sputum purulent, 1 oz. daily, contained tubercle bacilli in small number, one or two per field.

Conclusions

1. The bovine tubercle bacillus is a more frequent cause of phthisis pulmonalis in Great Britain than is generally supposed.
2. Phthisis pulmonalis due to bovine tubercle bacilli is often a late manifestation of an infection acquired in childhood through the channel of the alimentary tract.

MONOCYTIC LEUKÆMIA: TWO CASES

By John W. Orr, M.D. Belf.

LATE FIRST ASSISTANT PATHOLOGIST, ST. MARY'S HOSPITAL, LONDON

Anomalous types of white cells are often found in the blood in cases of acute and subacute leukæmia, more especially when the total leucocyte count is not greatly increased. In practice the problem is most frequently that of discriminating between myeloblasts and lymphoblasts, and it is sometimes difficult or impossible to make this distinction with certainty. The question is further complicated by the fact that in the literature cases are to be found in which the authors are convinced that the characteristic cell is related to the monocyte or large hyaline leucocyte. Hæmatologists are not agreed as to the existence of a true monocytic leukæmia, and the following two cases are therefore reported in some detail.

THE FIRST CASE

A stableman, aged 40, was admitted to St. Mary's Hospital in September, 1930, complaining of constriction of the neck, and attacks of giddiness and pain radiating into right neck. The family history was unimportant. He had had malaria during the late war. General weakness and swelling of face and hands had begun in the previous April, and had increased since then. He ascribed the illness to the removal of teeth in April. On examination he was pallid, feeble, with some dilatation of the veins of the neck, and puffy hands; a blood count (see Table I.) showed a marked leucopenia, especially of the polymorphonuclear leucocytes.

The condition was diagnosed as myxœdema, and subsided, with great alteration in the facial and cervical contour, as a result of treatment with thyroid gland. He was discharged at his own desire and returned to work but failed to continue with the thyroid, reappearing in the out-patient department with more œdema and weakness. In hospital for three weeks (December, 1930) he once more improved with thyroid. After returning to work he experienced considerable dyspnœa, palpitation, anorexia, great weakness, nausea, headache, giddiness, numbness, and tingling in the hands.

On June 15th, 1931, he was readmitted to hospital for the last time. Three weeks previously pain had developed in the left axilla. He was pale and sallow, looked very ill, and slept most of the day; the eyebrows were scanty. Temperature 101° F., later 104° F. and irregular; pulse 80 to 100, rapid and soft; respirations 22 per minute, deep and regular; blood pressure 120/60. A gland, the size of a pigeon's egg, was found in the left axilla, this caused him much pain and later developed into an abscess which opened (July 13th) and drained, staphylococci being recovered from the pus. X rays showed no evidence of any definite pulmonary disease.

On August 11th the condition was much improved, except that a discharge had developed from the antra which were drained on August 18th and again on the 21st. It was noted on the 29th that the skin seemed to have coarsened lately. Multiple small cutaneous "abscesses" began to develop from this time; these were painless and formed indolent craters with yellow pus from which *Staphylococcus aureus* was grown. Blood culture was negative.

Blood transfusion on Sept. 21st, 1931, was followed by a rigor and led to no permanent improvement. The liver first became palpable on Sept. 15th, enlarged to two inches below the costal margin. By the 25th the general condition showed a marked deterioration and albumin appeared in the urine. He complained of aching in the eyes, which was relieved by wearing deep blue glasses. On Oct. 2nd the back and neck were covered with cutaneous abscesses and X rays showed empyema of both antra, the left frontal sinus being also suspect. The antra were drained (Oct. 6th) and the general range of temperature became more limited, but his condition became progressively more lethargic, and he developed secondary broncho-pneumonia and died on Oct. 13th.

Table I.—*Blood Counts in Case 1*

	1930	1931				
Date	22/9	17/6	17/7	13/8	3/10	15/10
Red cells, millions per c.mm.	3·48	2·30	2·15	2·20	2·14	—
Nucleated red cells per c.mm.	—	—	100	A few	600	—
Hæmoglobin per cent. ..	70	36	38	36	34	—
Colour-index..	1·0	0·8	0·9	0·8	0·8	—
White cells per c.mm. ..	1800	5000	5000	4500	8000	10,000 approx.
Polymorphs	25 %	9 %	9 %	—	4 %	1 %
Myelocytes	1 %	1 %	—	—	—	
Lymphocytes	56 %	19 %	12 %	—	19 %	26 %
Lymphomonocytes	10 %	6 %	18 %	—	8 %	6 %
Monocytes	8 %	65 %	57 %	—	66 %	66 %
Ghosts	—	—	4 %	—	3 %	1 %
Oxidase-positive WBC ..	—	—	—	51 %	15 %	68 %

The *blood counts* are detailed in Table I. The cells classified as monocytes showed a considerable histological variation from the large hyaline leucocyte of the normal blood. In the later films they were large cells, averaging 15 to 20 microns in diameter, with (in Leishman preparations) muddy-blue cytoplasm frequently thrown out into pseudopodia and showing a varying amount of granulation. The granules had the staining reactions of "azur" granules, but in the later films were much more numerous than in normal cells; they were generally round dots but many were short rods. Not infrequently the cytoplasm was vacuolated. The nuclei were round, indented, reniform, or horseshoe shaped, but never showed true lobation; for the most part their chromatin had a uniform finely woven reticular pattern, but very occasionally nucleoli were present. The nuclei sometimes showed vacuolation similar to that seen in some of the lymphocytes. The oxidase reaction of the monocytes, as is apparent from the differential counts, was inconstant, and when positive the intensity of the reaction was variable. The lymphocytes showed much variation in the staining of their cytoplasm and nuclei, the latter frequently being fenestrated in a manner recalling the appearances of the blood film in glandular fever. The range of variation was so great that in the case of a number of cells it could not be stated with confidence whether they were monocytes or lymphocytes; such cells have been arbitrarily classified as lymphomonocytes. The rare examples of polymorphonuclears found in all the films were in every way typical. Supravital staining (Oct. 6th 1931) showed incision, 2½ in. long, was still not completely healed. Many small glands could be felt on both sides of the neck, and on palpating the abdomen enlarged glands (?) could be felt in the right iliac fossa. There were numerous enlarged venules over the chest but no active lesion was found in the lungs. Both eyes showed corneal nebulæ. The child had slight systemic disturbance, did not improve much, and was taken home in June, 1930. She was readmitted in October, 1932, thin and ill, temperature 100°, pulse 110, with small softened glands on both sides of neck, and evidence of active intestinal ulceration. There was also extensive disease of the lungs, more on the right than on the left side; on the right side the right upper lobe was chiefly affected and on the left there was a root-spread type of disease. The sputum contained tubercle bacilli. Early in January, 1933, a caseous and softened gland was excised from the neck.

Cultures of tubercle bacilli were obtained directly from the sputum on four occasions, twice in November, and twice in December, 1932. All the strains were dysgonic and highly virulent for the rabbit. Cultures were also obtained from the cervical gland, directly and through the guinea-pig. Both strains are dysgonic but have not yet been tested on the rabbit.

CASE 34.—Male, aged 17, of Linlithgow, West Lothian. (Clinical notes by Dr. C. Cameron.)

The patient was admitted to East Fortune in September, 1932, for treatment of advanced tuberculosis of the lower part of his spine. He stated that at the age of 3 he fell out of a railway wagon and hurt the foot of his back but it was impossible to determine whether or not this had anything to do with the present condition. The first definite treatment which he received for spinal tuberculosis was nine years ago (he was then eight years old) when he had treatment of some kind for six months in a Lanarkshire hospital. The disease must have been well established since there was some stiffness of the legs. He attended school again and so far as could be determined finished his school period. He had been confined permanently to the house during the six months preceding his admission to the sanatorium.

His condition on admission was deplorably bad. He was pallid, emaciated, and weak. His skin was harsh and dry, and he had the appearance of suffering from advanced active tuberculous disease. There was a sharp gibbus involving the lower lumbar spine and part of the sacrum, a radiogram showing advanced destructive tuberculous disease of the fourth and fifth lumbar vertebræ and upper part of the sacrum with extensive abscess shadowing, largely calcified, spreading around the lower lumbar spine and into the pelvis. No one appears to have examined his lungs, although he had passed through a surgical ward of an infirmary. I found him to have advanced and dense fibrocaseous disease involving practically the whole of his left lung. The left diaphragm was caught and raised by adhesions. He had similar disease of the right upper lobe again containing several cavities with some lighter infiltrative disease of the lung below. We obtained from him with difficulty a scanty sputum in which a few tubercle bacilli were found. The sputum was brought up at intervals, sometimes scanty but densely purulent, at other times watery and containing purulent streaks. He has remained irregularly febrile but his condition has undergone very definite improvement.

Until within the last year he practically never got milk apart from that given in tea. A brother, aged 13 years, had tuberculous neck glands excised three years ago, since when he has been well.

Pure cultures of bovine tubercle bacilli were obtained directly from the sputum in September and October, 1932. Both strains were fully virulent for the rabbit.

CASE 35.—Female, aged 28, housekeeper. Admitted to Lochmaben Sanatorium in December, 1932. The full clinical particulars and bacteriological results in this case are not yet available.

Summary

The number of cases of phthisis pulmonalis with bovine tubercle bacilli in the sputum reported in England and Scotland has now reached the startling figure of 49. The majority of these cases, namely 45, have been discovered within the last ten years. We cannot say whether this large addition indicates an increase in the proportional frequency of bovine phthisis in recent years or not, since most of the cases were found in parts of the country where investigations had not previously been made.

From a comparison of the findings in different parts of the country it would appear that phthisis due to bovine bacilli is less frequent in the south of England than in the north of England and in Scotland. The bovine percentages for these different regions are 0·6, 3·8,* and 3·9 respectively.

The ages of the patients when the bovine bacilli were found in the sputum ranged from 7 to 59 years. They were distributed in the various decennial age-groups, as follows :—

0– 9 years	..	1 patient,	7 years old.
10–19 ,,	..	12 patients,	8 of them 17 to 19 years.
20–29 ,,	..	25 ,,	14 ,, ,, 20 to 25 ,,
30–39 ,,	..	6 ,,	
40–49 ,,	..	4 ,,	
50–59 ,,	..	1 patient.	

The majority of the patients were therefore adolescents and young adults.

Of the 49 patients, 31 were females and 18 were males. At least 20 of the patients gave a history of enlarged glands in the neck or of abdominal trouble before the onset of phthisis pulmonalis. In the remainder no history of glands in the neck or symptoms suggestive of abdominal tuberculosis was elicited, but it may be mentioned that an autopsy on one of these cases showed the primary lesions in the mesenteric glands.

Generally there was a history of cough and sputum for one or two years before admission to the sanatorium, but in some instances there was a longer history, and one of Cumming's cases was known to have had positive sputum ten years before the bacteriological investigation established the type of bacilli present in the sputum. Some of the patients are still alive, five to nine years after the bacilli in the sputum were identified as bovine. It is remarkable in view of this fact that none of the cases, so far as we have been able to ascertain, has transmitted the infection to another human being, and that with two possible exceptions none of the cases appears to have acquired the infection from a previous human source.

Six of the cases were in persons who, in their employment on farms as milkers, &c., came into close contact with cattle. One of these persons, a woman aged 33 years, died, and an autopsy was made. No lesions were found in the lymph glands of the alimentary tract, but there was caseation of the glands at the bifurcation of the trachea. This may not be quite enough to enable us to affirm that the infection was of respiratory origin.

Twenty-two of the patients have died, the duration of life after the bacilli were identified ranging up to five years. Autopsies were made in six instances. The examinations were not in all cases complete, but in three instances the anatomical evidence was definitely in favour of the alimentary tract as the portal of entry of the bacilli.

The work is continuing, and we reserve a full discussion of the results until the investigations are completed, when, in collaboration with Dr. Cumming, we propose to collect together in one report all the facts ascertained in this important group of cases.

---

* The case from Cumberland (No. 29) in our series has been included in Cumming's figures for the North of England.

Two skin nodules.—Aggregations of monocytes in the dermis with necrosis of the central parts of the nodule.

Colon.—Macrophages containing coarse granules of iron pigment in stroma of mucosa.

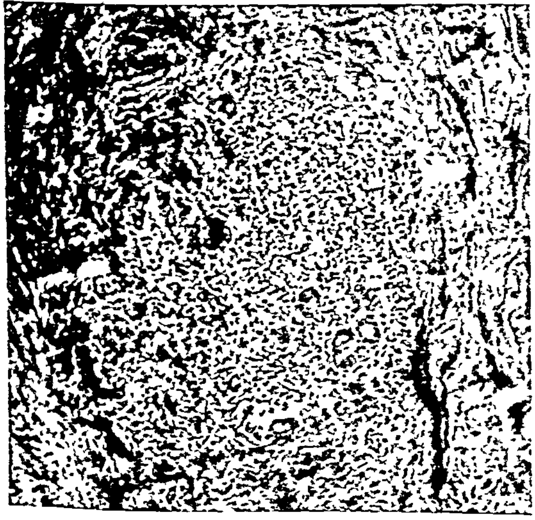
THE SECOND CASE

An upholsterer, aged 71, was in bed for three weeks with influenza in February, 1932, and this was followed a week later by a severe attack of vomiting and diarrhœa lasting four days. When he was seen in the out-patient department on April 14th his appetite was poor, and he had been losing weight and becoming increasingly pale. On admission to St. Mary's Hospital (April 18th) he was pale, feeble, and noticeably drowsy. The liver was slightly enlarged, the spleen not palpable, and the heart showed some dilatation with hæmic murmurs. Achlorhydria was present, and a trace of occult blood in the fæces. X rays showed no alimentary abnormality. He ran an irregular fever and gradually lost weight and strength, dying on May 21st.

TABLE II.—*Blood Counts in Case 2*

Date in 1932—	14/4	28/4	9/5	10/5	19/5	20/5
Red cells in mills...	2·68	1·96	—	1·88	1·50	—
Nucleated red cells	—	—	400	—	—	—
Hæmoglobin ..	54	40	—	36	26	—
Colour-index ..	1·0	1·05	—	1·0	0·9	—
White cells ..	35,200	4,400	18,800	6,200	140,000	—
Polymorphs ..	12 %	11 %	21 %	—	2 %	4 %
Lymphocytes ..	8 %	33 %	15 %	—	4 %	6 %
Lymphomonocytes	—	12 %	11 %	—	6 %	6 %
Monocytes ..	80 %	44 %	53 %	—	88 %	84 %
Oxidase-posit. WBC	—	—	25 %	—	18 %	—

FIG. 2



Thyroid from Case 1. (× 100.)

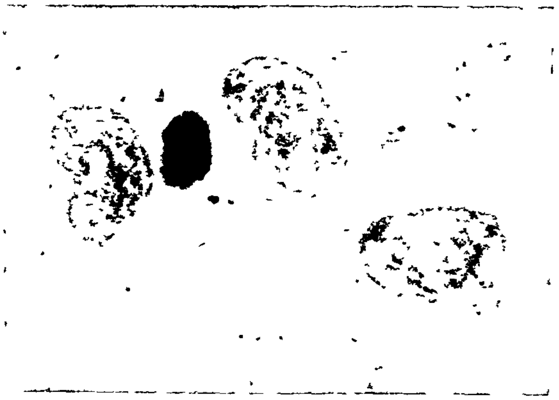
The blood counts are shown in Table II. The monocytes were large cells of morphology similar to those of Case 1, with muddy cytoplasm and pseudopodia, and finely reticular reniform or round nuclei, sometimes fenestrated (Fig. 3). In the films of May 19th two such cells were seen in mitosis, and on the 20th two of them contained an ingested red corpuscle. Supravital staining with neutral red demonstrated their characteristic phagocytic activity. Their oxidase reaction was inconstant but generally negative.

NECROPSY

Nutrition poor. Rigor passing off, greenish discoloration of anterior abdominal wall. Subcutaneous fat very small in amount.

Heart.—Slight, very recent, terminal fibrinous pericarditis. Subpericardial petechiæ. and a few dark pink leukæmic nodules (0·1 cm. diameter) on surface of heart. Myocardium soft and flabby, having a yellowish tinge on the endocardial surface with slight "tabby-cat" marking. Endocardium and valves normal. Much typical leukæmic clot in chambers of heart, pulmonary artery, and veins. Atheroma remarkably slight for age.

FIG. 3



Blood film from Case 2, showing three monocytes and a small lymphocyte. (× 1300.)

Larynx, trachea, and bronchi normal. Œdema, emphysema, and hypostatic congestion of *lungs.*

Tongue heavily furred, marked increase of lymphoid tissue at base. Tonsils enlarged, œdematous. and homogenously fleshy. Pharynx and œsophagus normal. Submucous myoma (0·7 cm. diameter) in anterior wall of stomach, 3·5 cm. from cardiac orifice. Multiple ulcers of *small intestine*—most of them were irregular patches covered with a fibrinous membrane of diphtheroid type; in the ileum they frequently involved Peyer's patches; in the jejunum a large ragged ulcer with irregular edges and a black base was firmly adherent to the sigmoid colon in the left iliac fossa. Solitary lymphoid follicles of large intestine enlarged (average 0·2 to 0·3 cm.); positive Prussian-blue reaction in entire length of mucosa of colon. Pancreas, gall-bladder, and bile-ducts normal.

The *liver* was enlarged (1870 g.) with post-mortem discoloration of lower edge and posterior surface. On section it was pale in colour and swelled over its capsule. The pattern was obscured, the peripheral parts of the lobules being pale and greyish-white in colour, and the centres brown. It contained free iron, as estimated by the Prussian-blue reaction, in considerable amount.

The *spleen* (510 g.) swelled slightly on section, the cut surface being pale pink and practically devoid of pattern. The Prussian-blue reaction was strongly positive, and after the test was carried out the Malpighian bodies became more readily distinguishable as minute unstained foci.

The *lymphatic glands* were all considerably enlarged, and contained free iron. On section they were generally pale, sometimes mottled with red, but many showed a distinct greenish tinge. The bone-marrow of the femur was red in the upper 30 cm. of the shaft, the colour becoming deeper from above downwards, and fatty with small reddish spots in the lower 10 cm.; free iron was present.

Kidneys slightly enlarged (300 g.), pattern blurred, free iron around the arcuate vessels. Bladder and prostate normal. Testes œdematous, small left varicocele.

Thyroid small, rather tough, with prominent fibrous trabeculæ and little colloid. Parathyroids, suprarenals, and pituitary normal. Thymus replaced by fat.

Brain and meninges normal.

HISTOLOGY

Lymphatic glands.—Cervical, aortic, and mesenteric glands all show changes comparable with those of Case 1, the pattern of the glands being lost to a great extent, and the largest proportion of monocytes being found in the subcapsular and medullary parts of the glands. Mitotic figures are fairly common. The capsules and periadenoid tissues are also infiltrated to some extent, as is the excess fibrous tissue of the medulla of the aortic glands. Some

33 per cent. of white blood-cells giving the reaction of monocytes.*

NECROPSY

Body thin and poorly nourished (weight 48 kg.). All tissues anæmic. Two sinuses leading from abscesses in the left axilla; abscesses also present in the right axilla, left side of neck, and over lower end of sternum. The skin of the whole body covered with brownish spots about 1 cm. average diameter, most of which showed a central scab of pinhead size.

Heart normal size, parenchymatous degeneration of myocardium; very little atheroma in arteries. Trachea and bronchi contained a little thin, frothy, slightly blood-stained fluid; 150 c.cm. clear fluid in each pleural sac. Right *lung* anæmic, with emphysema and œdema; broncho-pneumonia with peribronchial hæmorrhagic areas and in many places confluent, of the left lower lobe, and recent fibrin on its pleural surface. Mouth, tongue, and pharynx normal; tonsils enlarged with a greenish tinge on section; in the posterior wall of the *œsophagus*, 6 cm. below the bifurcation of the trachea, there was an oval dark rough granular area surrounded by a hæmorrhagic ring (2 × 1 cm.); on section this was superficial and its base consisted of a black line; just below it a similar smaller lesion. Stomach and small intestine normal. *Colon* showed dark brown pigmentation of mucosa which gave a positive Prussian-blue reaction, also a definite increase in the lymphoid tissue. Pancreas normal; lipoid deposits in the mucosa of gall-bladder.

The *liver* was markedly enlarged (2520 g.) and had a pinkish-brown colour. On section the lobular pattern was clear in some parts and blurred in others. The peripheries of the lobules contained fat, the centres were darker than normal, and the portal systems were unusually conspicuous. On treatment with potassium ferrocyanide and hydrochloric acid a well-marked Prussian-blue reaction was given, indicating the presence of free iron.

The *spleen* was somewhat larger than normal (270 g.), œdematous, and had a definitely brownish colour. The Malpighian bodies were smaller than normal, the fibrous trabeculæ somewhat more obvious than usual. Free iron was present.

All the *lymph glands* in the body showed a substantial increase in size. On section they were of a greenish colour with red and yellow mottling; some of them had a granular appearance; they contained free iron. The *bone-marrow* of the femur was red throughout the medullary cavity. In the upper part of the shaft it was a dull greyish-red and rather granular, in the lower part dark glossy-red and gelatinous in appearance.

The thymus was replaced by fat and fibrous tissue; left suprarenal small with thin cortex, right normal. *Thyroid* only slightly smaller than normal; on section white, tough, and fibrous. The *kidneys* were pale and œdematous, on section both the cortex and medulla swelled appreciably; the cortical pattern was clear in some places, blurred or lost in others. Right ureter double as far as the brim of the pelvis. Bladder, prostate, and testes normal.

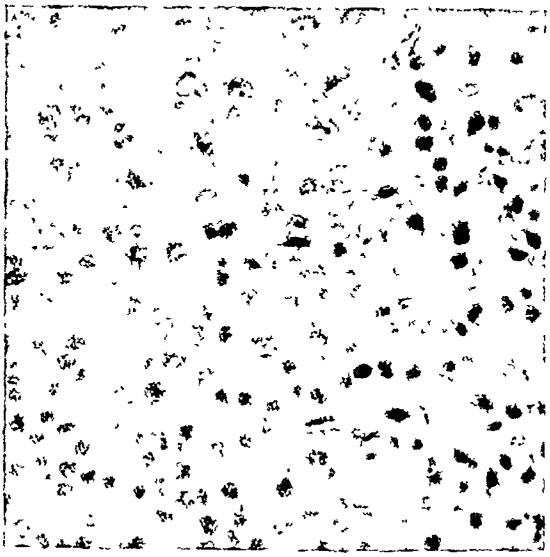
Examination of the head was not permitted.

HISTOLOGY

Lymphatic glands.—Several glands from the aortic, deep cervical, and mesenteric groups were examined, and all show numerous large mononuclears (which will in future be referred to as monocytes) infiltrating the gland substance and obliterating the pattern to a greater or less extent. These cells are large irregular cells, the cytoplasm of which stains slightly more with eosin than the normal reticulum cells. The nuclei are more or less round, with a well-marked nuclear membrane and though many show acidophil nucleoli, the latter are more usually absent. They are most numerous in the subcapsular lymphatic space and in the sinuses of the medulla, but all regions of the gland are invaded to some extent. Many of them contain much altered blood-pigment which gives a positive reaction for iron and occasionally there are ingested erythrocytes. In frozen sections a large number of oxidase-positive cells can be found, although polymorphs are conspicuously absent. Some of the monocytes show a coarse eosinophil granulation; this is particularly marked in large irregular cells lying in the pericapsular fibrosis around the aortic and cervical glands. A few multinucleated monocytic forms are seen, as well as occasional megakaryocytes (Fig. 1).

Spleen.—The Malpighian bodies are small and mis-shapen. The pulp is uniformly œdematous and the pattern is practically indiscernible, as a result of the presence of large numbers of monocytes comparable with those in the lymph glands and showing similar variants. There is a very large amount of iron-containing pigment in the pulp, partly in monocytes, and partly in large irregular macrophages which may be identical. Polymorphonuclears are absent, but the pulp contains numerous oxidase-positive elements.

FIG. 1



Lymph gland from Case 1; upper and lower parts of field mostly monocytes and lymphocytes respectively. (× 500.)

Liver.—General œdema. Fat is present in large amount, especially in the peripheral half of the lobules, the cells of which are distended with large droplets. The interlobular veins are dilated, and their blood contains many large mononuclears. Monocytes are scattered loosely and uniformly throughout the sinusoids. They are similar to, if slightly smaller than, those in other tissues, but show more variation in shape of nuclei. Some of them are drawn out in cytoplasmic processes and applied to the capillary walls like Kupffer's cells, and the distinction between the two cannot always be made apart from the oxidase and Prussian-blue reactions. Iron is present in large amount in the Kupffer's and the liver cells of the central zone of the lobules, to a less extent in the peripheral liver cells, and to a slight extent in the monocytes. The monocytes give a well-marked oxidase reaction.

Bone-marrow.—The fat is almost completely replaced by œdematous cellular tissue. Its cytology is unusually uniform, as nearly all the nucleated cells are monocytes, with only a few erythroblasts and an occasional megakaryocyte. The monocytes are similar to those found in other places but a few mitoses are observed, such cells having a more eosinophil cytoplasm. There is a number of multinucleated cells not unlike the Dorothy Reed type. Myelocytes and polymorphs are absent. Nearly all the monocytes give the oxidase reaction, in some it is weak and indefinite, but in fully half of the cells it is well marked. The oxidase-granules, however, are considerably less numerous than in true granulocytes. Much hæmosiderin is present.

Thyroid.—The gland is replaced by dense fibrous tissue and vessels, with numerous lymphoid foci and a few scattered atrophic epithelial tubules. Slight proliferation of elastic tissue around blood-vessels and tubules (Fig. 2).

Lung.—Broncho-pneumonia, the exudate being mainly composed of fibrin and monocytes, with very occasional polymorphonuclears. Necrosis in centres of foci of consolidation, œdema between them.

Kidney.—Cloudy swelling. A few monocytic foci in the connective tissue round the arcuate vessels.

Tonsil.—Numerous monocytes in the deeper layers.

Œsophagus.—Ulceration and necrosis (probably partly post mortem) with karyolysis and colonies of moulds on the mucous surface. Below this a wide zone of monocytes, and then some fibroblastic proliferation. No polymorphs.

---

* I do not use Sabin's method of supravital staining exactly as described by her, since we have no hot-box in the laboratory. The slides are prepared in the same way as that employed by Sabin, with a thin film of neutral red (with or without Janus green); the blood is taken in the same way; but after vaselining the edges of the cover-slip the slide is placed in the incubator, and removed for microsc time to time. If this is done fairly quic remain alive long enough to show the properties of the monocyte.

from 6600 (59 per cent. monocytes) to 416,000 (96 per cent. monocytes) in the four and a half months preceding death; the post-mortem histology was comparable with the present cases except that the monocytes in the tissues were oxidase negative. The case of aleukæmic monocytosis, published by Rosenthal in 1921, has a blood picture similar to that now recorded. The only example reported in this country seems to be that described by Cooke in 1931 in a boy of 19; the leucocyte count was 49,800, of which 87 per cent. were monocytes; autopsy was not permitted.[†]

Naegeli disputes the existence of monocytic leukæmia, coming to the conclusion after a review of published cases that they consist in a monocytosis of the blood associated with myeloid hyperplasia in the tissues. Piney suggests that the evidence is all in favour of the conception of monocytic leukæmia belonging to the group of myelosis. The tissue changes in the present cases, however, did not resemble myeloid hyperplasia, except that some of the cells were oxidase positive; apart from the distinctive morphology of the individual cells their uniformity was much greater than is the rule in myeloid infiltrates; the relatively much greater involvement of the lymph glands than of the spleen is quite unlike myelogenous leukæmia; the presence in the type cells of ingested erythrocytes and hæmosiderin indicates affinity to the monocyte rather than the granulocyte.

It seems desirable to indicate briefly certain points of inter-resemblance between the two present cases. Clinically these include the insidious onset, pallor and weakness, notably the marked drowsiness throughout, enlargement on palpation of the liver but not of the spleen, and the blood changes. Necropsy showed marked involvement of the lymphatic glands and liver, definite hyperplasia of the marrow, and relatively moderate enlargement of the spleen. Both cases showed necrotic ulcers of some part of the alimentary canal. Histologically the tissues were infiltrated with monocytes, and free iron was found in the liver, spleen, bone-marrow, and lymph glands; the iron in the liver was greater in amount in the hepatic cells in the centres of the lobules than in those at the peripheries—an unusual distribution of siderosis. Finally, in both cases degenerative changes were present in the thyroid gland; no similar record has been found elsewhere. This association may be of ætiological importance or may be only coincidence—a point which will be elucidated by future experience.

My thanks are due to Prof. F. S. Langmead for permitting me to use the clinical records of these cases, and to Dr. C. W. Morley for the photomicrographs.

PLEURAL EMPYEMA AS A COMPLICATION OF PYONEPHROSIS

BY STANFORD HOWARD, B.M., B.CH. OXF.,
F.R.C.S. ENG.
SURGICAL FIRST ASSISTANT AND REGISTRAR, LONDON HOSPITAL

AMONG surgical conditions of the kidney commonly met with pyonephrosis represents a considerable proportion, the total number of admissions to the London Hospital during the last ten years being 180. Among these, however, the incidence of severe pulmonary complications has been surprisingly small.

It is well known that operations on the kidney are occasionally attended by post-operative effusion of fluid in the corresponding pleural sac. This especially follows difficult cases of nephrectomy for new growth in which the diaphragm is involved. Even this complication, however, is not so common as might be expected from the close anatomical relation which the kidney bears to the diaphragm. In cases of pyonephrosis the incidence of pulmonary complications appears to be even less, and a search through the records for the last ten years reveals only five deaths from pulmonary complication in this condition. Two of these cases revealed empyema pleuræ and two broncho-pneumonia, and one showed broncho-pneumonia with peritonitis.

The following are the notes of three cases which came under my notice:—

THE FIRST CASE

History.—Four weeks before admission the patient, a man aged 43, was taken ill with severe pain in the left loin. The pain settled down into what he described as a worrying ache. He became more restless, and could not lie in one position for more than a few seconds at a time. That evening he became worse and vomited three times. There was no trouble with micturition and the bowels were opened that day. The temperature rose to 103° F., and he complained of feeling very dry and parched. The next morning he vomited again. The pain was still present, though not so severe, and the temperature was down to 100°. That night the temperature was again 103° and this diurnal variation persisted for seven days. On the fourth day the pain ceased, and an examination of the urine at this stage showed nothing abnormal. He remained in bed for 11 days, when he was allowed up, but the pain immediately returned with a sudden rise of temperature to 104°, accompanied by shivering. He returned to bed, and at this time began to notice a swelling in the left side and a feeling of tightness and distension of the upper abdomen. The urine was not examined. At night he now began to sweat profusely, was very thirsty, and had lost all appetite. Taking food increased the pain but he did not vomit again. He felt very weak and began to waste.

During the third and fourth weeks the symptoms were increased, and added to them was difficulty in breathing, with marked pain in the left chest. Coughing was especially painful. The bowels were open regularly without aperients during the whole course. The urine was not tested again after the first week.

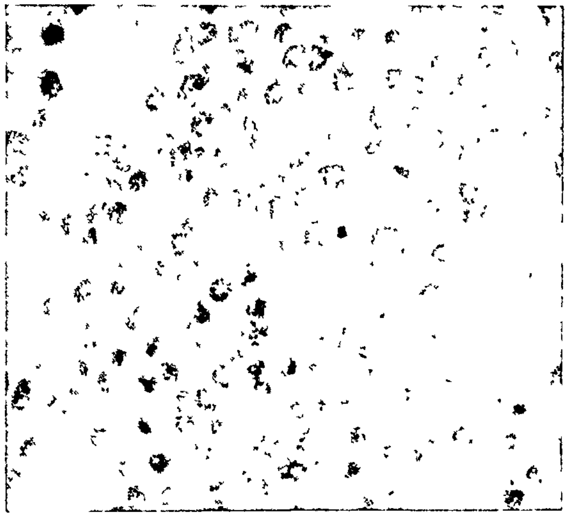
On admission the patient looked very ill. His temperature was 102·6°, his *pulse-rate* 112, and his respiration-rate 32. The face was sunken and pale, with a hectic flush on the cheekbones. The tongue was dry, with a dirty brown fur. He was sweating profusely. On inspection there was marked bulging in the left loin. No respiratory movement of the abdomen was seen on the left side. On palpation the swelling was very tender and did not move on respiration. The fingers could only with difficulty be depressed between the left costal margin and the swelling. On bimanual palpation of the loin the swelling could be pushed up from behind and a distinct cystic feeling was elicited. On percussion a band of resonance was found in front of the swelling, but posteriorly the dullness was continuous from the erector spinæ outwards and to the front until the band of resonance was met.

There was a distinct bulge of the lower intercostal spaces in the mid-axillary line. Tactile vocal fremitus was lost, and the left chest was stony dull up to the sixth rib in the mid-axillary line. Breath sounds were absent over the lower part of the chest, but in the upper part many moist phagocytosis of red cells. All glands show a high proportion of oxidase-positive monocytes. Iron-containing pigment in small amounts.

[†] This statement now requires qualification, as since this paper was completed a paper has been published by R. Gittins and J. C. Hawksley (Reticulo-endotheliomatosis, Ovarian Endothelioma, and Monocytic Leukæmia, Jour. Path. and Bact., 1933, xxxvi., 115). These authors include an exhaustive survey of the literature.

Bone-marrow.—Marked hyperplasia of monocytes, slight hyperplasia of erythroblasts, much karyorrhexis. Many of the monocytes are oxidase positive. Iron is mostly contained in large macrophages and elongated, possibly endothelial, cells, but there is some in the monocytes.

FIG. 4



Subpericardial leukæmic nodule from Case 2 ; cells are all monocytes, two being in mitosis. (× 500.)

Spleen.—Malpighian bodies very small; pulp packed with monocytes, mostly oxidase positive. Karyorrhexis in scattered foci. Much iron pigment in monocytes and reticulum cells of pulp.

Liver.—Monocytic infiltration most marked in portal systems, gradually becoming less dense as the centres of the lobules are approached. Monocytes generally oxidase positive. Siderosis of Kupffer's cells and liver cells, especially those in the centre of the lobule; less in the monocytes; hæmofuscin also present in considerable quantity. Very little fat, only a few globules in the peripheral cells.

Tonsil.—Monocytic infiltration; mitoses in both squamous epithelial cells and monocytes. Lymphoid tissue in immediate relation to crypts only.

Heart.—Fatty degeneration. Subpericardial periarteriolar nodule consisting of monocytes, several undergoing mitotic division; karyorrhexis at periphery (Fig. 4).

Intestine.—The membranous and ulcerated lesions show a coagulative necrosis involving all layers, the mucosa and muscularis mucosæ especially, and a small amount of fibrinous exudate. The cellular reaction consists almost entirely of monocytes with very few polymorphs. In Peyer's patches the deeper lying lymphocytes are replaced by monocytes.

Thyroid.—Definite degenerative changes are present. The gland is divided into lobules by trabeculæ of fibrous tissue, and finer collagenous fibres surround almost every individual vesicle. The vesicles show great variation in size, but most of them are very small, and are either empty or contain granular material; their epithelial cells are small, more or less flattened, and sometimes deficient. The few normal-sized vesicles contain colloid which generally stains poorly (Fig. 5).

Pituitary and parathyroids normal.

Lung.—Emphysema. Patchy œdema.

Kidney.—Monocytic infiltration in and around the adventitia of the arcuate and interlobular arteries, and around small groups of glomeruli.

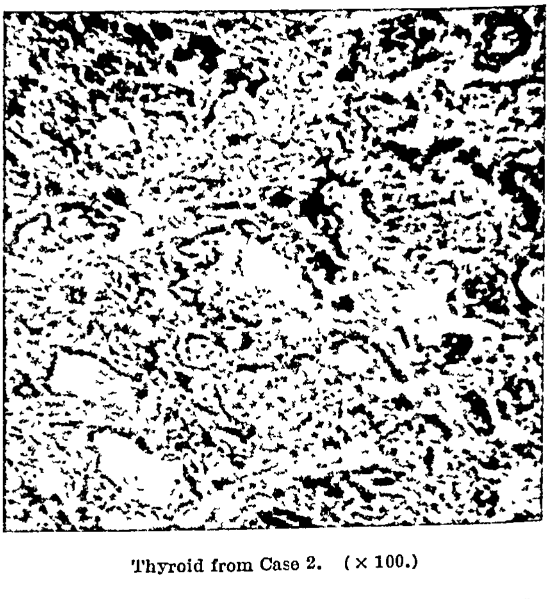
Discussion

These two cases conform to the usual conception of leukæmia in that there was a preponderance of one type of cell in the circulating blood associated with infiltration of the hæmopoietic organs, adult and fœtal, with the same type of cell. In Case 1 the total leucocyte count was at no time appreciably greater than normal, but this is not a serious objection to the use of the term "leukæmia," as many instances are on record in which the leucocyte count has been very low throughout, and it is well known that a so-called "aleukæmic phase" may occur in the course of a leucocythæmia of considerable magnitude. The leucopenia, especially of the granulocytes in Case 1, which was present 13 months before death, suggested the possibility of agranulocytosis, but the literature on this condition contains no comparable case. The granulopenia is, however, of interest, since Weiss (1927) has expressed the belief that every acute leukæmia is preceded by a greater or less degree of hypogranulocytosis.

In both the present cases the essential type of cell is the same. Its morphological characteristics, supravital staining reactions, and (in Case 2) ingestion of erythrocytes prove beyond reasonable doubt that it is related to the large hyaline leucocyte or monocyte.

Reschad and Schilling-Torgau (1913) described a "new leukæmia" characterised by the presence in the blood of numerous cells which were regarded as monocytes by Naegeli and Pappenheim. Their case, in a man aged 33, lasted eight weeks, started with gingivitis, and exhibited rigors, fever, and epistaxis. There was a generalised cutaneous rash consisting of focal accumulations of monocytes and histiocytes, enlargement of the spleen, and free iron in the liver. An ulcer in the large intestine is of interest in that it appears to have been histologically similar to the œsophageal and intestinal ulcers of the present Cases 1 and 2 respectively.

FIG. 5



Thyroid from Case 2. (× 100.)

Dameshek describes two cases and surveys the literature, coming to the conclusion that it contains 18 proven cases up to that date. Merklen and Wolf conclude that monocytic leukæmia is a justifiable term, review the literature, and record a case with 20,500 to 43,000 white blood-cells, which at autopsy showed diffuse proliferation of the reticular tissue of lymph glands, spleen, and marrow. In Hoff's case the total white count was 2500 to 1600, and the differential percentages were similar to those of the present Case 1. The example reported by Bingel in 1916 is admittedly doubtful. Swirtschewskaya records an instance where the leucocytes rose

Though coexisting peritonitis may to some extent explain the variation in the course of the two conditions we are considering, there is, in my opinion, a far more important factor—the time element. I refer to the time which elapses between the onset of the infective process and the diagnosis of its presence. In my experience subphrenic abscess is most frequently met with as a complication of perforated gastric or duodenal ulcer. The operation appears to have been successful and the patient to be on the road to recovery when the temperature begins to swing. As chest complications of a mild nature are common after upper abdominal operations, particularly those of the emergency type, often little importance is attached to this variation in temperature until a day or two has elapsed, in some cases even longer. Examination of the chest then usually shows pleural effusion. Even then the surgeon is often hesitant to diagnose subphrenic abscess, and thus a long period elapses during which the inflammatory process is free to exert its action upon the diaphragm. Added to the hesitancy on the part of the surgeon to diagnose what he fears, but hopes is not present, is the difficulty of being clinically certain that subphrenic abscess is present, and the condition may be missed, in spite of the most careful efforts to detect its presence.

With pyonephrosis, however, the diagnosis is usually swift and certain. There is usually a history of pain in the renal angle and in some cases renal colic. There is in nearly all cases a palpable cystic tumour, pus and blood are commonly present in the urine, and on cystoscopy pus can be seen exuding from the corresponding ureteric orifice.

The explanation of why the particular cases quoted above were complicated by empyema is, in my opinion, to be credited to the time element as represented by the period between the onset and the late diagnosis. In all three cases a more than usually long history of illness is present, and it is to be expected that had operative interference been carried out earlier the empyema would not have developed.

There remains one other reason why pyonephrosis should unusually produce empyema as a complication. This is anatomical. The kidney is surrounded by a tough fibrous capsule which limits the spread of the infection, and this is probably a potent factor in preventing pulmonary complications.

SUMMARY

(1) Cases of pyonephrosis very unusually give rise to severe pulmonary complications, only 5 cases out of a series of 180 being so complicated.

(2) Other cases of subphrenic acute infective processes, notably subphrenic abscess, very often give rise to severe pulmonary complications, 67·44 per cent. being accompanied by effusion of some kind, and 27·9 per cent. by purulent effusion.

(3) The explanation of this apparent inconsistency is probably threefold: (*a*) The long period usually elapsing between the formation of a subphrenic abscess and its detection, as contrasted with the usual early diagnosis of pyonephrosis. (*b*) The upper abdominal peritonitis associated with subphrenic abscess and the resulting immobility of the diaphragm. (*c*) The tough fibrous capsule of the kidney exerting a limiting effect on the spread of infection.

(4) Cases of acute pyonephrosis left untreated for long periods are likely to develop severe intrathoracic complications.

In conclusion, my thanks are due to Mr. Russell Howard, Mr. Hugh Lett, and Prof. Arthur Ellis for permission to publish the details of these cases.

THE CLINICAL SIGNIFICANCE OF THE NERVE-ENDINGS IN THE MESENTERY

By Donal Sheehan, M.D., M.Sc. Manch.
DEMONSTRATOR IN THE DEPARTMENT OF ANATOMY, UNIVERSITY OF MANCHESTER

The sensitivity of the mesentery to ordinary mechanical stimuli and its possible rôle in the causation of abdominal pain has recently been brought to the fore largely through the writings of Tyrrell-Gray. He describes (1922) the mesentery as exceedingly sensitive to every kind of stimulus, mechanical, chemical, and thermal, and advances the view that true visceral pain primarily arises from the mesentery, partly by impulses arising in the Pacinian corpuscles. Breslauer has suggested that the impulses which initiate visceral pain do not arise in the intestine but in the mesentery, and in particular in the mesenteric blood-vessels. He observed that areas of the peritoneum which contain large blood-vessels are more sensitive than areas in which no large vessels are present. The sensitivity of the mesentery to ordinary mechanical stimuli has apparently been doubted by many investigators, but the recent work of Morley has finally established this fact. As a result of his observations under local anæsthesia Morley concludes that the mesentery is decidedly sensitive from its root to a point a little distance away from its attachment to the bowel. In another paper (Sheehan) an account is given of the exact distribution and proportion of the Pacinian corpuscles and of other afferent nerve-endings in the mesentery. The clinical significance of the free myelinated nerve-endings and of the fine non-myelinated plexus has already been discussed. In view, however, of the possible significance of the Pacinian corpuscles in the mesentery in regard to the causation of abdominal pain, a short discussion on the views advanced as to the function of these bodies appears important.

FUNCTIONS ATTRIBUTED TO THE PACINIAN CORPUSCLES

First noticed by Vater, professor of anatomy at Wittenburg in 1741, and later fully described by Pacini, an Italian physiologist in Pisa, in 1830, these encapsulated nerve-endings have been the subject of much controversy. After assessing all the known facts concerning them, we find very little firm basis on which to build any true conception of their function. We can perhaps summarise the theories that have been advanced, and the views held as regards them, as follows:—

1. *Touch*—i.e., end-organs for the reception of the sensation of touch. This view was put forward in the early days of the knowledge on sensation, when the discovery by Blix in 1885 of the punctate distribution of sensibility of the skin first led to the belief in the existence of specific end-organs, each subserving a special form of sensibility.

Though the belief in specific end-organs is still supported by many authorities, the view of looking upon the Pacinian corpuscles as special receptors for the sensation of touch is now no longer held. Waterston has made sections and examined microscopically such spots as were known to be sensitive to touch stimuli, and failed to demonstrate the presence of these corpuscles. Furthermore the presence of these bodies lying deeply in the subcutaneous tissues, around the periosteum of bones, and in the mesentery of the cat, where touch stimulation can be obviously excluded, shows conclusively that they cannot be looked upon as agents subserving this function.

sounds were heard. The heart sounds were normal in all areas, but the position of the apex-beat could not be determined.

The urine was dark red with a large amount of deposit; a quarter-volume of albumin was present, and the guaiac test was positive to blood. Naked-eye inspection of the deposit showed pus.

A diagnosis of left pyonephrosis with associated pleural effusion was made and, in view of the serious condition of the patient, drainage of the kidney was determined upon as an immediate measure.

At operation the patient was given a general anæsthetic (A.C.E. and open ether). To confirm the diagnosis a cystoscope was passed. The bladder was very injected and œdematous, especially in the neighbourhood of the left ureteric orifice and trigone. Clear urine was seen issuing from the right orifice, which was contracting rhythmically and at normal frequency. The left ureteric orifice showed the contractions to be less frequent and of longer duration, and from time to time a bead of yellow pus was extruded. The patient was then placed in the right lateral position and the kidney approached by Morris's incision. The parietal tissues were very œdematous. The perirenal fat was almost entirely absent, and the kidney greatly enlarged and pale pink. There was no perinephric suppuration. A trocar and cannula were inserted into the kidney, and 22 ounces of foul-smelling, blood-stained pus was evacuated. On inserting a finger into the pelvis of the kidney several pieces of calculus debris were felt. Removal of the cannula was followed by an immediate brisk hæmorrhage. All attempts to control the bleeding by mattress sutures through the kidney substance were of no avail. Immediate nephrectomy was decided upon, as the hæmorrhage was becoming increasingly severe and the pulse-rate had risen to 140.

The kidney was very adherent to the diaphragm, and during the operation of stripping it there was a sudden gush of pus from above, and a further 15 to 20 ounces drained out through a small rent in the diaphragm. The removal of the kidney was then completed. Drainage of the kidney-pouch was arranged and, as the condition of the patient was now very poor, all thought of rib resection for drainage of the thorax was dismissed as impracticable. A second drainage-tube was consequently passed up through the rent in the diaphragm and sutured in position with its outlet through the wound in the loin. The wound was then closed.

At this time the patient was scarcely alive, respirations being very shallow and rapid, and the pulse imperceptible. Infusion of one pint of intravenous saline was without effect, so it was decided to send out an emergency call for a blood donor. A Group 4 donor was available after two hours, and 800 c.cm. of whole blood with 200 c.cm. of 2 per cent. citrate solution were given into the median basilic vein. The result was immediate, and the patient improved rapidly.

Progress.—Drainage was free for several days, especially from the thoracic tube. The temperature was normal on the second day and the pulse-rate had settled to about 90. Breathing was painless, and by the end of three days the respiration-rate was 18. The tube draining the kidney bed was removed after the third day, but the tube in the thorax continued to drain until the tenth day, when it was removed. Culture of the pus from the kidney showed *Staphylococcus aureus* with *B. proteus*, and that from the pleural cavity grew the same types of organism.

The patient was discharged well on the 27th day. Pathological examination of the kidney showed marked expansion of the pelvis with severe inflammatory changes. There was much phosphatic debris, and several small abscesses were present in the cortical substance of the kidney which had escaped destruction.

THE SECOND CASE

History.—The patient was a woman, aged 34, admitted on Jan. 31st, 1931. For 13 years she had been complaining of pain in the back but no other symptoms. Two years before the pain had begun to get much worse, radiating to the left groin, with occasional attacks of hæmaturia. In the last eight months she had been suffering from severe attacks of giddiness, thirst, and headache. The last menstrual period had occurred six months before admission.

On admission her temperature was normal, her pulse-rate 96, and her respiration-rate 17. She had a mitral facies and cyanosis. The uterus was one inch below the umbilicus, and fœtal parts could be felt. There was a large tumour in the left flank. The heart showed mitral stenosis. The lungs were clear. There was considerable œdema of the feet, and the urine showed pus and one-seventh volume of albumin. The blood-urea was 0·021 per cent. After three weeks in bed the patient was much better and was discharged. A radiogram taken at the time revealed calculi in the left kidney.

On April 10th she was *readmitted* for labour. There was a large swelling in the left flank. Her temperature was 99° and her pulse-rate 80. She had a precipitate labour lasting 20 minutes. The child was premature, weighed 3 lb. 7 oz., was alive, and did well. She was transferred from the obstetric ward to a medical ward on the tenth day. She still had a tumour in the left flank. The temperature was swinging, and her pulse-rate was 100. The chest revealed bronchial breathing over the left lower lobe, and the left base of the lung was dull to percussion. The swelling in the loin, after ten days, began to increase in size, and the skin became reddened over it.

She was then transferred on May 8th to surgical care. An operation was deemed advisable, and on the 9th exploration of the kidney was carried out. A large pyonephrosis was drained, and several calculi withdrawn from the kidney pelvis. The temperature continued to swing and the patient did not respond as well as would be hoped, so on May 31st a further exploration was carried out, when a fresh loculus of pus was released. The temperature continued to swing, and on June 21st the patient died. At *post-mortem examination* the kidney area was more or less clear, whereas the left chest showed a large empyema.

A THIRD CASE

The third example occurred many years ago and was a case of left-sided pyonephrosis which was untreated for 14 days. Perinephric abscess was then diagnosed, and an incision made which drained off much pus from around the kidney. After a week, however, the condition was further diagnosed as pyonephrosis, and a further operation performed for drainage of the kidney itself. The patient was very ill by this time and the possibility of serious pulmonary complication was apparently overlooked. The patient died, and at autopsy a large empyema pleuræ was revealed.

DISCUSSION

In viewing these cases from their pathological aspect, an attempt has been made to comprehend why in these instances the kidney condition should have been complicated by empyema; why the complication is usually rare; and also what bearing these cases have upon other infective processes close to the inferior surface of the diaphragm.

Among the commonest of these latter cases is the condition of subphrenic abscess. During the five years ending 1930, 43 cases of subphrenic abscess were treated in the London Hospital. Of these 67·44 per cent. were complicated by pleural effusion, and in 27·9 per cent. the effusion was purulent. In many of the cases there was direct communication between the subphrenic and pleural collections of pus.

A consideration of the pathology and clinical course of these cases gives the clue to the answer of the first two questions. In both subphrenic abscess and pyonephrosis there is an active infective process close to the inferior surface of the diaphragm. Lymphatic communication through the diaphragm is rich, and consequently the infection can be transmitted easily to the upper surface. This will call forth a corresponding inflammatory reaction in the parietal pleuræ covering the diaphragm and, if the condition beneath the diaphragm be unrelieved, effusion of fluid into the pleural cavity will result. The effect of the inflammatory process above the diaphragm will, however, be heightened if there is any factor which will tend to limit the movements of this muscle, and in subphrenic abscess this factor is present—namely, peritonitis. With an abscess in the upper part of the peritoneal cavity abdominal respiration is decreased or non-existent, and hence we already have one explanation why pleural effusion and its later manifestation, empyema, should be more prevalent in cases of subphrenic abscess than in pyonephrosis. Where there is direct communication between the subphrenic abscess and the pleural cavity the empyema is nearly always preceded by a simple pleural effusion before the more serious and usually fatal complication supervenes.

4. Periosteum and interosseus membranes.
5. Serous membranes—e.g., pleura, pericardium, synovial membrane, mesentery and mesocolon, parietal peritoneum, and in peritoneum over bladder.
6. Genital organs—glans penis.
7. In the capsule and interstitial tissue of certain organs, notably, pancreas, lymphatic glands, ovary and prostate, thyroid and parathyroid.

In an investigation involving the examination of the pancreas in man Ceelen found the Pacinian corpuscles in 89 per cent. of cases. They varied widely in number and distribution, and were most numerous on the posterior aspect of the head. Ceelen described them directly in relation to the parenchymatous tissue.

They do not exist only in mammalia; they are also to be found in reptiles and in birds in the beak and tongue (corpuscles of Herbst); but they are present in much greater frequency in mammalia. The prevailing opinion seems to be that they are *not* present in amphibia. Now it is clear that any function or functions which we may assign to the Pacinian corpuscle must necessarily be in accordance with this wide distribution in the body.

A second point to be emphasised is that all the well-known forms of corpuscular end-organs are built upon a uniform plan, consisting of an outer lamellated connective tissue capsule with a core of softer material through which the nerve-axon runs to its final arborescence. Between the largest Pacinian corpuscles that are plainly visible to the naked eye, and those of Golgi-Mazzoni, which can only be detected with the microscope, there is an uninterrupted series of intermediate or transitional forms. And from the so-called genital corpuscles there is a further gradual transition to the more elaborate corpuscles as described by Golgi and Mazzoni. Thus we have to remember in ascribing any particular function to one type of end-organ that there are all grades of corpuscles between the typical Pacinian and the other similar lamellated corpuscles. This point was very clearly demonstrated in the previous work, where the corpuscular end-organs in the mesentery varied so markedly in size and in thickness of lamellation.

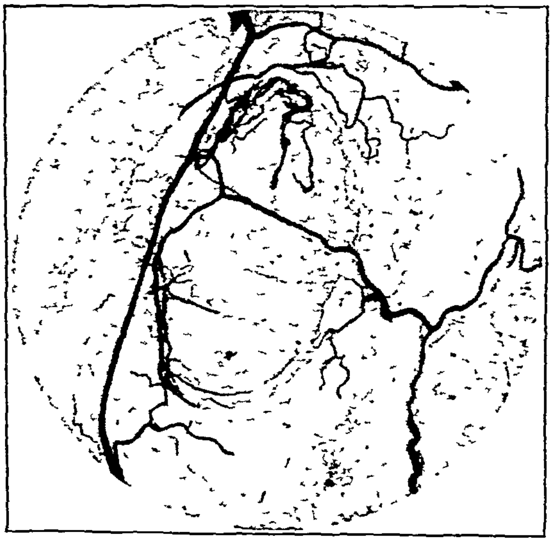
And lastly, previous work has demonstrated that the nerve-endings in the Pacinian corpuscles, at least in the mesentery of the cat, are splanchnic in origin—i.e., are presumably part of the sympathetic system. It is of course questionable whether this can be extended to all the Pacinian corpuscles in the body, but the fact that groups of these corpuscles have been dissected along the finer branches of the radial and median nerves is no argument against the view, as the sympathetic fibres are known to supply practically every tissue in the body, and to reach them via the main somatic nerve-trunks. Woollard, however, finds that the nerve-endings in Pacinian bodies lying close to blood-vessels do not degenerate following sympathetic denervation of the lower extremity.

It is of interest in regard to this question that in the lower limbs of two patients upon whom bilateral lumbar sympathectomy had been performed some months previously, it was found impossible to stain the nerve-axon in the corpuscles in the ball of the foot, although the nerve-fibres in the proximity stained clearly with silver. Although more light is required on this question of sympathetic afferents, it seems apparent, from the present state of our knowledge, that any function of the Pacinian bodies, at any rate in the mesentery, must inevitably be intimately associated with the sympathetic system.

With these aspects of the problem before us can we form any truer conception of the function of these bodies?

THE VASCULAR SUPPLY OF THE PACINIAN CORPUSCLE

It has been known for a long while (Herbst, 1848) that the Vater-Pacinian corpuscle possessed a particular blood-supply, not only in relation to its outer surface but also by the possession of a capillary network which penetrated the base of the corpuscle along with the main nerve-fibre. Schumaker (1907 and 1911) and Michailow (1909) both investigated this aspect of the problem, and though differing in their findings as regards a capillary network existing in the central core of the corpuscle, they both concluded that the corpuscles responded to changes in blood pressure owing either to an increased amount of fluid in or around them. Schumaker found that the shape of the corpuscles became altered on raising the pressure in the mesenteric vascular system. On the surface of the lamellated bodies Michailow was able to demonstrate a fine elastic network. Previously, Thoma in 1884 had expressed the view that Vater-Pacinian corpuscles, which he found in the outer zone of the adventitia of the aorta, may act as regulators of vascular tonus.



Section of a Pacinian corpuscle showing the vascular supply.

The view that the Pacinian bodies were in some way associated with the reflex contraction and dilatation of the blood-vessels was expressed by Raines (1909), Van de Velde (1908), and by Collin (1921). Lawrentjew and Dowgjallo make similar suggestions, and Dowgjallo adds that their function appears to be to perform a coördinating apparatus between the lymphatic and blood vascular systems.

Thus it became essential in any study of Pacinian corpuscles from the functional aspect to make a confirmatory investigation of the blood-supply to these bodies. This was done by the injection of carmine gelatin injection mass into the superior mesenteric artery, after previously washing out the mesenteric circulation with warm saline solution. The mesentery was then removed and placed into 10 per cent. formol saline, and left in the ice-chest overnight, to allow the injection mass to set. Isolated corpuscles were then selected, dehydrated, and cleared in xylol and mounted. Several cats were injected in

2. *Pain.*—The evidence that the Pacinian corpuscles may possibly act as receptors for pain is largely clinical and is supported chiefly by the writings of Tyrrell-Gray. He (1922) attributes the greatest importance to these bodies in the mechanism of abdominal pain, and even suggests that intestinal colic is caused by pressure upon them in the mesentery. He argues (1926) that in acute appendicitis inflammation first involves the mesentery of the ileocæcal angle, thus causing irritation of the Pacinian corpuscles from which proceed (*a*) pain impulses and (*b*) afferent impulses resulting in rigidity of the abdominal muscles. Kinsella in his article on abdominal pain also suggests that the Pacinian bodies may in some way be associated with pain—"The parietal peritoneum is very sensitive and pain is produced by dragging on it. The presence in the parietal peritoneum of the sensory corpuscles of Pacini are of significance." Head in 1893–94, drawing an analogy from his divisions of sensation of the skin, attributed to the viscera a protopathic sensibility only, and assumed that the Pacinian bodies are the means by which we gain a power of appreciating intestinal movement similar to that of joint and muscle sense.

From observations made in a previous communication it seems that the corpuscles are present in far too small a number in the human mesentery to account for the acute pain associated with appendicitis and intestinal colic. The theory cannot be excluded from a review of the distribution of the corpuscles in the body, as in all situations where they occur, pain can become an important feature. But the view is purely theoretical and is based on no practical evidence of any kind. Further, from the work of von Frey the balance of evidence is now in favour of accepting the free nerve-endings as the specific organs for pain.

3. *Thermal Sense.*—Luciani supposes the Pacinian corpuscles function partly as end-organs for the sensation of heat. He does not elaborate this view, and there does not appear to be very much in support of it. Adrian and Ulmrath (1929) in their researches showed that changes in temperature do not excite any discharge of impulses from the corpuscle along the nerve.

4. *Deep Pressure and Muscle and Joint Sense.*—Although essentially different, these two functions may be considered here together, as the supporters in most cases uphold this double function for the Pacinian corpuscle. The view was based on the knowledge of the structure and of the distribution of these corpuscles in the body. Those lying deeply in the subcutaneous tissues are from their position admirably suited to respond to deep pressure stimuli, whilst the corpuscles so constantly found in the neighbourhood of joints, particularly on the flexor aspects, were considered to respond to the movements of the muscles and joints. Furthermore the histological appearance of the corpuscle was advanced in support of this view. The multi-lamellated capsule was looked upon as a protection for the fine nerve-ending against all lighter stimuli as from touch and small degrees of heat and cold. The theory received support from many authorities, and is the prevalent view at the present day in regard to the function of these bodies. Herrick states it clearly as follows: "By these end-organs relatively coarse pressure may be discriminated and localised (exteroceptive function) and movements of muscles and joints can be recognised (proprioceptive function)." Sherrington (1900) and Bayliss (1915) both gave this explanation.

In support of this theory is the work of Adrian and Ulmrath cited above.

They devised an experiment for recording the impulse discharge on stimulating an isolated group of Pacinian corpuscles, lying beneath the tendons in the hind foot of the cat. An immediate discharge of impulses was recorded when joint movement or pressure stimuli were applied, but varying temperatures, as previously stated, caused no impulse discharge. Pressure on a single isolated Pacinian corpuscle with a glass rod drawn out to a small rounded point gave a similar record of impulse discharge along the nerve. Furthermore, if the corpuscles are destroyed, movement of the toe and pressure over the same area gave rise to no discharge of impulses.

This work confirmed in a striking manner the theory of the corpuscles subserving the sensations of deep pressure and joint and muscle sense. But Adrian and Ulmrath point out that sensations of joint movement are probably derived from more than one type of end-organ, for in the frog, which has no Pacinian corpuscles, impulse discharge along the sciatic nerve is recorded on movement of the knee-joint, after all nerve branches to the muscles are cut. "In mammals the corpuscles which are in close relation to the joints will evidently signal the changes of pressure produced by the joint movement, though other forms of ending may take some part in the message."

It is interesting in view of these findings to look back to the work of Ramström. He showed (1908 *a*) that Pacinian corpuscles occurred in the parietal peritoneum, and he further demonstrated (1908 *b*) in a series of operations under local anæsthesia that the parietal peritoneum is insensitive to pressure and thermal stimuli. This observation was confirmed by Capps and Coleman in 1922. Ramström naturally concluded that Pacinian corpuscles were in no way related to the function of pressure recognition, a view which, he states, is quite untenable with his clinical findings.

5. Ceelen in 1912 gave a review of a hundred human post-mortems with special reference to the presence of Pacinian corpuscles in the abdomen. He suggested some possible trophic function associated with the growth of the body, the corpuscles possibly disappearing later in life like the thymus. This he based on the rather insufficient evidence that in 11 per cent. of the cases he was unable to find any Pacinian corpuscles, but in every infant and 95 per cent. of the children examined they were present. It surely seems more feasible to suppose that the corpuscles are more easily found and identified in the infants and young children, where the view is not so obscured by the large accumulations of fat, commonly discovered in the mesentery and omentum of elderly subjects. He also observed that where the corpuscles occurred in very large numbers the lymphatic apparatus appeared swollen, and in some cases he found the Pacinian corpuscles themselves œdematous, a watery fluid lying between the lamellæ.

6. *Regulators of Circulation and Blood Pressure.*—This will be discussed fully below.

DISTRIBUTION AND STRUCTURE OF THE PACINIAN BODIES

This formidable list of conflicting views and theories serves to show how little is really known regarding the function of these corpuscles. One or two general and more essential aspects of the problem seem important. In the first place, where are Pacinian corpuscles to be found elsewhere in the body? We can tabulate the distribution in the body as follows:—

1. Deep layers of the skin, especially fingers and toes.
2. Tendons and sheaths of muscles.
3. Near joints, especially flexor aspects.

4. Periosteum and interosseus membranes.
5. Serous membranes—e.g., pleura, pericardium, synovial membrane, mesentery and mesocolon, parietal peritoneum, and in peritoneum over bladder.
6. Genital organs—glans penis.
7. In the capsule and interstitial tissue of certain organs, notably, pancreas, lymphatic glands, ovary and prostate, thyroid and parathyroid.

In an investigation involving the examination of the pancreas in man Ceelen found the Pacinian corpuscles in 89 per cent. of cases. They varied widely in number and distribution, and were most numerous on the posterior aspect of the head. Ceelen described them directly in relation to the parenchymatous tissue.

They do not exist only in mammalia; they are also to be found in reptiles and in birds in the beak and tongue (corpuscles of Herbst); but they are present in much greater frequency in mammalia. The prevailing opinion seems to be that they are *not* present in amphibia. Now it is clear that any function or functions which we may assign to the Pacinian corpuscle must necessarily be in accordance with this wide distribution in the body.

A second point to be emphasised is that all the well-known forms of corpuscular end-organs are built upon a uniform plan, consisting of an outer lamellated connective tissue capsule with a core of softer material through which the nerve-axon runs to its final arborescence. Between the largest Pacinian corpuscles that are plainly visible to the naked eye, and those of Golgi-Mazzoni, which can only be detected with the microscope, there is an uninterrupted series of intermediate or transitional forms. And from the so-called genital corpuscles there is a further gradual transition to the more elaborate corpuscles as described by Golgi and Mazzoni. Thus we have to remember in ascribing any particular function to one type of end-organ that there are all grades of corpuscles between the typical Pacinian and the other similar lamellated corpuscles. This point was very clearly demonstrated in the previous work, where the corpuscular end-organs in the mesentery varied so markedly in size and in thickness of lamellation.

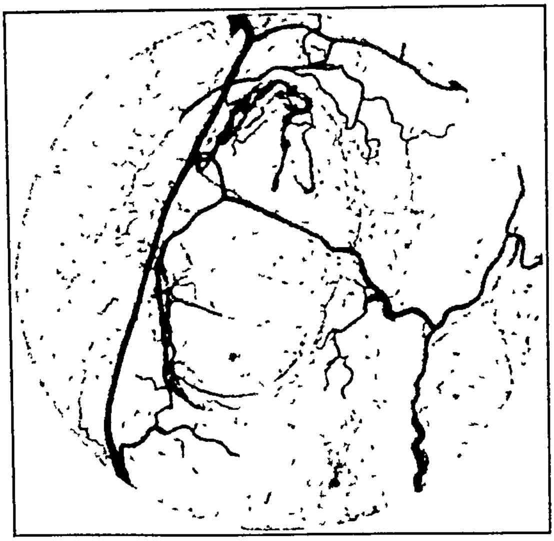
And lastly, previous work has demonstrated that the nerve-endings in the Pacinian corpuscles, at least in the mesentery of the cat, are splanchnic in origin—i.e., are presumably part of the sympathetic system. It is of course questionable whether this can be extended to all the Pacinian corpuscles in the body, but the fact that groups of these corpuscles have been dissected along the finer branches of the radial and median nerves is no argument against the view, as the sympathetic fibres are known to supply practically every tissue in the body, and to reach them via the main somatic nerve-trunks. Woollard, however, finds that the nerve-endings in Pacinian bodies lying close to blood-vessels do not degenerate following sympathetic denervation of the lower extremity.

It is of interest in regard to this question that in the lower limbs of two patients upon whom bilateral lumbar sympathectomy had been performed some months previously, it was found impossible to stain the nerve-axon in the corpuscles in the ball of the foot, although the nerve-fibres in the proximity stained clearly with silver. Although more light is required on this question of sympathetic afferents, it seems apparent, from the present state of our knowledge, that any function of the Pacinian bodies, at any rate in the mesentery, must inevitably be intimately associated with the sympathetic system.

With these aspects of the problem before us can we form any truer conception of the function of these bodies?

THE VASCULAR SUPPLY OF THE PACINIAN CORPUSCLE

It has been known for a long while (Herbst, 1848) that the Vater-Pacinian corpuscle possessed a particular blood-supply, not only in relation to its outer surface but also by the possession of a capillary network which penetrated the base of the corpuscle along with the main nerve-fibre. Schumaker (1907 and 1911) and Michailow (1909) both investigated this aspect of the problem, and though differing in their findings as regards a capillary network existing in the central core of the corpuscle, they both concluded that the corpuscles responded to changes in blood pressure owing either to an increased amount of fluid in or around them. Schumaker found that the shape of the corpuscles became altered on raising the pressure in the mesenteric vascular system. On the surface of the lamellated bodies Michailow was able to demonstrate a fine elastic network. Previously, Thoma in 1884 had expressed the view that Vater-Pacinian corpuscles, which he found in the outer zone of the adventitia of the aorta, may act as regulators of vascular tonus.



Section of a Pacinian corpuscle showing the vascular supply.

The view that the Pacinian bodies were in some way associated with the reflex contraction and dilatation of the blood-vessels was expressed by Raines (1909), Van de Velde (1908), and by Collin (1921). Lawrentjew and Dowgjallo make similar suggestions, and Dowgjallo adds that their function appears to be to perform a coördinating apparatus between the lymphatic and blood vascular systems.

Thus it became essential in any study of Pacinian corpuscles from the functional aspect to make a confirmatory investigation of the blood-supply to these bodies. This was done by the injection of carmine gelatin injection mass into the superior mesenteric artery, after previously washing out the mesenteric circulation with warm saline solution. The mesentery was then removed and placed into 10 per cent. formol saline, and left in the ice-chest overnight, to allow the injection mass to set. Isolated corpuscles were then selected, dehydrated, and cleared in xylol and mounted. Several cats were injected in

2. *Pain.*—The evidence that the Pacinian corpuscles may possibly act as receptors for pain is largely clinical and is supported chiefly by the writings of Tyrrell-Gray. He (1922) attributes the greatest importance to these bodies in the mechanism of abdominal pain, and even suggests that intestinal colic is caused by pressure upon them in the mesentery. He argues (1926) that in acute appendicitis inflammation first involves the mesentery of the ileocæcal angle, thus causing irritation of the Pacinian corpuscles from which proceed (*a*) pain impulses and (*b*) afferent impulses resulting in rigidity of the abdominal muscles. Kinsella in his article on abdominal pain also suggests that the Pacinian bodies may in some way be associated with pain—" The parietal peritoneum is very sensitive and pain is produced by dragging on it. The presence in the parietal peritoneum of the sensory corpuscles of Pacini are of significance." Head in 1893–94, drawing an analogy from his divisions of sensation of the skin, attributed to the viscera a protopathic sensibility only, and assumed that the Pacinian bodies are the means by which we gain a power of appreciating intestinal movement similar to that of joint and muscle sense.

From observations made in a previous communication it seems that the corpuscles are present in far too small a number in the human mesentery to account for the acute pain associated with appendicitis and intestinal colic. The theory cannot be excluded from a review of the distribution of the corpuscles in the body, as in all situations where they occur, pain can become an important feature. But the view is purely theoretical and is based on no practical evidence of any kind. Further, from the work of von Frey the balance of evidence is now in favour of accepting the free nerve-endings as the specific organs for pain.

3. *Thermal Sense.*—Luciani supposes the Pacinian corpuscles function partly as end-organs for the sensation of heat. He does not elaborate this view, and there does not appear to be very much in support of it. Adrian and Ulmrath (1929) in their researches showed that changes in temperature do not excite any discharge of impulses from the corpuscle along the nerve.

4. *Deep Pressure and Muscle and Joint Sense.*—Although essentially different, these two functions may be considered here together, as the supporters in most cases uphold this double function for the Pacinian corpuscle. The view was based on the knowledge of the structure and of the distribution of these corpuscles in the body. Those lying deeply in the subcutaneous tissues are from their position admirably suited to respond to deep pressure stimuli, whilst the corpuscles so constantly found in the neighbourhood of joints, particularly on the flexor aspects, were considered to respond to the movements of the muscles and joints. Furthermore the histological appearance of the corpuscle was advanced in support of this view. The multi-lamellated capsule was looked upon as a protection for the fine nerve-ending against all lighter stimuli as from touch and small degrees of heat and cold. The theory received support from many authorities, and is the prevalent view at the present day in regard to the function of these bodies. Herrick states it clearly as follows: " By these end-organs relatively coarse pressure may be discriminated and localised (exteroceptive function) and movements of muscles and joints can be recognised (proprioceptive function)." Sherrington (1900) and Bayliss (1915) both gave this explanation.

In support of this theory is the work of Adrian and Ulmrath cited above.

> They devised an experiment for recording the impulse discharge on stimulating an isolated group of Pacinian corpuscles, lying beneath the tendons in the hind foot of the cat. An immediate discharge of impulses was recorded when joint movement or pressure stimuli were applied, but varying temperatures, as previously stated, caused no impulse discharge. Pressure on a single isolated Pacinian corpuscle with a glass rod drawn out to a small rounded point gave a similar record of impulse discharge along the nerve. Furthermore, if the corpuscles are destroyed, movement of the toe and pressure over the same area gave rise to no discharge of impulses.

This work confirmed in a striking manner the theory of the corpuscles subserving the sensations of deep pressure and joint and muscle sense. But Adrian and Ulmrath point out that sensations of joint movement are probably derived from more than one type of end-organ, for in the frog, which has no Pacinian corpuscles, impulse discharge along the sciatic nerve is recorded on movement of the knee-joint, after all nerve branches to the muscles are cut. " In mammals the corpuscles which are in close relation to the joints will evidently signal the changes of pressure produced by the joint movement, though other forms of ending may take some part in the message."

It is interesting in view of these findings to look back to the work of Ramström. He showed (1908 *a*) that Pacinian corpuscles occurred in the parietal peritoneum, and he further demonstrated (1908 *b*) in a series of operations under local anæsthesia that the parietal peritoneum is insensitive to pressure and thermal stimuli. This observation was confirmed by Capps and Coleman in 1922. Ramström naturally concluded that Pacinian corpuscles were in no way related to the function of pressure recognition, a view which, he states, is quite untenable with his clinical findings.

5. Ceelen in 1912 gave a review of a hundred human post-mortems with special reference to the presence of Pacinian corpuscles in the abdomen. He suggested some possible trophic function associated with the growth of the body, the corpuscles possibly disappearing later in life like the thymus. This he based on the rather insufficient evidence that in 11 per cent. of the cases he was unable to find any Pacinian corpuscles, but in every infant and 95 per cent. of the children examined they were present. It surely seems more feasible to suppose that the corpuscles are more easily found and identified in the infants and young children, where the view is not so obscured by the large accumulations of fat, commonly discovered in the mesentery and omentum of elderly subjects. He also observed that where the corpuscles occurred in very large numbers the lymphatic apparatus appeared swollen, and in some cases he found the Pacinian corpuscles themselves œdematous, a watery fluid lying between the lamellæ.

6. *Regulators of Circulation and Blood Pressure.*—This will be discussed fully below.

DISTRIBUTION AND STRUCTURE OF THE PACINIAN BODIES

This formidable list of conflicting views and theories serves to show how little is really known regarding the function of these corpuscles. One or two general and more essential aspects of the problem seem important. In the first place, where are Pacinian corpuscles to be found elsewhere in the body? We can tabulate the distribution in the body as follows:—

1. Deep layers of the skin, especially fingers and toes.
2. Tendons and sheaths of muscles.
3. Near joints, especially flexor aspects.

THE HEART AFTER DIPHTHERIA

By Stanley Alstead, M.D. Liverp.

EXTRA DISPENSARY PHYSICIAN, WESTERN INFIRMARY, GLASGOW; POLLOK LECTURER IN MATERIA MEDICA AND THERAPEUTICS IN THE UNIVERSITY OF GLASGOW

Franklin White and H. H. Smith[1] examined nearly 1000 patients recently discharged from hospital convalescent after diphtheria. They found that 75 per cent. still showed evidence of myocardial defects and relative insufficiency of the mitral valve, while about one-third of the cases (not including babies) suffered from tachycardia and irregularity of the pulse. They pointed out that such cardiac abnormalities were not commonly found after scarlet fever, measles, typhoid, or pneumonia.

Some 78 cases of convalescent diphtheria were described; all of them had signs of heart damage when they left the isolation hospital, 29 of them having been "very severe" cases and the remainder "moderate" or "mild" cases. Care was taken to exclude from the series any patient who gave a history of other ætiological factors such as rheumatism. Most of the cases were found to have murmurs and some degree of cardiac enlargement. Five had a persistently rapid heart-rate, and in four cases there was enlargement of the heart out of proportion to the other signs. After repeated observation over a period of from 2 to 12 months they were able to state that the majority of these cases showed a steady improvement in the condition of the heart. About a quarter of the cases, however, were still abnormal at the end of four months from the onset of the disease, but 6 of these had recovered when re-examined a few months later. Of the remaining 13, 5 were kept under observation for five months, 4 for six months, and 2 for eight months before recovery was complete.

The persistence of signs as late as 11 months after diphtheria led them to believe that in some cases the defects might be permanent.

Hoskin[2] has described a smaller series of cases convalescent after diphtheria in which electrocardiographic records were also obtained. The abnormalities noted were: (*a*) increased heart-rate; (*b*) symptoms of cardiac insufficiency in half the cases and diminished cardiac reserve; (*c*) presence of heart abnormalities in almost every case on physical examination; and (*d*) changes in the electrocardiogram, notably "slurring" of the Q R S complex.

Although there is general agreement that cardiac abnormalities may persist up to about a year after diphtheria, opinions vary as to the possibility of later after-effects from this disease. Duckett Jones and P. D. White[3] examined 100 patients who had suffered from diphtheria five to eight years previously, and their results are summarised in their own words as follows: "*No evidence of organic heart disease was found by history, physical examination, routine electrocardiogram or X ray (when needed). There were a number of patients showing functional systolic murmurs, sinus arrhythmia, third heart sounds, and two exhibiting premature beats.*" Furthermore, the authors cast some doubt upon the positive findings of previous workers on the grounds that their criteria of abnormality were probably unsound. Again, Sutherland[4] states definitely that after excluding rheumatism and other common ætiological factors there is nothing to support the suggestion that diphtheria has a lasting effect upon the heart. On the other hand, many experienced observers consider that diphtheria may be the ætiological factor responsible for heart disease appearing in later years. Rolleston[5] states that "*In view of the liability of the toxins of diphtheria to affect the myocardium it is probable that diphtheria may be responsible for many cases of permanent cardiac weakness in patients who recover. The writer (Rolleston) has often met with examples of cardiac insufficiency in adults who dated their symptoms from an attack of diphtheria many years ago.*" Recently, Butler and Levine[6] published some interesting observations on the ætiology of heart-block, showing that in a group of 20 cases of heart-block more than half gave a history of diphtheria previously—i.e., and incidence three times as great as in a large group of control cases.

While the frequency of post-diphtheritic heart complications is a matter of controversy, there can be no doubt that proved cases do occur occasionally. Parkinson[7] described the "first undoubted case" of auricular fibrillation supervening upon heart-block due to diphtheria. A case of permanent bradycardia has been recorded by W. D. Reid.[8] Auricular flutter as a complication five weeks after diphtheria has been reported by O'Donovan.[9] Jones and White[3] mention a case of high-grade heart-block which developed on the third day of diphtheria and became permanent, and it was this case that prompted these workers to undertake the investigations to which reference has been made above. The cases which are described in what follows were examined for much the same reason—namely, the appearance of two patients who had sustained permanent damage to their hearts owing to diphtheria; these cases have been described elsewhere.[10]

THE PRESENT INQUIRY

Nearly two hundred patients were interviewed and a history obtained from each one with particular reference to the following facts: (1) Age. (2) Date when diphtheria was contracted. (3) Previous illnesses (especially for such common ætiological factors as rheumatism and chorea). (4) Any cardiac symptoms or change in general health since diphtheria. A routine examination of the heart, arteries, and pulse was then made, and an electrocardiogram was obtained, using a Cambridge Instrument Company electrocardiograph fitted with immersion electrodes. Sphygmomanometer readings were not taken, as the psychical disturbance usually present on making a

this manner, and the corpuscles in the mesentery examined.

A very striking feature became evident immediately, that the Pacinian corpuscle possessed two sources of blood-supply. The first consisted in a vascular plexus surrounding the external aspect of the capsule. This was present in every case, and in the majority a series of vascular loops or bands could be discerned encircling the body of the corpuscle transversely to its long axis (see Figure). In addition, each Pacinian body received a central vessel. This ran into the corpuscle with the main afferent nerve, often as far as the central core, but contrary to most descriptions it always appeared to form vascular loops (more often single) and twist backwards to emerge from the corpuscle at the same pole. Frequently a second, but usually smaller, vascular loop could be seen penetrating the opposite pole, but in no case, no matter how thin the injection mass, could any connexion be established through the corpuscle between the two vascular loops. This was the case when the injection had distended even the finest capillaries visible under the microscope. Not every corpuscle possessed a vascular loop at each pole. These two sources of blood-supply, the capsular and central, occasionally arose together off the same vessel, but more frequently issued from quite different arterial branches. From these findings it became evident that there must be some definite association, some interrelation between the blood vascular system and these sensory nerve-endings, for it cannot be supposed that these small bodies would require such an extensive blood-supply purely for their own nutrition.

THEIR FUNCTION

The evidence before us in regard to the function of the Vater-Pacinian corpuscles can therefore be briefly summarised as follows:—

1. The histological structure of these encapsulated nerve-endings and their intimate relationship, at least in the mesentery, with the sympathetic nervous system.
2. The wide distribution of these corpuscles throughout the body.
3. Their complex vascular supply, apparently far in excess of their own nutritional requirements.
4. The results of the critical experiments of Adrian and Ulmrath, an immediate discharge of impulses being recorded when joint movement or pressure stimuli were applied directly to an isolated group of Pacinian corpuscles.

It is difficult from our present knowledge to come to any final conclusion as to the function of these bodies. The theory that the impulses originating in Pacinian corpuscles may cause reflex contraction and dilatation of blood-vessels still leaves unanswered the question of the nature of the adequate stimulus required to give rise to an impulse in the Pacinian body. The explanation is probably to be found in the results of Adrian and Ulmrath's work, pressure at once suggesting itself as the most probable factor. By some such interpretation is it possible to correlate the two prevailing views as to the function of these end-organs?

But such an explanation does not quite answer all the aspects of the problem. Pressure cannot account for the stimulation of corpuscles buried deeply in the tissues and lying in the posterior abdominal wall. Tension on the root of the mesentery is the most obvious cause here, stimulation of the afferent fibres of the splanchnic nerves being caused presumably through the nerve-endings in the Pacinian bodies. Extending this view to the corpuscles situated elsewhere in the body, it is interesting to note that they have been found, in addition to the root of the mesentery, on the peritoneum covering the bladder, on the pudic nerves in the penis and clitoris, on the nerve-fibres around the nipple, in tendons and ligaments, and in relation to joints, all situations where pulling or stretching (both resulting in tension) play an important part. It is difficult to dissociate the two methods of stimulation, pressure and traction, and von Frey and Kriessow (quoted by Greenwood) have found that the sensation experienced in pulling and pushing appeared to be identical, provided the magnitude of the pull in one case was equal to that of the push in the other; that is to say, the end-organ is excited by a change in the existing pressure relations whether the change be positive or negative, increase or decrease.

Secondly, it is a possibility that the change in blood pressure may in some cases be the *cause* and not the result of impulses arising in Pacinian bodies. Sherrington, in 1900, showed that a condition of the blood or lymph could be easily conceived to not only affect the nerve-centres centrally, but also by peripheral changes to excite sensory nerve-endings. A deficiency of lymph might certainly induce a relaxation of the structures to which afferent nerve-fibres are related—e.g., capsules of Pacini. This interpretation would give us some explanation for the "sinking feeling" and vague sensation, bordering on pain, and obviously sympathetic in origin, which accompany all conditions of shock, a period of profound capillary dilatation. It would also explain the conscious awareness that we experience during over-activity of any gland. Luciani points this out clearly. He says:

> "Normally we have no clear and distinct consciousness of the functions of the internal organs and tissues, but we have a dull and obscure knowledge—i.e., an incessant awareness of our body termed 'the fundamental sense of existence.' In the state of perfect health this remains below the threshold of consciousness, and is prevented from becoming a distinct sensation with specific localisation. But when it reaches a certain intensity it is perceived as a vague sense of general well-being or the reverse. These are transmitted by the afferent nerves of the sympathetic system."

Finally, what is the meaning of the complex-lamellated capsule? The finding of a nerve-fibre running straight through a corpuscle without termination, seems to give us a possible explanation. The lamellæ of the capsule can be seen in any section to be continuous with the neurilemmal sheath of the issuing nerve; the entire capsule can thus be looked upon as an enlargement of the neurilemma to act no doubt as a "shock absorber." In most cases this is arranged around the delicate nerve-ending, but in certain cases, in order possibly to ensure against slight stimuli, causing profound changes in arterial pressure and blood volume, a double "shock absorber" is included in the circuit, and the nerve-fibre can be seen traversing two adjacent corpuscles before terminating.

It is impossible at this stage to come to any more definite opinion as to the function of the Vater-Pacinian corpuscles. It appears from a study of the structure and distribution of these bodies that their function is in some reflex manner related to the contraction and dilatation of blood-vessels, and that the adequate stimulus for the nerve-ending is pressure or traction. It is hoped that further light will be thrown on the problem in the near future.

My sincere thanks are due to Prof. J. S. B. Stopford, under whose direction this work has been done; and to Prof. E. D. Telford and Prof. Stopford for permission to use the amputated limbs mentioned above.

(*Continued at foot of opposite page*)

cases and the control cases with regard to this characteristic.

CONCLUSIONS

From this comparison of 150 cases having a history of diphtheria with 100 cases having no history of the disease, it is at once evident that there is nothing to suggest the occurrence of gross cardiac lesions as the result of a previous attack of diphtheria. Age-grouping was therefore considered unnecessary, and although the number of cases in the two groups was unequal the average ages were used. The difference of two years between the average ages is mainly accounted for by a small group of young adults who were examined as "post-diphtheritic heart" cases.

—	Diphtheria (150 cases).	Controls (100 cases).
Average age	14 years.	12 years.
Cases excluded for other ætiological factors	4	0
Clinical evidence of valvular incompetence	5	1
P–R interval of 0·2 sec. or over ..	4	2
Intraventricular block	0	0
Splintering of R in leads I. or II. ..	9	13
Negative or iso-electric T waves in lead III.	90	30
Bizarre Q R S in lead III... ..	42	39
Ventricular preponderance	8	11

In a study of the electrocardiogram during the acute phase of diphtheria[11] it was often found that the T wave in lead III. varied considerably during the course of the disease, and a patient might apparently recover clinically and functionally before the T wave in lead III. of the electrocardiogram became positive. This observation was made on an independent group of cases, but in view of the findings in the present series the question is raised as to how long such T wave changes might persist after diphtheria. It is widely accepted, however, that inversion of the T wave in lead III. is of no pathological significance, and whatever may be the cause of an increased frequency of this feature in persons who have had diphtheria, there can be no doubt that there is no coexistent clinical abnormality.

I am indebted to Dr. Claude Rundle, the medical superintendent of Liverpool City Hospitals for Infectious Diseases, for allowing free access to all the hospital registers and case-records for the past ten years. Dr. E. Noble Chamberlain, senior honorary assistant physician at the Royal Southern Hospital, Liverpool, kindly gave assistance in reporting on the electrocardiographic records, and the X ray department of the hospital carried out the photographic work for this part of the investigations. For help in the statistical analysis of the records I am grateful to Mr. John H. Smith, assistant lecturer in the mathematics department of the University of Glasgow.

Clinical and Laboratory Notes

OBSERVATIONS ON THE CHEMISTRY OF THE LIQUOR AMNII *

By J. F. D. SHREWSBURY, M.B. LIVERP., D.P.H.
BACTERIOLOGIST TO THE QUEEN'S HOSPITAL, BIRMINGHAM

THE following short series of chemical examinations of the liquor amnii was carried out in collaboration with Mr. W. E. Barnie Adshead, hon. assistant obstetrical officer to the Queen's Hospital, Birmingham.

Except in one fatal case of pneumonia, in which the liquor amnii was obtained from the gravid uterus at autopsy, a subtotal hysterectomy was performed on each of the patients in this series, and the liquor amnii was withdrawn from the intact uterus as soon as possible after the removal of that organ from the body. Each uterus was sent directly from the operating theatre to the laboratory, where I withdrew as much of the fluid as I could obtain by aspiration with a sterile needle and syringe, after searing the surface of the organ. The chemical examinations were made upon the fluid very shortly after its removal.

The papers that I have been able to consult do not contain much detailed information about the chemical composition of the normal liquor amnii, and I have not found any reference to the chemistry of the fluid in the presence of maternal disease.

De Lee[1] gives the reaction of the liquor amnii as faintly alkaline or neutral, and the freezing-point as slightly higher than that of the maternal blood. Sandmeyer found 0·22 per cent. of albumin present, comprising serum-albumin, globulin, and an ovo-vitelline-like substance. The salts of the liquor amnii are present in about the same proportions as the salts in the blood-serum—i.e., 0·5 per cent. They are the chlorides, phosphates, sulphates, and carbonates of sodium and calcium, with very little potassium. The urea content ranges from 0·02 to 0·4 per cent., and increases towards the end of pregnancy.

Fairbairn[2] states that the normal liquor amnii is a slightly turbid, straw-coloured fluid, with a specific gravity of 1002 to 1020, and a faintly alkaline reaction. It contains a variable amount of albumin (6 to 8 parts per 1000, Esbach); urea (usually in very small quantity), creatin, and salts. Sugar is said to be present in the liquor amnii of diabetic mothers.

Eden[3] gives the following details: a clear, pale fluid of low specific gravity; albumin, 0·19 per cent.; inorganic salts, 0·59 per cent.; extractives, 0·81 per cent. The amount of albumin may reach 10 per cent. in the early months of pregnancy. The most important extractive is urea, which is present in traces from the sixth week onwards. Glucose may be found in cases of maternal diabetes.

In the accompanying Table all the figures for the various chemical estimations represent mg. per cent. The method of estimation is included in the Table, because different methods of estimation may yield different values when performed in parallel by the same worker. It is therefore necessary to state the method of estimation used in any series of biochemical investigations in order to make the work of value for comparative purposes.

The reaction and the specific gravity of the fluids examined conform to the accepted values for the normal liquor amnii. In seven out of the eight fluids tested glucose was present in estimable quantity, and in one fluid the sugar content lay within the normal range of the blood-sugar. It is not possible to express an opinion upon the relationship of this comparatively high sugar content in the liquor amnii to the clinical condition, especially in the absence of a coincident blood-sugar estimation, but the finding

---

* From the Biochemical Laboratory of the Queen's Hospital, Birmingham.

single examination in a child was considered sufficient to render such readings valueless.

A considerable number of cases were excluded because of (1) a history of recent febrile illness—e.g., common cold or tonsillitis, (2) rheumatism or chorea, or (3) doubtful evidence of diphtheria on reference to the notes of the patient when in the isolation hospital. Thus the number of cases was reduced to about 150. These "patients" had had diphtheria from one to ten years before the time of re-examination, and though the majority of them were children and young people, a few adults were also included.

The following electrocardiographic information was obtained in each case to supplement the clinical data mentioned above: (1) P–R interval. (2) Q R S interval. (3) R–T interval. (4) Ventricular preponderance. (5) Splitting of the R wave in leads I. or II. (6) Progressive flattening of the T wave from lead I. to lead III. (7) Negative or iso-electric T wave in lead III. (8) Abnormality of the P wave in any lead. (9) Bizarre Q R S in lead III. (10) Large T waves in leads I. or II.

OBSERVATIONS ON THE DATA

1. As already stated above, the great majority of the patients were children, the average age being 14 years.

2. Rheumatism and chorea were the only ætiological factors taken into consideration. Ten of the patients gave some kind of history of these diseases, but only four were considered to be definite enough to be excluded on these grounds.

3. A history of cardiac abnormalities during the acute stage of diphtheria was remarkably rare, but allowance must be made for the fact that only the patients who survived the disease were examined, and many cases in which there had been a greater possibility of permanent cardiac damage find no place in the series. There were 21 cases (14 per cent.) which had a history of clinical abnormalities in the heart during diphtheria. On analysis it was found that only two of these had any symptoms or signs of a cardiac lesion on re-examination. Three of the cases showed splitting of the R wave in leads other than lead III., and two were characterised by irregularity of the P wave. All the measurements were within normal limits, and the P–R interval was always well under 0·2 sec. Vagaries of the T wave and the Q R S complex in lead III. were frequent, and further reference will be made to this below.

4. The following patients, eight in number, presented signs or symptoms suggestive of cardiac abnormality:—

No. 9.—Heart not enlarged. Heart sounds normal except for duplication of the second pulmonary sound. Mitral systolic bruit conducted towards the axilla; basal systolic bruit not conducted.

No. 29.—Heart not enlarged. Sounds normal; aortic second sound duplicated. Soft, blowing, mitral systolic bruit conducted towards the axilla.

No. 31.—Doubtful case; no abnormality except a localised aortic systolic bruit.

No. 35.—Heart normal in size. Heart sounds normal. Mitral systolic bruit conducted appreciably towards the axilla.

No. 62.—Size of heart and character of the sounds normal. Mitral systolic bruit conducted about 2 inches towards the axilla; basal systolic bruit not conducted to the neck.

No. 71.—Heart sounds and size of heart normal. Mitral systolic bruit conducted about 3 inches towards the axilla.

No. 90.—Heart rather large for a boy of 12 years, but possibly within normal limits. Excessive cardiac thrust and faint systolic thrill palpable. First mitral sound accentuated; a mitral systolic bruit present, but not conducted appreciably towards the axilla.

No. 141.—No abnormality, but extrasystoles and a mitral systolic murmur not conducted to the axilla.

Omitting Cases 31 and 141, where the cardiac abnormality was of doubtful importance, it was found on referring to the detailed analysis that in none of these cases was there a history of rheumatism or other ætiological factors, and in only one case (No. 62) was any cardiac abnormality mentioned during diphtheria. The evidence points, then, to a greater or lesser degree of mitral incompetence in five cases—i.e., 3·3 per cent. of the series. The electrocardiograms were for the most part normal, except that Cases 9 and 141 showed a split R wave in significant leads. If mitral incompetence was present in this group of five cases it was evidently fully compensated in each case, for no history of cardiac insufficiency was obtained in any of them, and with the exception of one case there was no appreciable enlargement of the heart.

5. The P–R interval was remarkably constant. A detailed analysis showed that the vast majority of the cases had a P–R interval of about 0·14 sec. If 0·2 sec. be taken arbitrarily as the maximum normal reading for this interval, it can be said that the series does not show an example of delayed conduction, four cases reaching this limit of normality—Cases 17, 35, 61, and 140; the heart-rate in these cases was 80, 65, 120, and 95 beats per minute respectively. The minimum P–R interval was in Case 77 and measured 0·06 sec. when the heart-rate was 90 per minute, and a similar case was No. 38, with a P–R interval of 0·08 sec., the heart-rate being 100 per minute.

6. The character of the Q R S complex in this series showed the complete absence of any evidence of intraventricular block, though it is reasonably certain that this phenomenon was present in a considerable proportion of the cases during the acute stage of the disease. The average duration of this interval was about 0·05 sec., though the limits were 0·03 sec. in one case (No. 77), with a rate of 90 per minute, and a maximum reading of 0·08 sec., which was found in Case 19, with a heart-rate of 78 per minute.

7. The R–T interval was more variable than were the other measurements given above. The reading was in the region of 0·3 sec. for the majority of the cases. There was, however, a considerable difference in the limits; the minimum (Case 77) being 0·14 sec. and the maximum (Case 154) was 0·4 sec. Thus the R–T interval was found to be within normal limits, though in two cases in which the interval amounted to 0·4 sec. the arbitrary maximum for the normal duration of this phase was reached.

The remaining characteristics contained in the detailed analysis are usually regarded as variations within normal limits, but they have been tabulated for comparison with a series in which neither diphtheria nor any other ætiological factor could be elicited in the histories. (See Table.)

Applying the χ^2 test for independence it can be shown that the differences between the numbers is attributable to chance factors except in regard to the negative or iso-electric T wave in lead III. In this case the probability of the results arising due to chance is considerably less than 1 in 100, which for this form of analysis indicates definitely a significant difference between the two figures. As the number of cases where the phenomenon is shown is adequate, this indicates a real difference between the diphtheria

On examination the left knee seemed to be very swollen and tender with limitation of movement in all directions. Temperature 101° F., pulse-rate 120, respirations 30. Hot fomentations were applied every four hours to the knee. A skiagram showed no bony changes of the knee-joint. On Sept. 7th an incision was made over the swelling, which proved to be a suppurative bursitis, and pus was evacuated and a drain inserted. By the 22nd the wound was healed.

On Oct. 4th she was *readmitted* with very severe pain in the left knee and was unable to extend it; since her discharge she was said to have been jaundiced several times. On examination the left knee seemed to be swollen, and was warmer than the other knee, and limitation of movements, especially those of flexion and extension, was marked. A skiagram showed mottled rarefaction of the patella with ? periosteal reaction. The pain disappeared in a few hours. Temperature 101° F., pulse-rate 120, respirations 30. On Oct. 11th an incision was made down to the periosteum, which was retracted, and three holes were drilled in the upper part of the patella, which was soft and necrotic in parts. During this procedure fluid was seen to exude from the joint. The wound was packed with paraffin and flavine gauze. Bacteriological examination revealed a growth of *Staphylococcus albus* on culture. On Nov. 4th the child knocked her knee and profuse hæmorrhage occurred from the wound, which had practically healed. By the 12th the local condition had cleared up completely, without any stiffness of the joint. A skiagram showed some sclerosis of bone in the patella.

The chief features of interest in this case seem to be: (1) There was no history of previous exanthemata or injury. (2) The condition started as a suppurative bursitis, which apparently cleared up but either predisposed to succeeding infection or some of the causative bacteria remained in a quiescent state and later came into a state of activity. (3) Since the operation there has been no indication of involvement of the knee-joint, although *Staphylococcus albus* was obtained from the swab which was taken from the knee-joint.

I have to thank Mr. W. E. Tucker for permission to publish this report.

AN UNUSUAL JARISCH-HERXHEIMER REACTION

ACUTE SPINAL THROMBOSIS OCCURRING DURING THE TREATMENT OF PRIMARY SYPHILIS WITH NOVARSENOBILLON

By W. H. Hargreaves, M.R.C.S. Eng.
LATE HOUSE PHYSICIAN, METROPOLITAN HOSPITAL, LONDON

A SURVEY of the recorded examples of the Jarisch-Herxheimer reaction has failed to reveal a case similar to the following.

A male patient, aged 30, unmarried, attended the special department at the Metropolitan Hospital on Nov. 27th, 1931, on account of a sore on the penis for three weeks. There was a history of risk of infection 12 weeks previously in the West Indies. A meatal chancre and enlarged glands in both inguinal regions were found. Spirochætes were demonstrated by Dr. H. C. Lucey in serous discharge from the chancre. The Wassermann reaction of the blood was negative.

At his first attendance novarsenobillon (0·45 g.) was given intravenously, and bismuth cream (2 c.cm.) intramuscularly without ill-effects. One week later these doses were repeated, and on waking the next morning the patient noticed weakness in both legs, and during the day developed difficulty in starting micturition. Both these symptoms rapidly increased in severity and within 24 hours the patient was unable to move his legs, and there was a constant dribble of urine. Four days after the onset of the symptoms (Dec. 11th) he was brought up to the hospital and admitted under the care of Dr. C. Worster-Drought.

On admission there were signs of a transverse lesion of the spinal cord at the level of the fourth thoracic segment. Both rectus abdominis muscles were completely paralysed, the bladder was distended up to the level of the umbilicus, there was retention-overflow of urine, and incontinence of fæces. The lower limbs were completely paralysed, the knee-jerks were just present on the right side and absent on the left side. The plantar responses were extensor on both sides. There was loss to pain, thermal, and light-tactile sensibility below the level of the fourth dorsal segment, above which no abnormal physical signs were detected.

Lumbar puncture was performed. The cerebrospinal fluid was clear and under reduced pressure. Dr. Lucey reported as follows:—"Appearance: clear, colourless, contains no coagulum. Cells: 1 per c.mm. Total protein: 18 mg. per 100 c.cm. Wassermann reaction: negative."

A diagnosis was made of acute specific spinal thrombosis precipitated by the administration of novarsenobillon. It was decided to continue the course of novarsenobillon up to a total dose of 4·5 g., in addition to which potassium iodide grs. 50 was given three times daily by mouth, and collosol mercury 5 c.cm. intramuscularly at weekly intervals.

Recovery ensued as follows:—

Two weeks after admission the level of sensory loss began to be slightly lower. There was some return of tone in the recti muscles. Daily massage to the lower limbs was instituted. Three weeks after admission the sensory level was at the first lumbar segment. For the first four weeks the bladder had to be drained by a catheter. The urine became heavily infected, and this was cleared by the administration of neotropine grs. 3 three times daily by mouth.

Four weeks after admission the recti muscles were normal, the abdominal reflexes were present, and urine was passed naturally after some difficulty in starting. There was slight return of power in the legs, which were markedly spastic, the knee-jerks being very brisk, the ankle-jerks present, and the plantar responses still extensor.

Five weeks after admission micturition and defæcation were almost normal. The muscular power of the legs was rapidly returning. The knee- and ankle-jerks were all exaggerated; the plantar responses were extensor, and bilateral sustained ankle-clonus was present. The sensory loss was now down to the level of the fourth lumbar segment.

After six weeks in bed the patient was allowed to get up, the legs being very stiff at first, but walking gradually improved up to the end of the twelfth week after admission, when he was discharged.

Lumbar puncture was repeated before his discharge, and the Wassermann reaction of the cerebro-spinal fluid was again found to be negative. The blood Wassermann reaction was also negative. On discharge (March 2nd, 1932) the patient walked with the aid of a stick with a lightly spastic gait. The knee- and ankle-jerks were all brisk, the plantar responses extensor, and ankle-clonus was present on the right side. There was slight sensory loss to pain at the first sacral segment.

Treatment with potassium iodide (grs. 50 t.d.s.) was continued, and, on examination four months after discharge, the patient was walking well without a stick. There was very slight weakness and spasticity of the right leg. The knee- and ankle-jerks were still exaggerated, more on the right side, but the plantar responses were flexor, with no ankle-clonus. There was no sensory loss. Slight hesitancy of micturition was still present.

The Jarisch-Herxheimer reaction has been attributed either to the effect of endotoxins liberated from spirochætes destroyed by a specific spirillicidal agent, or to stimulation of the spirochætes by an inadequate dose of the drug. In several cases the reaction has been observed in the cranial nerves, the optic, facial, and auditory nerves being affected. Wechselmann[1] has described a case in which facial paresis occurred two hours after an injection of salvarsan. No case of acute spinal thrombosis or of acute transverse myelitis occurring as a Jarisch-Herxheimer reaction appears to have been recorded.

My grateful acknowledgments are due to Dr. Worster-Drought for permission to publish this case, and to Dr. Lucey, who performed the pathological investigations.

* All fluids gave a negative reaction.

is of interest in comparison with the low readings obtained on the remaining fluids in the series. Urea was present in estimable quantity in all the fluids. The single high reading of 73 mg. per cent. is not comparable with the other readings, because this fluid was obtained at autopsy several hours after the death of the patient, when some degree of decomposition had undoubtedly occurred. The high uric acid reading of 5·7 mg. per cent. is of interest, though its significance is not understood. The relatively constant values obtained for the creatinine content of the liquor amnii, even in the presence of maternal renal disease, are of much interest in connexion with the known stability of this substance in the blood and the urine. The chloride content does not vary much from the normal content of the blood, and seems to be, like the creatinine, one of the relatively stable chemical constituents of the liquor amnii. The absence of cholesterol is of interest in view of the known importance of this substance to the body, and the precautions taken by the body to conserve its supplies. Whatever may be the value of the liquor amnii to the fœtus—and conflicting opinions are held—it is certain that the fluid is a waste product to the mother, and the absence of cholesterol in the fluid may possibly be associated with this fact. The calcium readings are fairly constant at a slightly lower level than the readings for the normal serum calcium, but it must be remembered that the fœtus is a drain upon the maternal stores of calcium and that, in consequence, the serum calcium tends to fall towards the end of pregnancy, so that the readings obtained on this series of fluids are possibly only very slightly lower than the readings of the maternal serum calcium. The high phosphorus reading of 8 mg. per cent. was obtained on a fluid removed at autopsy, and cannot be compared with the other readings in the series. The total protein content shows much variation, and the variations are difficult to explain, especially the low reading of 50 mg. per cent. in the second case of maternal phthisis.

This short series of chemical examinations suffers from two serious disadvantages: (1) the absence of coincident blood chemical analyses, and (2) the absence of any normal standards for the chemical constituents of the liquor amnii. It is not possible to rectify the second defect in a general hospital that does not cater for normal cases of labour, but it should not prove difficult to obtain an accurate knowledge of the chemical composition of the normal liquor amnii from the material available in one of the large maternity hospitals, and the above series of observations has been published chiefly in the hope that it will stimulate the prosecution of this useful work.

In conclusion I wish to express my thanks to my colleague, Mr. Adshead, for his generous collaboration, and to acknowledge my indebtedness to my technical assistant, W. R. Hackett, who has carried out most of the estimations under my supervision.

OSTEOMYELITIS OF THE PATELLA

By Richard A. Manclark, M.R.C.S. Eng.
HOUSE SURGEON, ST. JOHN'S HOSPITAL, LEWISHAM, S.E.

A girl, 7 years of age, was admitted to St. John's Hospital, Lewisham, on Sept. 3rd, 1932, with a swollen left knee, which had been painful for four days. There was no history of injury. Apparently the child had not seemed well for the last five weeks—she had "just sat about and did not want to play at all."

the fact that it involved a laboratory test the sign was omitted as not being of clinical interest in most urgent cases.

(4) *Deep tenderness in the left costo-muscular angle.*

Mr. Wells was convinced that this last sign was of great value in arriving at a diagnosis. Its presence was no doubt explicable on the assumption that the pressure was transmitted to the tail of the pancreas. He had so far failed to find any specific reference to this sign, except in one American text-book (Homans's), which said: "more especially is tenderness in the left costo-vertebral angle, due to inflammation of the tail of the pancreas, of great diagnostic significance."

In the discussion which followed, the PRESIDENT said he had hitherto regarded acute pancreatitis as undiagnosable; certainly surgical treatment had usually to precede diagnosis. In the few cases he had seen the symptoms and physical signs were so alarming that an urgent laparotomy was obviously indicated, and only during its performance was the diagnosis made. In his last case, a man of 51 was in perfect health until one hour after an unusually hearty meal of curried veal, when violent pain began in the upper abdomen. This was unrelieved by morphia, and 20 hours after its onset operation disclosed an acutely inflamed pancreas and the usual fat necrosis. The man recovered rapidly.

Dr. I. HARRIS read a paper on a Method of Measuring the Force required to Compress an Artery, and Mr. BRYAN MCFARLAND a paper on the Treatment of Congenital Club-foot.

REVIEWS AND NOTICES OF BOOKS

Diseases of the Eye

Practitioners Series. By ANDREW RUGG-GUNN, M.B. Edin., F.R.C.S. Eng., Surgeon to the Western Ophthalmic Hospital. London: William Heinemann (Medical Books), Ltd. 1933. Pp. 188. 12s. 6*d*.

FOR the general practitioner who does not profess to specialise on the eye there is already a choice of text-books, but this is certainly one of the most practical and useful yet produced. No attempt is made to deal with those parts of the subject which are more properly left to the specialist—that is, all operative procedures, refined diagnosis of fundus conditions, and the optical diagnosis and treatment of errors of refraction. All the more common types of ocular disease, however, are efficiently dealt with, and we would specially commend the detail with which the treatment of comparatively trivial diseases such as the more common inflammations of the conjunctiva and eyelids is discussed.

The lesions of the eye are described always in such a way as to emphasise their association with disease elsewhere. Interstitial keratitis, for instance, has long been known to be a manifestation of congenital syphilis, but the fact that most cases tend to get well without specific treatment has had the result that in the past many ophthalmic surgeons have not considered it necessary to employ it. Mr. Rugg-Gunn takes the contrary view, which has been expressed even more strongly by Mr. Lindsay Rea, a colleague of his at the Western Ophthalmic Hospital. Some remarks on various methods for the medical treatment of cataract, none of which is recommended, may be found useful by the practitioner who has to deal with patients anxious to know if any non-operative treatment is likely to be effective. In dealing with primary glaucoma Mr. Rugg-Gunn mentions the two conflicting views of its pathology which are now held without supporting either. The commoner diseases of the fundus are well described and some of them pictured. Concerning detachment of the retina, a condition which it is important for the practitioner to be able to recognise, information concerning the encouraging results of modern methods of operative treatment is up to date, although it is fairly certain to need elaboration before the next edition of the book is published. The differential diagnosis between paralytic and concomitant strabismus comes within the scope of the general practitioner; this book will help him to make it. The importance of recognising true squint in children at the earliest possible time is perhaps hardly sufficiently emphasised here. The figures, so far as they go, are useful; one of them pictures a useful form of bandage not generally known, and there are eight excellent plates. Two of them are noteworthy: one shows a photograph of the ciliary processes and zonule of Zinn taken from behind, and another shows the radiogram of an injected mucocele on one side and an injected normal lacrymal sac and nasal duct on the other.

The practitioner will find this book really helpful.

Les sequelles de l'encéphalite épidémique

By GEORGES GUILLAIN and PIERRE MOLLARET (La Pratique Médicale illustrée). Paris: G. Doin et Cie. 1932. Pp. 106. Fr.28.

WHEN encephalitis lethargica was first recognised in its acute form (1917–18), certain manifestations, such as an alteration in the mental condition, residual cranial nerve palsies, athetoid movements, and paresis were observed in a limited number of patients who in other respects had recovered from their attacks of illness, and the original investigators expressed concern about the possible risks of after-effects in the disease. We know now that this concern was fully justified. As early as 1921 the subject of post-encephalitic paralysis agitans (Parkinsonism) was brought forward by Prof. Netter at the Congress of the Société de Neurologie de Paris. In 1922 the Ministry of Health Report on Encephalitis Lethargica was able to furnish a lengthy list of sequelæ. Since then we have had comprehensive descriptions of the types and associated signs and symptoms of encephalitic after-effects from Gabrielle Lévy in France, from C. von Economo in Austria, and from A. C. Parsons in this country. There is, in addition, a large and increasing amount of literature on the subject dealing with individual groups of cases. The great frequency of the parkinsonian syndrome is a marked feature of continental reports. The manifestations of the after-effects of encephalitis lethargica may be grouped into (*a*) those appearing in the course of the original acute malady and persisting after partial or complete disappearance of all other symptoms, and (*b*) those which ensue after the original acute malady has apparently terminated or in some cases has passed unrecognised. Such effects are declared after a latent period of extreme variability ranging from some weeks to two years. In some reported cases the after-effects cleared temporarily, but reappeared some months later. No definite opinion, therefore, can be expressed until after the lapse of some years as to whether an attack of encephalitis, however mild in appearance, may or may not result in serious sequelæ. The general and merciful decline in new cases of encephalitis

MEDICAL SOCIETIES

MANCHESTER MEDICAL AND PATHOLOGICAL SOCIETIES

A JOINT meeting of these societies was held on Jan. 11th, with Prof. E. D. TELFORD in the chair. A paper on

Grades of Immunity

was read by Prof. W. W. C. TOPLEY (London). The term immunity, he said, does not define an entity, the characters of which we can describe with precision. It is a loose generic term that covers all grades of resistance beyond complete susceptibility up to that ideal, and perhaps hypothetical, condition in which a person is entirely indifferent to the attacks of a potentially pathogenic parasite. We can recognise several different grades of immunity, though we cannot separate them sharply from one another. In the case of an invasive parasite complete susceptibility is associated with an acute bacteræmic type of infection, almost uniformly fatal, with minimal local lesions. A low grade of partial immunity is associated with less frequent or less severe bacteræmic infections, more frequent and rather more extensive local lesions, and occasional cases of latent infection. With partial immunity of a moderate grade bacteræmic infections decrease still further in frequency and severity, and the local lesions dominate the clinical picture, while latent infections become more frequent. With partial immunity of a high grade bacteræmia is rare or absent, the local lesions are slight or minimal, and latent infections are the rule. As this grade passes into complete immunity latent infections become less and less frequent, until the parasite can no longer find any foothold in the host's tissues. The clinical syndrome displayed by many of our commoner infective diseases is an expression of partial immunity; and immunological methods of prevention and cure must be regarded, in most cases, as procedures that allow us to increase resistance from a lower to a higher grade, rather than to confer solid immunity on an initially completely susceptible host. Such minor changes in resistance may be of considerable value in the prevention or treatment of infective disease; but—because they are minor changes—their effect is difficult to measure, and there is a risk of persisting with a useless method, or of neglecting a valuable one. The assessment of any immunological method of prevention or cure demands close coöperation between the laboratory worker and the clinician or epidemiologist, and adequate data can seldom be obtained without a carefully planned group inquiry on an extensive scale. Preventive inoculation against typhoid fever, against the common cold, or against diphtheria, and the serum treatment of pneumonia or of poliomyelitis, afford instances in which we have obtained some measure of the actual effect in man. There are, however, very many cases in which we have as yet no knowledge of the real value of a possibly useful procedure, and it is very desirable that steps should be taken to remedy our ignorance, and so to place our practice on a firmer scientific basis.

At a meeting of the Pathological Society on Feb. 8th, Prof. S. L. BAKER discussed

Intrarenal Obstruction during the Excretion of Hæmoglobin

He said that the excretion of large quantities of hæmoglobin, as in blackwater fever, might produce severe renal damage. The renal lesion consisted in an obstruction of the tubules by granular material derived from hæmoglobin and precipitated in the tubules during the course of excretion. A similar obstruction might occur during the hæmoglobinuria that follows the transfusion of incompatible blood; in this case there was a rapid intravascular hæmolysis of the transfused corpuscles. Two such cases in which fatal renal obstruction followed the transfusion of incompatible blood were studied by S. L. Baker and E. C. Dodds (1925), and it was shown that death resulted from blockage of the intrarenal tubules by granular material derived from hæmoglobin. The factors determining this precipitation were (*a*) the hydrogen-ion concentration of the urine, (*b*) the salt content. If the patient were excreting an acid urine (pH 6 or less) with a salt content of 1 per cent. NaCl or over, such precipitation was likely to take place. This precipitate was hæmatin. A similar intrarenal precipitation could be produced in rabbits by the intravenous injection of hæmoglobin solutions if the animal's urine were rendered acid, as by cutting off the supply of green food. If the urine were alkaline the hæmoglobin was excreted unchanged, and no ill-effects on the kidney were produced.

In all conditions in which hæmoglobinuria occurred it was important to make the urine alkaline, and so avoid the possibility of intrarenal obstruction.

LIVERPOOL MEDICAL INSTITUTION

AT a meeting of this institution on Feb. 9th, with Dr. H. R. HURTER, the president, in the chair, a note on the

Diagnosis of Acute Pancreatitis

was read by Mr. C. A. WELLS. His object, he said, was to quarrel with the common belief that the diagnosis of this condition was almost impossible until after the abdomen had been opened, and also to draw attention to a sign which was not generally described. For descriptive purposes cases were divided into two classes: (*a*) the fulminating, in which Moynihan spoke of "profound collapse and unendurable agony"; and (*b*) the less fulminating, which at present seemed to be the commoner. Attention was chiefly directed to the second and larger group.

Mr. Wells believed that a pre-operative diagnosis could and should usually be made. The condition was suggested by the onset of pain, both in the upper abdomen and back, combined with the discovery on physical examination of a distinct upper abdominal localisation, possibly a sense of soft fullness and commonly incomplete rigidity. The diagnosis having been suggested by these findings could be confirmed by certain signs and tests:—

(1) *Loewi's sign.*—Most writers agreed that this was worth trying, but was not always positive in proved cases, whilst it might be positive in cases other than pancreatitis. The speaker's experience was that the sign was interesting but of small value.

(2) *Cyanosis.*—(*a*) A vague degree of cyanosis, associated with collapse and difficulty in breathing. (*b*) Patches of discoloration in almost any part of the body, generally agreed to be almost diagnostic but obviously very rare. (*c*) Grey Turner's sign of staining in the left flank, clearly a late manifestation of the disease.

(3) *Metabolic changes.*—The only reliable change in this group seemed to be the increase in diastase, and owing to

THE LANCET

LONDON: SATURDAY, FEBRUARY 25, 1933

WORKMEN'S COMPENSATION—ACCIDENT OR DISEASE?

Like the original statute of 1897, the present Workmen's Compensation Act of 1925 awards compensation for "personal injury by accident." But what does "accident" mean? The House of Lords a week or two ago, in Partridge Jones and John Paton Ltd. *v.* James, carried a little further the accepted extension of "accident" to the cases where the workman, as Lord Shaw once said, is carrying about with him a fatal disease. The husband of Mrs. James (the respondent) suffered from disease of the coronary arteries. His work consisted of drossing—i.e., dipping metal sheets in a pot of dross, taking the sheets out and finally cleaning the dross from the pot. He finished cleaning out the dross one day at 12.30 P.M., stepped from the staging, exclaimed "Oh! my chest," and died within ten minutes. The county court judge held that the disease of the arteries caused a failure of blood-supply resulting in angina pectoris; the physical exertion of performing the man's ordinary work accelerated death and caused death to occur when it did. He held that this was "personal injury by accident" and awarded compensation. The Court of Appeal and the House of Lords have upheld the award. The personal injury would not have happened but for the disease; nevertheless the combination of disease and employment made it a personal injury by accident.

In Clover Clayton & Co. *v.* Hughes (1910) Sir John Simon tried hard to persuade the judges that injury by disease cannot be injury by accident. The Act, he said, says injury by accident, not injury by the work which workmen are doing. He was dealing with the death of a workman who suffered from an aneurysm in such an advanced condition that it might have burst during sleep; very slight exertion or strain would have been sufficient to cause a rupture. The man was merely tightening a nut with a spanner; he had given a couple of turns only where half a dozen turns were required. It was an ordinary operation involving no special strain, but the aneurysm burst and he died. The House of Lords decided that it was an accident arising out of his employment; Lord Macnaghten explained why. An aneurysm, he said, is understood to be an unnatural or abnormal dilatation of an artery; still, it is part of the artery and so of the man's body. The man "broke part of his body," as Lord Robertson said once (in Brintons *v.* Turvey), and he certainly did not mean to do it.

> "The fact that the man's condition predisposed him to such an accident seems to me to be immaterial; the work was ordinary work but it was too heavy for him. . . . The fact that the result would have been contemplated as a certainty by a medical man of ordinary skill if he had diagnosed the case is, I think, nothing to the purpose."

The judges interpreted accident in the popular sense of the word. We meet with an accident if we miscalculate our powers. Lord Atkinson took a contrary view, but Lord Macnaghten's view prevailed. Even if judges feel that a series of decisions has pushed the law into a position which Parliament never dreamt of when the original Workmen's Compensation Act was passed, the House of Lords had settled the position and it was bound recently to follow its own ruling.

There was once much judicial uncertainty in the matter—partly because the higher courts felt themselves bound by the findings of fact and these findings varied greatly. A generation ago the judges had to deal with several claims for compensation by workmen injured in the course of ordinary work. It was no use to argue that accident must connote some outward injury, for on this basis the seaman who fainted in the rigging and fell into the sea might fail to obtain compensation. It was equally useless to contend that accident must be something caused by an untoward external event like the bursting of a boiler or the misbehaviour of a machine: a workman's hand can be crushed between two wheels when the machinery is working perfectly. In Hensey *v.* White (1900) a workman, physically unsound, had strained himself in turning the wheel of his machine. The arbitrator held it was not an accident and the Court of Appeal agreed. In Roper *v.* Greenwood (1900) a woman, suffering from prolapsus uteri, strained herself in carrying heavy boxes in the course of her work: this again was held not to be personal injury caused by accident. But in the same year in Timmins *v.* Leeds Forge Co. a workman, who strained himself in trying to lift planks which were frozen together, was held to have been injured by accident. Two years later in Boardman *v.* Scott a man had been carrying a heavy beam and, in jerking it to get it level on his shoulder, he lacerated the muscles of his back: this was deemed accident. Finally in 1903 in Fenton *v.* Morley, where a workman had ruptured himself in doing his ordinary work of turning a wheel, the House of Lords unanimously held it was personal injury by accident. This decision overruled Hensey *v.* White (where the facts had been almost identical) and many other cases. The judges definitely state that the employers must pay compensation for internal injuries occurring in the course of a workman's employment no matter what the state of his health. Thus the cases where a man "carries about with him a fatal disease" become a serious industrial problem. If a more frequent and systematic examination of the workman's physical condition will help to solve the problem, how are we to set about it?

◆

ALLERGY IN RHEUMATISM AND GOUT

After histological study of rheumatic nodules and joint lesions and gouty tophi, M. P. Weil and J. Delarue[1] have come to the conclusion that lethargica has caused attention to be even more intently focused on the character of the sequelæ which concern the different domains of neurology, psychiatry, general pathology, and legal medicine.

---

[1] Presse Méd., 1932, xli., 1969.

This monograph reviews and assembles in succinct form the protean manifestations of the disease and provides a useful introduction to more intensive study of the subject.

Protoplasmic Action and Nervous Action

Second edition. By RALPH S. LILLIE, Professor of Physiology, University of Chicago. The University of Chicago Press. 1932. Pp. 417. *16s. 6d.*

Prof. Lillie is well known as a worker in general physiology, using that term in its most modern sense. The field covered by this work is very wide, and contains expressions of personal opinions and interpretations which would not be universally accepted. The 15 chapters in the book deal with the consideration of physiology from a purely cellular point of view. Chapter IV. is perhaps the most interesting since it deals with protoplasm as a physical system. A wider discussion of catalysis in living matter, and a separate chapter devoted to the energetic considerations of living matter would have been useful. The general question of oxidation and reduction by living tissue is hardly dealt with at all.

It is, however, somewhat presumptuous to suggest what should or should not be included in a monograph, for, while a text-book must conform to pattern, the author of a monograph may surely limit its scope at his pleasure. Prof. Lillie has given us an ably written and stimulating collection of essays.

A Manual of Bacteriology, Medical and Applied

Ninth edition. Revised by R. T. HEWLETT, M.D., F.R.C.P., D.P.H. Lond., Emeritus Professor of Bacteriology in the University of London; Director of Pathology, Seamen's Hospital, Greenwich; and JAMES MCINTOSH, M.D., B.Ch., Professor of Pathology, University of London; Director of the Bland-Sutton Institute of Pathology, Middlesex Hospital. London: J. and A. Churchill. 1932. Pp. 746. *18s.*

IN the production of this edition of his classic text-book, which first appeared in 1898, Prof. Hewlett has had the collaboration of Prof. James McIntosh. The invigorating effect of this infusion of new blood is noticeable in a book which has always been characterised by its wide scope and the well-balanced presentation of the subject. The work has been completely recast in somewhat larger type, so that the addition of a further 100 pages does not represent its bulk of new matter. All the sections have been carefully overhauled and some of them rewritten, notably those on undulant fever, diphtheria, spirochætal diseases, and the virus diseases and bacteriophagy. The last-named chapter is especially interesting and well written. In this chapter Plate XLI., B. appears to illustrate variolar encephalitis, whereas the text (p. 612) suggests that the condition shown is post-vaccinal encephalitis. The figure may mislead in so far as it does not indicate the characteristic perivascular demyelination of post-vaccinal encephalitis to which Prof. McIntosh himself primarily called attention, although he holds the view that the two forms of encephalitis are closely related. The table of blood groups (p. 196) might puzzle a student who adopts the prevalent Moss nomenclature; the bacterial mill, illustrated on p. 38, is held by many who have tried to use it to be an unsatisfactory piece of apparatus. Such questions, however, may be largely a matter of personal preference. We can commend this book as a thoroughly sound text-book of bacteriology. The ground is covered very thoroughly, and the relation of medical bacteriology to pathology and public health is admirably maintained.

Anatomy (Upper Extremity)

Catechism Series. 4th edition. By C. R. WHITTAKER, F.R.C.S.E., F.R.S.E. Part I. Edinburgh: E. and S. Livingstone. 1932. Pp. 80. *1s. 6d.*

THE issue of books such as this are deprecated by anatomists, but welcomed by students anxious to pass an examination. This is a good collection of questions of the sort commonly asked in ordinary examinations in descriptive anatomy, with model answers. These answers, as might be expected from the reputation of the author, are thoroughly sound, and, within its limits, the little book can be recommended to students.

La Belgique Sociale

By Dr. RENÉ SAND, Agrégé de l'Université de Bruxelles; Membre des Conseils supérieurs de l'Assistance, de l'Instruction publique et des Œuvres de l'Enfance. Brussels: J. Lebègue et Cie. 1933. Pp. 196. Belg. fr.18.

Dr. Sand, who is the technical counsellor to the League of Red Cross Societies and president of the International Hospital Association, has used his wide experience of international affairs as a background in this study of public health and social welfare in his own country. The book deals almost exclusively with Belgium; yet it is easy to read between the lines that the praise the author allots, and the judgments he passes on matters in his own country largely reflect his intimate knowledge of what is happening elsewhere. His account of the public health and social welfare machinery starts from the year 1830. From then onwards there has gradually developed a patchwork garment with which the community has been clothed in a rather helpless fashion. Dr. Sand emphasises his running comments on this patchwork with statistics and other data which make his book not only a powerful plea for reforms, but also a valuable summary of what is being done to-day with regard to such problems as housing, food, infectious and mental diseases, alcoholism, cancer, infant and maternal welfare, sickness and accident insurance, occupational diseases, unemployment, and all the many other subjects with which public health and social welfare are concerned. Rural hygiene—a problem whose importance and urgency have but recently been discovered—receives special attention; and Dr. Sand shows how glaringly defective is the hygienic state of many a rural community in Belgium. The administrative autonomy such communities "enjoy" in the matter of public health is their undoing. For how can local talent, in the few spare moments it can devote to public affairs, grapple satisfactorily with the highly technical problems of a modern community? Dr. Sand's remedy for all this is centralisation. And at the centre he would like to see one body, not 15 bodies, as is the case at present, overlapping each other with great and unnecessary loss of efficiency. The conditions here revealed have so many parallels in other countries that this book will be read with sympathetic interest by many besides the Belgians.

being given, through a daily bonus, an adequate incentive to do their best. In no case was training at one process found of value when taking up a second process; in other words there was no "positive transfer" of dexterity. A view has also been put forward that the acquirement of dexterity at any process creates a habit which stands in the way of acquiring dexterity at some other process; in the field of sport, rowing coaches agree that those who have learned their rowing while engaged in sea fishing prove difficult pupils in racing eights. No evidence, however, was found to support a theory of negative transfer. On the other hand, the Board's inquiry reveals instructive facts about the best period of daily training for increasing productive speed. Eighty minutes' training per day in the simple process of chain assembling was found to give just as much improvement as double this length. Hence, where rapid training is required, a subject could be trained advantageously at one process in the morning and at another process in the afternoon without either interfering with the progress of the other. (Such results would appear to support the scheme of training adopted by that well-known athlete, Pollock Hill, who is famed for having won on the same day the mile and the three-mile in the Inter-varsity Sports. This athlete used to go out on the track each afternoon and train as if for the mile event: then he came into the pavilion and rested quietly for over an hour; after which he went out again to train for the three-mile event, as if he had not been previously on the track.) The best training period for chain assembling may be even below 80 minutes. Discussing the length of spell advantageous for maximum efficiency, the report found a four-hour spell too long; on the other hand, the introduction of rest pauses in a two-hour spell of work did not help. Adjustment to the length of work-spell, indicated by a slower rate of work, took place in a four-hour spell; but it was not shown in any spell shorter than four hours. A tendency to variability in the rate of output was found to increase with the length of work-spell; this variability increased with the onset of fatigue, and indeed was a more sensitive measure of its onset than any actual decrease in output. The more efficient subjects were found on the whole to produce a more constant output—that is to say, their work curves of output were maintained hour by hour at a constant level, just as a well-trained long distance runner maintains the same pace lap after lap over a ten-mile distance.

This question of transfer is part of the larger question of the relations existing between types of human skill, the nature and extent of which was discussed in an earlier report [2] of the Board which answered to some extent the popular criticism levelled against our public schools, that its gods are recognised in its athletes and not in its intelligentsia. Dr. A. A. MUMFORD, whose studies of the physical measurements of schoolboys are well known, has now taken much of the sting out of this gibe by showing that the gods, as a matter of fact, combine both attributes. Examination of 797 boys attending the upper part of the Manchester Grammar School leads to the conclusion [3] that physique and scholarship are in general correlated. Amongst a group of boys all winning "colours" at games or sports, those with advanced scholastic attainments are more advanced in growth than those of lower mental attainments, their advantage being shown in height, weight, chest girth, and vital capacity. Similarly amongst boys none of whom do well at sports the better scholars show the better physical measurements. When various forms of athletics are considered it is found that the group of most advanced scholarship boys show to more advantage in team games than in feats of individual prowess, which suggests that their greater intelligence assists them materially in the combined forms of sport. Following the history of those boys who went to Oxford or Cambridge, we see that those who obtained first-class university honours had won more games colours and sports credits while at school than those who obtained only second-class honours, while the latter in their turn had obtained more colours and credits than those who gained only third-class honours. In this material there is no doubt of the correlation between brain and brawn.

ANNOTATIONS

A HOSPITAL SURVEY OF LONDON

LAST week-end was issued the first complete survey ever made of the services available for the sick poor in the County of London. Such a survey was rendered possible when the Local Government Act of 1929 placed under the London County Council the whole of the publicly provided hospital services for London, formerly under the management of the Metropolitan Asylums Board and the several boards of guardians, which Act created at the same time a consultative body representing the voluntary hospitals, known as the London Voluntary Hospitals Committee. The survey [1] consists of two parts, one dealing with the voluntary hospitals, clinics, and dispensaries, prepared by the hospitals committee, of which Lord Riddell is chairman and Dr. Geoffrey Evans hon. secretary; the other dealing with the municipal hospitals, clinics, and dispensaries, prepared by the London County Council, under the guidance of Sir Frederick Menzies. Both surveys are for the calendar year 1931, and the latter especially must be regarded as provisional, inasmuch as the process of bringing the public health institutions fully into use for the purpose for which they were allocated is still proceeding as circumstances permit.

these lesions are all essentially the same, and have a common origin in tissue supersensitiveness or allergy. The significant features of the process are "fibrinous" necrosis, peripheral cellular infiltration, and a fibroblastic reaction leading to encapsulation of the lesion. The necrosis may be inconspicuous, as in the well-known Aschoff bodies of acute rheumatism, or it may be extensive and liable to calcareous and uratic deposits, as in gouty tophi.

Of late years the notion that allergy governs rheumatic fever has gained much ground, whilst the theory that it influences gout has also found supporters. H. F. Swift[2] recalls that as long ago as 1902, before the development of the modern theory of allergy, A. Menzer suggested that rheumatic lesions were dependent not so much on actual bacterial invasion of the tissues as on some mechanism involving the union of bacteria and their antibodies in the tissues. Since then, with the recognition of the Arthus phenomenon, and because of the occurrence of polyarthritis in serum disease, many workers have been attracted to the allergy hypothesis. Joint lesions have been experimentally produced in appropriately sensitised animals by injections of non-hæmolytic streptococci and other antigens; allergic skin reactions to streptococcal vaccines and filtrates have been demonstrated in rheumatic subjects; and the various investigations have been summarised in critical and comprehensive reviews—among others by Swift[2] and by H. Zinsser and H. Yu in 1928. Allergy in gout has received less attention but some suggestive observations have nevertheless been recorded. L. J. Llewellyn put forward the hypothesis in our columns in 1922, and later F. Gudzent subscribed to it. These and other writers have drawn attention to the familial distribution of gout, and to the occurrence of skin rashes in gouty persons, as supporting the hypothesis. F. Widal and his colleagues in 1925 demonstrated cutaneous supersensitiveness to certain wines, especially red burgundy, in gouty subjects. At this point mention may also be made of the disease known as hop-gout, seen among hop-pickers in Kent, which is characterised by acute joint and tendon lesions, and seems (as B. M. Smithies[3] remarked) to be a manifestation of supersensitiveness to the hop or to something connected therewith. If a disease that resembles podagra closely enough to merit the colloquial name hop-gout can be explained in terms of allergy, it seems not unlikely that true gout is susceptible of similar explanation. Evidence of this kind is, of course, far from sufficient to turn the tide of opinion away from belief that the disease is due to an error of metabolism, but it is interesting to observe that an excess of uric acid in the blood and an abnormal excretion of this substance, which have so long been the centre of interest in the study of gout, are now found to be also features of the allergic state. For example, H. W. Barber and G. H. Oriel,[4] who studied the blood chemistry of patients suffering various manifestations of allergy, not specifically including gout, found that during the acute attacks there was a rise of amino-acid, uric acid, and creatinine, and that the urinary excretions before and afterwards fluctuated accordingly. Thus uric acid seems to be in danger of losing its claim on gout; and of course it is well known that urate deposits are by no means essential to gouty lesions.

Airy and disjointed as these observations may be, they indicate a case for consideration, and the purely histological findings recorded by Weil and Delarue may serve as a useful connecting link in the study of allergy in relation to articular diseases.

◆

TRANSFERENCE OF DEXTERITY

A popular belief is that training at one type of dexterity assists in acquiring another type; that is to say, that if a player has acquired dexterity at rowing or cricket, for example, he will acquire dexterity at golf or tennis more quickly than if he had not previously become a skilled player at anything. This popular belief can neither be proved nor disproved, for there cannot be controlled experiments. Some people have a natural flair for games, and it would be easy to cite examples of men who have been successful in several branches of sport; but for the most part they played all these more or less simultaneously, and one cannot say that the training of one game was a preliminary to any other. There are indeed odd cases of great lawn tennis players who took up golf comparatively late in life and did very well at it, but even so they might have done as well—if not better—had they started with golf; and there is one department of athletic skill in which the evidence points in the opposite direction, for it seems to be agreed that few rowing men become prominent at any other form of sport taken up later; nor does any other sport, pursued concomitantly, help to make an oarsman. On the other hand many supporters could undoubtedly be found for the argument that, even if rowing is an exception, dexterity in sport can be transferred to a considerable extent in accordance with individual proclivity.

Similarly in industry the view has been held that training in one kind of manual skill can be transferred to another, and here it may prove possible to devise controlled tests yielding trustworthy information. This has been attempted in a prolonged and careful investigation by the Industrial Health Research Board, a pertinent report from which department has just appeared.[1] In an introductory note Prof. Pear defines the terms "skill" and "dexterity" for the purpose of this report. Skill is taken to be an integration of well-adjusted muscular performances; it is applied to the higher, more complex integrations of performance, the term dexterity to the simpler patterns of specific habits. Simple dexterity only was the subject of the present study, in which boys were called upon to perform manual processes,

The most important fact emerging from the research is that complications occurred just as frequently in the treated cases as in the control series. This agrees with observations on a smaller number of cases made in this country, and it leads Dr. King to the disappointing conclusion that overbreathing does nothing to prevent post-operative lung complications. It is impossible to reconcile this failure with the hypothesis that collapse is the first and essential stage in post-operative pneumonia. It is not disputed that some degree of collapse is often present, for there is no doubt the aeration of the bases of the lung is defective after laparotomy and, as M. Printzmetal, S. Brill, and C. D. Leake[4] have recently shown, the intrapleural pressure is actually increased. But collapse, if present, is of secondary importance. The available evidence suggests that the sequence of events is as follows. The patient returns from the operating theatre with a painful gash in his abdomen which effectually discourages him from *coughing*. Mucus then tends to accumulate in his bronchi and so the path is prepared for bronchitis and all its attendant dangers. No amount of *overbreathing* will remove this mucus. Indeed, it is probable that inspiration, being more efficient than expiration, will tend to suck the stagnant secretions still further into the bronchial tree. In its final analysis, then, the problem amounts to this: the patient develops bronchitis mainly because it hurts him to cough. His attendants can help him most, apart from avoiding tight binders and encouraging early movement, by pointing out to him the error of his ways.

A HABITATION FOR THE INSANE

EVERYBODY knows the kind of treatment that was meted out to the insane in the eighteenth century. In April, 1790, a Quaker named Hannah Mills died in York Asylum, and suspicions of the treatment she had received were aroused in the minds of York Friends. A practical idealist, William Tuke, turned his thoughts and energy to a scheme for providing for Friends "an habitation" where others afflicted like Hannah Mills might receive more tender care. At that time the lunatic was regarded as a person whose main, if not only, need was protection, and the story of The Retreat, told by its present steward,[5] is largely the story of the development of the conception of a mental home as a hospital. A home-like atmosphere has, however, always been maintained, and the process of hospitalisation has been that of building up a combination of club and hospital life, and not that of substituting for the home an institution run more by the head than by the heart.

The first patient was admitted on June 13th, 1796, and soon such modern methods as the warm bath and the liberal diet were in use. Drugs and medicine were found to be of little value. The treatment of a case of insomnia illustrates the simple and practical way in which the first superintendent, George Jepson (not a medical man), faced difficulties. He argued that animals seek repose after a full meal, and therefore caused a patient whose "violent excitement of mind indisposed him to sleep, to be supplied freely with meat or cheese, and bread and good porter." The result was satisfactory, and in subsequent cases where the patient was adverse to food, beer alone was used with great advantage, "always avoiding, in all cases, any degree of intoxication." Depite the attitude of the early Quakers to frivolity, some amusements were allowed even at this time; writing and reading, chess, draughts, and so on. Novels, however, were not allowed until the time of John Kitching, who was the second resident medical officer (1879–1884), and introduced many other amenities: lectures, botanical studies, a rocking boat, and a donkey. It was he who first advocated the villa system, which was adopted under the régime of his successor, Robert Barker. The plan of sending some of the patients to the seaside for a holiday was introduced by Thomas Allis, the superintendent (non-medical) from 1823–1841.

All these things are now commonplaces but they were startling innovations at the time, and only towards the end of the nineteenth century did The Retreat cease to be unique. It is difficult to realise now how much interest the experiment aroused. The Retreat always encouraged visitors, and from the beginning appointed three official varieties. In 1816 Dr. Duncan came from Dublin "for the purpose of visiting the most celebrated lunatic establishment in Great Britain." Elizabeth Fry came several times, and recorded in her diary in 1799: "We saw the Friends' Retreat for crazy people, which my father thought extravagantly carried on."

The story of The Retreat was well worth the telling. It has been set forth in an attractive format, and in lucid prose full of quiet humour. A foreword was contributed by Dr. Bedford Pierce, the greater part of whose long and fruitful life was devoted to the hospital, and to whom the book forms an apt memorial. At its close is a note by the superintendent, Dr. Neil Macleod, forecasting the future of mental treatment in general and of The Retreat in particular. The book is illustrated by photographs of the worthy men and women who have played their part in building up the institution, and the whole forms an inspiring record.

THE MECHANISM OF DYSPNŒA IN HEART FAILURE

OBSERVATIONS have been made by T. R. Harrison and collaborators[1] on the cause of dyspnœa produced by mild exercise in cases of heart disease. They assert that an adequate explanation of such patients' dyspnœa has not yet been offered, and object to the one based on lowered circulation-rate on the ground that neither in arterial nor venous blood have the altered hydrogen-ion concentration, carbon dioxide content and pressure, and oxygen content postulated by this view been demonstrated. The cause of this dyspnœa experienced on mild exercise was therefore sought elsewhere. The subjective symptom of respiratory distress—that is dyspnœa—was found to be proportional to the ratio of ventilation to vital capacity. Thus dyspnœa tends to appear with increased ventilation or with reduced vital capacity. The latter is common in heart disease. Experimental work on dogs showed that reduction of the vital capacity, using various methods, led to a reflex increase in breathing, the afferent path being through the vagus. No further reduction in vital capacity was noted on exertion, so it evidently plays no part in the production of dyspnœa on mild exertion, and the cause must be looked for in changes in ventilation. Observations on ventilation made on normal men and on dogs strongly suggested that the increase produced by limited muscular movements was due to nerve

The London County Council is now spending well over £7,000,000 a year in maintaining 79 general and special hospitals, convalescent hospitals, and institutions, 49 dispensaries for giving outdoor medical relief, 13 institutions under the management of its public assistance committee, and 20 mental hospitals, colonies, and homes under the management of its mental hospitals committee. In addition the Council is spending nearly £450,000 a year on the medical inspection and treatment of school-children, including 73 voluntary treatment centres and arrangements with 17 voluntary hospitals. The survey shows that the total number of beds for sick persons in the Council's hospitals and institutions, apart from mental, at the end of the survey year was 38,945. The total number of in-patients treated in the year was 210,074 (of whom all but 5535 were resident in the county), and out-patient attendances numbered 259,036. The corresponding number of beds in voluntary hospitals was 14,833, the total number of new in-patients treated during the year 216,788 (of whom 79,385 came from outside the county), and the total out-patient attendances 8,355,756, being a number slightly greater than the whole population of Greater London. The significance of these figures is enhanced by admirably clear tables in both reports analysing the purpose of the beds allotted in each hospital and the purpose of out-patient attendances, giving full details of the numbers of medical and surgical staff, the percentage of beds occupied, and the average stay of the patient in them.

Most interesting because most novel is a geographical analysis showing for each hospital the numbers of patients coming to them from the various regions and boroughs of the county of London. The analysis is strikingly dissimilar in the two surveys. The general municipal hospitals are populated to a large and often preponderating extent by patients drawn from the borough in which they are situated. St. Giles', for instance, draws all except 6 of its 8511 in-patients from the borough of Camberwell; St. Charles' draws 2589 of its 3918 in-patients from the borough of St. Marylebone. Little more than 1 per cent. of the patients come from outside the county. On the other hand, some of the voluntary teaching hospitals draw quite a large proportion (in the case of Charing Cross more than half) of their in-patients from outside the county; and there is scarcely a borough in the whole of London which does not send an important contingent of patients to one or other of the 12 teaching hospitals. As was to be expected, the first choice of hospital in the case of each of the 30 metropolitan boroughs follows the path of least resistance.

In the north-western area Hammersmith, Fulham, and Chelsea choose St. George's; Kensington and Paddington choose St. Mary's; the City of Westminster chooses the Westminster Hospital. In the northern area Marylebone and Hampstead choose the Middlesex; St. Pancras chooses University College; Holborn and Islington choose the Royal Free; Finsbury and Shoreditch choose St. Bartholomew's. In the north-eastern area Stoke Newington, Hackney, Bethnal Green, Stepney, and Poplar choose the London Hospital; the City of London chooses St. Bartholomew's. In the south-eastern area Woolwich, Greenwich, Deptford, Bermondsey, and Southwark choose Guy's; Lewisham and Camberwell choose King's College. In the south-western area Lambeth, Battersea, and Wandsworth choose St. Thomas's.

But it must be added that in many cases the second choice was not so far behind the first, and in general the total number of patients going to other hospitals largely exceeds what we have called the first choice. Table C in fact is a striking example of how the hospital patient has maintained the voluntary system by an apparently arbitrary choice of hospital which he shall attend. This gigantic game of hospital halma is a fact to be reckoned with in any scheme of hospital reorganisation. The rules of the game are complex, but no doubt include the selection of cases for teaching purposes, the loyalty of practitioners to the school at which they were trained, and the prestige of well-known specialists.

By a happy coincidence the survey is made more complete by the reissue this week of a list[2] of "pay beds" now available in the London voluntary hospitals. This provision for the professional and middle classes is growing rapidly, the number of such beds known to King Edward's Fund on the last day of 1932 being 1667, compared with 590 in 1920. The list contains a description of the provision, whether in the form of single rooms, small wards for two or four persons, or cubicles, and a note of the normal weekly charge.

POST-OPERATIVE PULMONARY COMPLICATIONS

PULMONARY complications still rank among the commonest and most serious risks of major operations, especially those entailing an abdominal incision. If the broadest definition is adopted and a pulmonary complication is diagnosed in every patient who calls for a sputum-pot, it appears that bronchitis or some more serious condition occurs after well over half of all abdominal operations in men. In women, for some inscrutable reason, the incidence is notably lower. The type of anæsthetic chosen is thought to have little bearing on the problem and improvements in anæsthetic technique of the last few years do not seem to have improved matters. Unfortunately, too, there is no very general agreement about the pathogenesis. It is true that massive collapse of one or more lobes of the lungs is occasionally encountered; but there is no convincing evidence that minor degrees of this condition are at the root of the more common complications. As a rule the clinical picture is fairly clear-cut. Within 48 hours of the operation the patient develops a cough with tenacious mucopurulent sputum. In most cases the trouble goes no further, but in some the temperature and pulse begin to climb and more or less definite signs of consolidation appear at one or both bases. Clinically, then, the condition appears to be primarily one of basal broncho-pneumonia.

Among the many prophylactic and therapeutic measures which have been recommended, overbreathing, induced by administration of carbon dioxide mixtures, has enjoyed considerable popularity, largely owing to the enthusiastic advocacy of Yandell Henderson and H. W. Haggard. It is claimed that overbreathing removes the last traces of irritant anæsthetic vapour from the lungs and also corrects any tendency to focal atelectasis. These, however, are merely theoretical arguments; the proof of the pudding is in the eating. Controlled observations have up to the present been few, but a recent paper by D. S. King[3] is very much to the point. It is based on a series of 648 laparotomies in which hyperventilation was induced during the first three post-operative days, either by inhalation of mixtures containing carbon dioxide, or by rebreathing of expired air. Another series of 667 cases served as a control. Cases of simple bronchitis were ignored, but even so the incidence of lung complications approached 50 per cent. in operations on the stomach and duodenum and the gall-bladder.

and a fibrous scar at the base of the left ventricle posteriorly. White also has under observation a patient, aged 67, who had his original attack of coronary thrombosis 20 years ago, and has survived two further attacks. At present he is still leading an active life as a minister of religion, with little restriction on his movements. Such cases show that myocardial infarction may be followed by complete and lasting functional recovery. and the paper by the late Dr. Carey Coombs, reviewed in our issue of Jan. 28th (p. 209), provided numerical evidence that a fair proportion of patients survive their first attack.

EXERCISE AND DIGESTION

It is a pleasant and. occasionally, a profitable pastime to review old tags and proverbs by the light of modern knowledge. For example, we are exhorted to rest awhile after dinner, but after supper to walk a mile, and. superficially, there seems to be no foundation for a different ritual attending the two meals. Is the assumption that midday dinner is the more substantial meal and so calls for a rest which is less necessary after supper? Or may an arbitrary distortion be employed and the conclusion be accepted that after both dinner and supper rest is advisable followed after an interval by walking exercise? Natural inclinations go for something. and the lethargy and disinclination for activity following a full meal are certainly safeguards against syncope due to the pressure of a distended stomach upon a rapidly beating dilated heart. On the other hand, it is a matter of common observation that the digestion of a comparatively light meal may be assisted by gentle exercise, and scientific support for this experience is provided by the fractional test-meal and by radioscopy. Campbell, Mitchell, and Powell[1] found that in normal healthy young men moderately severe exercise, such as running at the rate of eight miles an hour, delayed the digestion of a recently ingested light meal; but that gastric secretion was not inhibited, and the rate at which the stomach emptied itself was increased by easy walking, especially in company and with conversation—concomitant factors which seemed to show the importance of psychological influence, an influence which is too well recognised to require elaboration.

The latest investigators in this field, F. A. Hellebrandt and M. M. Miles,[2] of the University of Wisconsin, confirm the impression that gentle exercise before or after a test-meal encourages and augments gastric acidity. The duration of exercise is not necessarily in itself, they find, an adverse factor; but the element of exhaustion, whether before or after the meal, is definitely inimical to secretion. To ensure exhaustion rapid bicycle riding and rope jumping were employed; whilst in further researches to introduce the element of competition with the inevitable psychical accompaniments they enlisted the coöperation of basket-ball players—young women—in a contest of spirited rivalry. Moderate or mild muscular exertion increases general metabolism, improves the circulation, and has a stimulating effect upon the organism as a whole, the stomach naturally participating in the general increase of functional activity. Exercise carried on at high speeds incurs an oxygen debt and the rapid accumulation of acid metabolites—in a word, exhaustion, or at least fatigue. The accumulation of lactic acid in the blood lowers its bicarbonate content and accelerates the output of carbon dioxide. The lungs cannot wash out the carbon dioxide sufficiently rapidly and the hydrogen-ion concentration rises. In the light of experimental observations the reduction in gastric acidity as a result of violent exercise may be due to the concomitant fall in plasma-bicarbonate. Hypo-acidity then appears when muscular exertion is associated with the incurring of an oxygen debt. Further, during severe exercise, splanchnic vasoconstriction diverts blood from the viscera to the actively contracting limb muscles and to the skin, producing a relative diminution of oxygen to the stomach which again will reduce gastric acidity. Confirmation of these chemical tests is forthcoming on the radiographic side. From the physiological laboratory of Guy's Hospital, T. W. Adams, D. J. Clarke, J. M. Lees, M. S. Pembrey, and R. S. Vine[3] submit the results of experiments to show the influence of muscular work upon the movements of the stomach. The meal employed consisted of ¼ lb. cold pressed beef, two rolls, two pats of butter, ½ oz. bovril, and 6 oz. barium sulphate minced together and made into a stiff paste with water. Radiographic observations followed on hard muscular work, such as running a mile in eight minutes or swimming 450 yards in 13 minutes in a bath at a temperature of 60·8° F. They found that such exercise is associated with relaxation of the stomach and delay in passage of the food, and that even if the work is started at a longer interval after the meal, a definite inhibition of the movements is produced.

It has been the experience of radiographers that moderate and natural exercise helps the stomach to empty, and it is often their practice to advise patients under investigation to go for a walk after their first examination of an opaque meal. before subsequent examinations, to reproduce physiological processes at their optimum. Finally, in connexion with the relationship of exercise to digestion, the subject of stitch is pertinent. This phenomenon described in these columns[4] as an acute physiological visceroptosis, is a painful sensation arising from strain upon the coronary and other peritoneal ligaments, produced by the weight of the heaviest viscera in the erect attitude. And although jerkiness and vibration and motor irregularities of all kinds are the prime determining factors, anything which contributes to the weight of a viscus will be an additional factor of importance. It is not surprising, therefore, that stitch is likely to come on when exercise follows soon after a heavy meal.

NON-TOXICITY OF FORMOL-TOXOID

FORMOL-TOXOID, the anatoxin of Ramon, is prepared by digesting diphtheria toxin with formaldehyde. The resulting product, whilst completely or almost completely non-toxic, retains unimpaired the antigenic value of toxin. Anatoxin, the preparation generally used for prophylaxis on the continent and in Canada, is injected subcutaneously in doses which range from 0·5 to 1·5 c.cm. That it is devoid of toxicity even if injected by inadvertence in massive doses appears to be conclusively shown by an experience recorded by E. Aubertin and P. Boudou.[5]

> A young workman contracted faucial diphtheria of moderate severity. The clinical diagnosis was confirmed bacteriologically by the Pasteur Institute at Bordeaux, and the practitioner decided to inject diphtheria antitoxin. A neighbouring chemist was asked for a supply, but found that he was out of stock. Remembering, however, that he had some 10 c.cm. ampoules of anatoxin intended for the immunisation of children in the town, he sent a number of

impulses from the moving muscles. Further experiments on animals demonstrated increased ventilation as a result of increasing the pressure in the right auricle, provided the vagus was intact. In cardiac disease the venous pressure is very often higher at rest than in normal persons, and undergoes a greater rise on exertion. The results of the author's investigations lead them to the conclusion that the cardiac patient experiences dyspnœa on mild exertion through a threefold mechanism: diminished vital capacity, afferent impulses from the moving muscles, and increased venous pressure in the right side of the heart. The second factor is in operation in the normal person, and only the first and last are peculiar to the cardiac patient. But the conclusion that the data presented are evidence against "the widely accepted but erroneous theory that the symptoms of cardiac failure are essentially and primarily due to a diminution in the minute output of the heart," does not seem to be sound. For increased venous pressure is after all generally accepted as indicating a diminished capacity for work on the part of the heart, while diminished vital capacity in heart disease is itself attributed to venous engorgement of the lungs.

PER-URETHRAL OPERATIONS ON THE PROSTATE

THE key to success in per-urethral operations is the proper selection of cases. Dr. T. J. Kirwin,[1] whose paper is conspicuous for its restrained judgment on this controversial subject, believes that the per-urethral approach is suitable for the following types of obstruction: contracted bladder neck, median bar obstruction, enlargement of the middle lobe of the prostate with slight lateral lobe hypertrophy, subcervical gland hypertrophy, carcinoma of the prostate, congenital urethral valves, slight lateral lobe hypertrophy, and cases of obstruction where, for some reason or other, total prostatectomy is contraindicated. Outside these bounds, he says, the surgeon is likely to meet with difficulty from hæmorrhage both during and after the operation; moreover, the results are uncertain, and when a long time is spent in removing masses of tissue so great a strain may be thrown on the patient that his life is endangered. In discussing technique, Kirwin is emphatic about the advantage of a current of low amperage. If high-amperage currents are employed the effects of the heat generated are felt far beyond the area actually resected. Fluid in the tissues is converted into steam which scalds and otherwise damages the surrounding bladder neck, and this damage may be followed by sloughing, cicatrisation, and eventually contraction of the tissues. Unfortunate sequelæ of this kind are obviated by the employment of radiothermy of low amperage. The instrument he uses is one of his own device. It has an outer sheath of bakelite, and the resection is done by means of a wire electrode which rotates across a large window in the ventral aspect of the outer sheath. This electrode rotates along a circumference corresponding to a 32 French catheter, the calibre of the instrument itself being only 28. By this means a sheath can be used of several sizes smaller than would otherwise be possible for obtaining so large a cut.

Besides laying stress on the need for care in the selection of cases he draws special attention to the importance of adequate pre-operative measures. If per-urethral resection is regarded as minor surgery, disaster is likely to follow. Post-operative drainage is secured by the introduction of a whistle-tipped catheter large enough to exert pressure on the walls of the posterior urethra and diminish post-operative oozing. Employing this technique, Kirwin has had 3 deaths in a series of 70 cases; the first patient dying of cerebral hæmorrhage, the second of myocarditis, and the third of peritonitis. Post-mortem examination of the last of these fatal cases showed a rent in the posterior urethra.

THE PROGNOSIS FOR FRACTURES OF THE VERTEBRÆ

THE fate of 304 insured persons whose fracture of the vertebral column was notified in the ten-year period 1918–27 has recently been analysed by Prof. J. Akerman,[1] chief medical officer of the Swedish Government insurance bureau, which deals with about 75,000 accidents every year. His analysis ignores partial fractures of the axis, the apophyses, the sacrum, and accidents complicated by fractures of the skull, pelvis, large bones of the limbs, or by lesions of the internal organs, and the cases in which death followed so quickly that there was no time to examine or treat the patients are also excluded. All the patients, of whom 274 were men, were treated in public hospitals, and the diagnosis was verified by repeated X ray examinations. The cervical vertebræ were involved in 68 cases, the dorsal in 102, and the lumbar in 134. The fatal cases numbered 68. The total mortality was 22 per cent., divided as follows: lumbar region 12 per cent., dorsal region 22 per cent., and cervical region 44 per cent. In 112 patients a recovery was effected without a degree of invalidism exceeding 10 per cent. In all the cases terminating fatally taken together, the average duration of life after the accident was 43 days, and in cases of fracture in the cervical region it was ten days. These averages are vitiated by a few cases in which the patients survived for several months; most of the patients who died did so after only two or three days. The difference between the temporary compensation and the permanent compensation finally allowed was only about 10 per cent.—a finding which shows that there is not much to be hoped for in the way of late recoveries.

LONGEVITY AFTER CORONARY THROMBOSIS

TWENTY years ago myocardial infarction from coronary obstruction was held to be of interest only to the pathologist; clinically it received attention merely as a cause of sudden death. Since the war, however, it has become generally recognised that acute coronary obstruction has a well-defined clinical picture; and now that it can be diagnosed during life we have learnt that it is by no means always fatal. A good example is a case just reported by Dr. Paul D. White,[2] in which a man had a typical attack at the age of 63. He made a perfect recovery, and two years later was passed for life insurance despite a very careful examination of his heart. At the age of 72 he did a great deal of mountain climbing, and his average time for a climb of 3000 feet over a distance of five miles was two hours and a quarter. Eleven years after the attack he began to suffer anginal pain on exertion. By modifying his life and living at a lower level he progressed well until, at the age of 80, he died in a few days from a cerebral hæmorrhage. Post-mortem examination revealed an old occlusion of a branch of the right coronary artery

THE EFFECT OF PASTEURISATION UPON THE NUTRITIVE PROPERTIES OF MILK

By William G. Savage, M.D. Lond., B.Sc., D.P.H.
COUNTY MEDICAL OFFICER OF HEALTH, SOMERSET

Since milk is chemically very complex it can hardly be anticipated that heat will be without any effect upon its composition. The practical question is whether any changes result which affect the nutritive qualities of cow's milk as a food for man.

The expression "pasteurisation" is often employed without exact definition and not always in reference to the same heat action. In this paper, unless otherwise stated, it is used as the official definition of the Ministry of Health. This involves heating the milk to 145° F. and holding it between 145° F. and 150° F. for 30 minutes, after which the milk is rapidly cooled.

Changes Produced by Pasteurisation

A good deal of confusion in the past has been caused by writers discussing, without any clear distinction, changes produced at various temperatures, including the boiling of milk, and not merely changes induced by pasteurisation. These contributions have to be excluded unless they include results obtained at pasteurisation temperatures. Only the latter are here under consideration.

No changes have been reported in the fat, apart from slight physical alterations which may cause the cream to rise less readily. The milk proteins are not altered, apart from the fact that a very small proportion (round about 5 per cent.) of the lactalbumin becomes insoluble, but there is no evidence that it is rendered less digestible. The lactose is not affected. The only constituents round which discussion centres, and which have to be considered, are the mineral constituents, the enzymes, and the vitamins.

MINERAL CONSTITUENTS

Bell (1925),[1] using the method of filtration under pressure through a Pasteur-Chamberland filter, obtained very small losses of diffusible calcium and of phosphorus, but not beyond the limit of experimental error. Much greater variations were found when the milk was centrifugalised. Magee and Harvey (1926)[2] found that about 26 per cent. of the total calcium oxide is in the diffusible or soluble form in fresh milk, pasteurisation (65° C. for 30 minutes) reduces this to about 20 per cent. The losses in soluble calcium were believed to be due to the formation of a colloidal form of calcium phosphate. Mattick and Hallett (1929)[3] found that at 145–150° F. the amount of the total calcium which becomes indiffusible is about 2 per cent., while the evidence of any change at pasteurisation temperatures in diffusible phosphorus is inconclusive. Their tables show that the total calcium is not reduced, and that only 25 per cent. of the calcium is in a diffusible form. The reduction in the percentage of diffusible calcium is 9·5 per cent. Bell's figure for diffusible calcium was 23·8 per cent. (as CaO), while Magee and Harvey quote Kona and Michallis 44 per cent. (CaO) and Grosser 23·4 per cent.

These results suggest that only about 25 per cent. of the calcium of cow's milk is present in a diffusible form, and that the effect of pasteurisation is to slightly alter this proportion by reducing the diffusible fraction by about 6 per cent., estimated as CaO. There is no evidence from these reports that this calcium is lost or that this small change in the diffusible proportion affects the availability of the calcium, but this point is discussed in the section on animal experiments. Magee and Glennie (1928)[4] estimated the iodine in 135 samples of fresh milk, and these showed considerable variations from 4·2 to 7·46 γ per 100 c.cm., the average being 5·69. With pasteurised milk the variations were from 3·68 to 5·90, the average being 4·51. These figures show an average loss of 20 per cent. This was evidently due to volatisation. Unfortunately no information is given either as to the pasteurisation temperatures or as to the method of pasteurisation—i.e., if open or closed. Approximately 83 per cent. of the total iodine of separated cow's milk was found to be in diffusible form.

ENZYMES

Most of the numerous investigations deal with temperatures above those of pasteurisation, and their general tendency is to show that at 150° F. they are not destroyed. Peroxidase is definitely not destroyed (Zilva and others). Mattick and Hallett[3] found that milk heated to pasteurisation temperature showed delay in the time of coagulation to rennet, a point of interest for cheese-making but of no significance from the human nutritive aspect.

Allen (1932),[5] in his valuable survey, points out "very few accurate data appear to be available on the effect of heat on the enzymes of milk, so that it is impossible to say in most instances to what extent pasteurisation may induce inactivity." In any event, the point would appear to be purely of academic interest as there seems to be no evidence that their presence is of any importance in human feeding. (For a review of this question see Lane-Claypon, 1916.[6])

VITAMINS

While milk contains all the vitamins they are very unequally present in it. Vitamin A is abundant in milk and is not affected by the temperature of pasteurisation. The amount of vitamins B_1 and B_2 in milk vary, being affected by the food of the cow. B_2 is particularly heat stable, but B_1 also possesses considerable resistance to heat. The report on vitamins[7] published by the Medical Research Council last year remarks: "There is general agreement that the resistance of vitamin B_1 to heat in faintly acid or acid media is considerable. Most observers have detected little or no destruction of the vitamin after exposure to 100° C." Even with milk heated for some time at high temperatures, round about 100° C., such as evaporated milk, the work of Samuels and Koch (1932)[8] shows that only about one-sixth to one-fifth of the antineuritic heat-labile fraction (B_1) is destroyed. At pasteurisation temperatures there is no evidence of any destruction.

Vitamin D is very variable in milk, and under certain conditions of diet and feeding there may be very little in milk. There is no evidence that it is affected by pasteurisation.

Vitamin E is present in milk, and the Medical Research Council report remarks: "Vitamin E appears to be remarkably stable to heat, resembling in this respect vitamin A."

Vitamin C is the least heat stable of the known vitamins. The earlier reports suggest that most of this vitamin is destroyed at a low temperature, but, as with other vitamin heat studies—i.e., as regards canned foods—further investigations show that this extreme view must be modified. Schwartze, Murphy,

> these instead, thinking that they would answer the purpose equally well. The unsuspecting practitioner injected subcutaneously a first dose of 100 c.cm. of what he believed to be antitoxin, and on the following day a further 50 c.cm. It was only when casually examining the labels of some of the remaining unopened ampoules that the mistake was discovered. After the first dose the patient complained of slight local pain in the abdomen, the site of injection. This was quickly succeeded by signs and symptoms of severe shock; pallor and drawn features, irregular and uncountable pulse, dilatation of the pupils, and abdominal pain. The shock was of short duration, but the patient remained in an exhausted condition for the rest of the day. In the evening there was some rise of temperature and some spread of the membrane. The patient had a restless night, but next morning was very much better. The membrane had almost entirely disappeared, the pulse was good, and the temperature barely above normal. He had passed a litre of urine free from albumin. Although satisfied with the progress of the case, the doctor determined upon a second injection. This immediately produced shock which was, however, far less severe than that of the preceding day. The following morning the last remaining traces of membrane were readily detached, and the general condition of the patient was very satisfactory. At the site of the first injection an area of œdema and redness with a radius of 10 cm. was noted. The patient made an uninterrupted recovery.

Aubertin and Boudou emphasise this history as evidence of the non-toxicity of anatoxin. They note that the reactions to which its injection in prophylactic doses on occasion gives rise are allergic in nature, and clearly in the case described the shock from which the patient suffered was allergic. They point out that in diphtheria, at any rate, allergy and immunity are two separate processes which may coexist. Although the former is often manifest earlier than the latter, there is no evidence that it prepares the way. Some have held that the abortive, *formes frustes* of the disease are allergic in character, but Aubertin and Boudou think rather that they are to be explained as the beginnings of immunity. (Whether the abortive attack occurs in a subject who is completely non-immune or who has, as is more probable, a certain degree of basal immunity, there is certainly an antigenic response and a step, at least, towards immunity is thereby taken.) A. T. Glenny[6] has shown that the antigenic response to diphtheria and other toxins varies greatly according to whether the stimulus is primary or secondary. After primary injection of toxin into an animal no antitoxin can be demonstrated for three weeks, but if then a second injection is made, the antigenic response is not only much quicker but much greater. The latent period is reduced to three days, at the end of which the antitoxin curve rises steeply. It would seem that in the present case, the large dose of anatoxin in addition to causing allergic shock had the effect of a secondary stimulus. As a result, the patient's antitoxic titre increased rapidly and effected his clinical cure. Although Aubertin and Boudou do not allude to the important work of Glenny, they suggest the same process in other terms and consider that it might be of interest to inject anatoxin in cases of diphtheria with or without concomitant antitoxin therapy.

This claim that anatoxin can do no harm was made before the accident which followed its employment at Bourbon Lancy, near Charolles (Saône et Loire) just before Christmas and attracted much public attention. The facts, as given by the French Ministry of Health on Jan. 28th, are these. A child who had been vaccinated with diphtheria anatoxin supplied by the Pasteur Institute had died, and seven others had been ill, but had recovered. Since the anatoxin used was part of a large batch, and no other mischances had been reported, the Ministry presumed that the accident was due to lack of necessary precautions. It appears that the child who died had previously been in indifferent health; the seven others had signs of severe infection at the site of injection in the thigh, which for some reason had been selected instead of the usual site at the back of the arm or shoulder. None of the other children in the village who had been vaccinated with the same material by other medical men had shown similar symptoms. The further inquiry which is in progress should clear up any doubt.

CHILDREN AND THE ECONOMIC DEPRESSION

QUESTIONS in Parliament have elicited replies from the Minister of Health and the President of the Board of Education that the effect of the economic depression on the health of school-children is being carefully watched, and that special inquiry on the lines of the League of Nations' memorandum is unnecessary. Both State departments pointed to the information available from official and other sources, amongst which is the report presented to the L.C.C. education committee on an inquiry conducted last December into the nutrition of children in a poor part of the East End of London. Nine families were selected for investigation by experienced social workers, the number of children being 25, none of them being fed at school. Although the nutrition of seven was found to be below the average, in no case did this appear to be due to general lack of nourishment; rather was it associated with illness. This committee is arranging for similar inquiries to be carried out in other districts of London, to be the subject of a fuller report later. A more extensive inquiry into the effect of unemployment on children in distressed areas is being organised by the Save the Children International Union, the results of which should be available by the end of May. In the meantime no doubt some of the reports of medical officers of health and school medical officers for the year 1932 will have appeared. Information is now available for Glasgow in a report on the education health service for the year ended July 31st, 1932; this contains a paragraph stating that no evidence of deterioration has been observed in the nutrition of the school-children as judged by average heights and weights, although rickets of a minor degree had shown a tendency to increase among the pre-school population. Other areas seem to have noted a similar increase of rickets in young children. The cold spell of the last few weeks will have thrown a greater strain on small household budgets, and is likely to make more manifest the under-nourishment present in children who are ill-clad and therefore likely to suffer from the cold. It may be, as Dr. F. L. Keith has satisfied himself for Deptford, that the mothers are increasingly starving themselves for the benefit of the children, and those public assistance committees are to be commended which make the feeding of school-children supplementary to transitional benefit rather than part of it. We find it disquieting to learn from the Parliamentary Secretary to the Board of Education that the number of free milk meals provided in Lancashire fell from 199,000 in November to 145,000 in January.

INDEX TO "THE LANCET," VOL. II., 1932

THE Index and Title-page to Vol. II., 1932, which was completed with the issue of Dec. 31st, is now ready. A copy will be sent gratis to subscribers on receipt of a post-card addressed to the Manager of THE LANCET, 7, Adam-street, Adelphi, London, W.C.2. Subscribers who have not already indicated their desire to receive Indexes regularly as published should do so now.

---

[6] Jour. of Hyg., 1924, xxiv., 301.

vitamin D. It has already been mentioned that vitamin D may be deficient or almost absent in cow's milk, and a deficiency may occur in human milk, since rickets is common amongst breast-fed babies.

As regards vitamin C human milk is probably a better source than cow's milk, but there is evidence that this vitamin may also be deficient in human milk.

When we utilise these facts to study the significance of the changes caused by pasteurisation, it is evident that, apart from vitamin C, they are in the direction of making cow's milk a little less unlike human milk. The diminution of diffusible calcium and phosphorus, of which so much is made, may be considered beneficial, at least for infant feeding, in that it does slightly reduce the gross excess of calcium and phosphorus available in cow's milk. Iron is markedly deficient in cow's milk and is not diminished in pasteurisation, but likely to be increased from contact with that metal. Vitamin C is often deficient in raw milk, so in feeding with cow's milk that has to be supplied from other sources, whether raw or pasteurised milk is used.

Animal Feeding Experiments

It will be simplest to describe the experimental work and then discuss its validity as applied to man.

A good deal of animal experimental work has been carried out using *boiled* milk, and the results have then been quoted as applicable to pasteurised milk. Since the changes which result from boiling are definitely more considerable this is unscientific, and here only results are considered which deal with milk subjected to pasteurisation temperatures.

ON RATS

Daniels and Loughlin (1920)[15] carried out rat-feeding experiments with five groups of treated milks—i.e., milk brought quickly to the boil and boiled one minute, milk brought slowly to the boil (35 minutes), milk pasteurised in bottles but usually at higher temperatures than in standard pasteurisation, unsweetened evaporated milk, and sweetened condensed milk. No controls with raw milk were used. The results show that when milk is fed after prolonged heating rats did not make satisfactory growth gains and fewer young were born. When a soluble calcium salt was added the rats made normal growth. As the authors point out all their results show is that there is some loss of available calcium on prolonged heating which varies with the conditions of heating, and that this loss affects the nutrition of rats.

TABLE I

Rats.	Milk treatment.	Total weights (g.)		Average gain in g. per rat.	Litters.	Pups.	Alive.	Weaned.
		Onset.	At mating (118 days).					
6 bucks 6 does	Raw "	488 430	1538 1106	175 113	6	47	41	18*
6 bucks	Pasteurised	480 431	1412 1100	155 111·5	6	42	22	7†

* From four litters. † From one litter only.

Mattick and Golding (1931).[16] The greater part of their paper deals with sterilised milk and does not affect the problem under consideration. Their pasteurisation work merely deals with 12 rats and 12 control rats. All 24 rats were fed on biscuit and as much milk as they would take. One-half received the milk raw, the other after pasteurisation at 145°–149° F. for 30 minutes. The results are shown in Table I. The weight differences are not marked for the bucks and negligible for the does. The points in regard to young rearing are considered below. The milk consumed was not known, and we do not know if the pasteurised milk was imbibed as freely or not as the raw milk. No confirmation of these findings has been forthcoming.

Scott and Erf (1932).[17] Most of the experiments of these authors were a comparison of rats fed with milk from cows fed on specially selected foods containing numerous added minerals, with rats fed on pasteurised milk, shop purchased and of unknown composition and source. As a United States committee (1931)[18] points out, these are worthless from the pasteurisation point of view. They merely suggest that superior milk is more nutritive than poor quality milk, which we already know.

In only a very few experiments is the same milk, raw and pasteurised, fed to rats. In one group of experiments the authors state that milk from cows fed on a special diet was divided into two portions, one fed raw, one after heating at 62° C. for 30 minutes. The number of rats fed is not stated, the duration of the experiment is not mentioned, and no details are given other than to state that the rats fed with the heated portion showed a loss of 21 g. in weight, loss of 6 per cent. hæmoglobin, with a decrease of 1,200,000 red blood corpuscles. Whether the controls gained or lost weight is not mentioned. As quoted, this experiment is valueless.

From another group of experiments with five series of rats, six in each group, fed in different ways it is possible to extract the following particulars. One group of six rats were fed with raw milk, while another six rats were fed with the same milk after heating to 145° F. for 30 minutes. The experiment extended over 11 weeks. The raw milk group gained 100 g. in weight and 2,340,000 red blood corpuscles, the pasteurised milk group gained 66·5 g. and lost 2,300,000 red blood-cells. It is not clear if the figures refer to the bulked six rats or is an average for each rat. It may be mentioned that the pasteurised group did better than two other groups which were fed with unheated milks from other sources.

It will be noted that merely six rats were included in the experiment and the records are so incomplete that very little of any significance can be deduced.

ON PIGS

Orr, Crichton, Crichton, Haldane, and Middleton (1926).[19] Growing pigs were fed on a ration of cereals to which was added either fresh milk, pasteurised milk, or sour milk. The addition to the ration of fresh milk caused the rate of absorption of calcium, phosphorus, and nitrogen to rise rapidly, but this was somewhat depressed when pasteurised was substituted for fresh milk, to rise again when sour whole milk took the place of pasteurised milk. This was shown to be due to the decrease in soluble calcium, since when soluble calcium was added equal to double the amount of soluble calcium lost in pasteurisation a greater retention of calcium, phosphorus, and nitrogen was obtained than when fresh milk alone was added. The increase in the retention of calcium was greater than the amount of soluble calcium added.

Magee and Harvey (1926).[20] Their results are interesting as showing the unsuitability of cow's milk for the young pig. Cow's milk contains on an average 0·16 per cent. CaO, and 0·24 per cent. P_2O_5 with a ratio of 1 : 1·5, whereas sow's milk contains 0·39 per cent. CaO and 0·36 per cent. P_2O_5, a ratio of 1 : 0·92. A young pig on a diet of cow's milk and cereals showed signs of rickets after 30 and Hann (1929–30)[9] found that by lightly boiling 3 quarts of milk for five minutes, after being brought to the boil in about 20–27 minutes in a glass beaker or in an aluminium pan, only 20 per cent. of the vitamin C was destroyed. This is a severer temperature test than pasteurisation.

Schwartze, Murphy, and Cox (1931)[10] deal with pasteurisation temperatures, and studied the influence of aluminium, tinned copper, and copper upon vitamin C content. With aluminium vessels and full aerobic pasteurisation the destruction of vitamin C was 20 to 40 per cent., with tinned copper slightly greater, but in naked copper it was at least 80 to 90 per cent. With anaerobic pasteurisation with the first two compounds they consider the vitamin destruction would be greatly reduced.

It must be accepted that there is some destruction of vitamin C by pasteurisation, but from the practical point of view this is of but little importance, since cow's milk is such a bad source of this vitamin that it ought to be supplemented in any case—i.e., if raw or pasteurised milk is the sole food-supply. As the Medical Research Council report states:

> "Milk is a variable and by no means rich source of the antiscorbutic vitamin. As much as 100 c.c. of some samples of fresh raw cow's milk daily and more may be required if scurvy in guinea-pigs is to be prevented by its agency alone, while as little as 20 c.c. of a summer pasture milk has been found to afford protection."

When these changes are all set down the essential fact which emerges is their comparative insignificance. What they amount to is that the already large proportion of insoluble calcium is increased by about 6 per cent., and possibly there is a similar change in the proportion of insoluble phosphorus. The very small and variable amount of iodine may be reduced by 20 per cent. There is some reduction of vitamin C. There is no evidence of any other significant changes. It may also be pointed out that these changes are much less than the natural variations which occur in different samples of cow's milk. If we are to attach the importance which some would have us do to these slight changes which result from pasteurisation, it is evident that the agricultural interests will have to accept the view that milk to be of value to man must be from cows so fed and treated that their vitamin content is up to standard and that other constituents cannot be neglected.

Comparison of Human and Cow's Milk

It is now evident that while the changes which result when milk is pasteurised are comparatively unimportant some changes do occur. It is important to realise that because there are changes they are not of necessity detrimental changes and damage the nutritive value of the milk for man, an assertion so often made. If we were dealing with the value of milk for the calf it is reasonable to assume that any physical agency which alters in any way the composition of cow's milk is likely to be detrimental to the calf. When, however, it is a question of the value of cow's milk as a food for an entirely different species with widely different metabolic requirements to make such an assumption is entirely unscientific. It may be the case that these changes which result from pasteurisation are wholly or partially beneficial in that they make an alien food rather less unsuitable than it otherwise would be as a food for another species. To assess the significance of any changes shown to occur it is essential to compare raw cow's milk, pasteurised milk, and human milk, both as regards their chemical composition and as regards their suitability as foods for the human species.

In making such a comparison we have to bear in mind the fact that both human and cow's milk vary widely in composition under the influence of different conditions. These differences cannot therefore be conveniently set out in tabular form. It is only necessary to consider in detail those constituents which are affected by pasteurisation.

Average human milk is rather poorer in fat than cow's milk, while there is no evidence of important quantitative differences. Lactose is more abundant in human milk. Since these constituents are not affected by pasteurisation they do not require further discussion.

The proteins show wide differences. In cow's milk caseinogen is approximately 3 per cent., lactalbumin about 0·5 per cent., and lactoglobulin about 0·05 per cent. In human milk the caseinogen is about 1 per cent., and lactalbumin about 0·5 per cent. or rather higher, but various figures are given by different authors. Lactalbumin is richer than caseinogen in the two amino-acids, cystine and lysine, both specially important for growth.

The quantity of ash is about three times as high in cow's milk as in human. The mineral constituents of cow's milk have recently been exhaustively reviewed by Allen (1931), but only some of them need to be discussed. Allen shows that there are considerable differences between individual cows in the calcium and magnesium content of the milk, both as regards the total quantities present and also for those portions present in true solution. Taking average figures, calcium varies from about 0·17 to 0·19 per cent. as CaO, phosphorus from 0·21 to 0·25 per cent. as P_2O_5. The stage of lactation has a definite influence. In human milk there are also considerable fluctuations. Lane-Claypon[6] gives many figures with averages about 0·04 per cent. CaO and 0·04 per cent. P_2O_5.

Telfer (1930)[11] finds the following figures for human milk CaO 0·045, MgO 0·006, P_2O_5 0·048, Fe 0·0001, and in cow's milk CaO 0·16, MgO 0·018, P_2O_5 0·21, Fe 0·00008 g. per cent. The concentration of these minerals showed no appreciable variations at different lactation periods.

Golding, Mackintosh, and Mattick (1932)[12] studied the milk of a typical herd of shorthorn cows over a period of three years. During 1928–29 the highest and lowest percentages of calcium were 0·136 and 0·122, with an average value of 0·127. For 1929–30 the figures varied between 0·140 and 0·115, the average being 0·124. For 1930–31 the figures varied between 0·141 and 0·124, the average being 0·131.

Of other mineral constituents iron is of importance, and Allen remarks "the quantity of iron in cow's milk is approximately one-quarter of that in human milk, and it appears to be independent of the nature of the feed." Davies (1931)[13] found that in fresh cow's milk the iron content ranged from 1·50 to 2·40 parts per million. In ten samples of pasteurised milk it ranged from 1·7 to 3·8 parts per million.

Vitamin A is abundant in both human and cow's milk. The B vitamins are usually adequate in amount in both milks, but in the Medical Research Council Report[7] the authors quote results from Detroit dealing with the amount of human milk required to prevent anti-vitamin symptoms in rats, and state "these results give an indication that human milk may easily be poor in vitamin D and in the B-vitamins. In point of fact there is good evidence that infants at the breast may in some cases suffer from lack of these vitamins." According to Outhouse, Macy, and Brekke (1928),[14] the ratio of calcium to phosphorus is a factor in rats as well as lack of tamin D. It has already been mentioned that tamin D may be deficient or almost absent in cow's ilk, and a deficiency may occur in human milk, nce rickets is common amongst breast-fed babies.

As regards vitamin C human milk is probably a etter source than cow's milk, but there is evidence at this vitamin may also be deficient in human milk.

When we utilise these facts to study the significance f the changes caused by pasteurisation, it is evident hat, apart from vitamin C, they are in the direction f making cow's milk a little less unlike human milk. he diminution of diffusible calcium and phosphorus, f which so much is made, may be considered beneficial, at least for infant feeding, in that it does slightly reduce the gross excess of calcium and phosphorus available in cow's milk. Iron is markedly deficient in cow's milk and is not diminished in pasteurisation, but likely to be increased from contact with that metal. Vitamin C is often deficient in raw milk, so in feeding with cow's milk that has to be supplied from other sources, whether raw or pasteurised milk is used.

Animal Feeding Experiments

It will be simplest to describe the experimental work and then discuss its validity as applied to man.

A good deal of animal experimental work has been carried out using *boiled* milk, and the results have then been quoted as applicable to pasteurised milk. Since the changes which result from boiling are definitely more considerable this is unscientific, and here only results are considered which deal with milk subjected to pasteurisation temperatures.

ON RATS

Daniels and Loughlin (1920)[15] carried out rat-feeding experiments with five groups of treated milks—i.e., milk brought quickly to the boil and boiled one minute, milk brought slowly to the boil (35 minutes), milk pasteurised in bottles but usually at higher temperatures than in standard pasteurisation, unsweetened evaporated milk, and sweetened condensed milk. No controls with raw milk were used. The results show that when milk is fed after prolonged heating rats did not make satisfactory growth gains and fewer young were born. When a soluble calcium salt was added the rats made normal growth. As the authors point out all their results show is that there is some loss of available calcium on prolonged heating which varies with the conditions of heating, and that this loss affects the nutrition of rats.

Table I

Rats.	Milk treatment.	Total weights (g.) Onset.	Total weights (g.) At mating (118 days).	Average gain in g. per rat.	Litters.	Pups.	Alive.	Weaned.
6 bucks	Raw	488	1538	175	6	47	41	18*
6 does	,,	430	1106	113				
6 bucks	Pasteurised	480	1412	155	6	42	22	7†
		431	1100	111·5				

* From four litters. † From one litter only.

Mattick and Golding (1931).[16] The greater part of their paper deals with sterilised milk and does not affect the problem under consideration. Their pasteurisation work merely deals with 12 rats and 12 control rats. All 24 rats were fed on biscuit and as much milk as they would take. One-half received the milk raw, the other after pasteurisation at 145°–149° F. for 30 minutes. The results are shown in Table I. The weight differences are not marked for the bucks and negligible for the does. The points in regard to young rearing are considered below. The milk consumed was not known, and we do not know if the pasteurised milk was imbibed as freely or not as the raw milk. No confirmation of these findings has been forthcoming.

Scott and Erf (1932).[17] Most of the experiments of these authors were a comparison of rats fed with milk from cows fed on specially selected foods containing numerous added minerals, with rats fed on pasteurised milk, shop purchased and of unknown composition and source. As a United States committee (1931)[18] points out, these are worthless from the pasteurisation point of view. They merely suggest that superior milk is more nutritive than poor quality milk, which we already know.

In only a very few experiments is the same milk, raw and pasteurised, fed to rats. In one group of experiments the authors state that milk from cows fed on a special diet was divided into two portions, one fed raw, one after heating at 62° C. for 30 minutes. The number of rats fed is not stated, the duration of the experiment is not mentioned, and no details are given other than to state that the rats fed with the heated portion showed a loss of 21 g. in weight, loss of 6 per cent. hæmoglobin, with a decrease of 1,200,000 red blood corpuscles. Whether the controls gained or lost weight is not mentioned. As quoted, this experiment is valueless.

From another group of experiments with five series of rats, six in each group, fed in different ways it is possible to extract the following particulars. One group of six rats were fed with raw milk, while another six rats were fed with the same milk after heating to 145° F. for 30 minutes. The experiment extended over 11 weeks. The raw milk group gained 100 g. in weight and 2,340,000 red blood corpuscles, the pasteurised milk group gained 66·5 g. and lost 2,300,000 red blood-cells. It is not clear if the figures refer to the bulked six rats or is an average for each rat. It may be mentioned that the pasteurised group did better than two other groups which were fed with unheated milks from other sources.

It will be noted that merely six rats were included in the experiment and the records are so incomplete that very little of any significance can be deduced.

ON PIGS

Orr, Crichton, Crichton, Haldane, and Middleton (1926).[19] Growing pigs were fed on a ration of cereals to which was added either fresh milk, pasteurised milk, or sour milk. The addition to the ration of fresh milk caused the rate of absorption of calcium, phosphorus, and nitrogen to rise rapidly, but this was somewhat depressed when pasteurised was substituted for fresh milk, to rise again when sour whole milk took the place of pasteurised milk. This was shown to be due to the decrease in soluble calcium, since when soluble calcium was added equal to double the amount of soluble calcium lost in pasteurisation a greater retention of calcium, phosphorus, and nitrogen was obtained than when fresh milk alone was added. The increase in the retention of calcium was greater than the amount of soluble calcium added.

Magee and Harvey (1926).[20] Their results are interesting as showing the unsuitability of cow's milk for the young pig. Cow's milk contains on an average 0·16 per cent. CaO, and 0·24 per cent. P_2O_5 with a ratio of 1 : 1·5, whereas sow's milk contains 0·39 per cent. CaO and 0·36 per cent. P_2O_5, a ratio of 1 : 0·92. A young pig on a diet of cow's milk and cereals showed signs of rickets after 30 and Hann (1929–30)[9] found that by lightly boiling 3 quarts of milk for five minutes, after being brought to the boil in about 20–27 minutes in a glass beaker or in an aluminium pan, only 20 per cent. of the vitamin C was destroyed. This is a severer temperature test than pasteurisation.

Schwartze, Murphy, and Cox (1931)[10] deal with pasteurisation temperatures, and studied the influence of aluminium, tinned copper, and copper upon vitamin C content. With aluminium vessels and full aerobic pasteurisation the destruction of vitamin C was 20 to 40 per cent., with tinned copper slightly greater, but in naked copper it was at least 80 to 90 per cent. With anaerobic pasteurisation with the first two compounds they consider the vitamin destruction would be greatly reduced.

It must be accepted that there is some destruction of vitamin C by pasteurisation, but from the practical point of view this is of but little importance, since cow's milk is such a bad source of this vitamin that it ought to be supplemented in any case—i.e., if raw or pasteurised milk is the sole food-supply. As the Medical Research Council report states :

> "Milk is a variable and by no means rich source of the antiscorbutic vitamin. As much as 100 c.c. of some samples of fresh raw cow's milk daily and more may be required if scurvy in guinea-pigs is to be prevented by its agency alone, while as little as 20 c.c. of a summer pasture milk has been found to afford protection."

When these changes are all set down the essential fact which emerges is their comparative insignificance. What they amount to is that the already large proportion of insoluble calcium is increased by about 6 per cent., and possibly there is a similar change in the proportion of insoluble phosphorus. The very small and variable amount of iodine may be reduced by 20 per cent. There is some reduction of vitamin C. There is no evidence of any other significant changes. It may also be pointed out that these changes are much less than the natural variations which occur in different samples of cow's milk. If we are to attach the importance which some would have us do to these slight changes which result from pasteurisation, it is evident that the agricultural interests will have to accept the view that milk to be of value to man must be from cows so fed and treated that their vitamin content is up to standard and that other constituents cannot be neglected.

Comparison of Human and Cow's Milk

It is now evident that while the changes which result when milk is pasteurised are comparatively unimportant some changes do occur. It is important to realise that because there are changes they are not of necessity detrimental changes and damage the nutritive value of the milk for man, an assertion so often made. If we were dealing with the value of milk for the calf it is reasonable to assume that any physical agency which alters in any way the composition of cow's milk is likely to be detrimental to the calf. When, however, it is a question of the value of cow's milk as a food for an entirely different species with widely different metabolic requirements to make such an assumption is entirely unscientific. It may be the case that these changes which result from pasteurisation are wholly or partially beneficial in that they make an alien food rather less unsuitable than it otherwise would be as a food for another species. To assess the significance of any changes shown to occur it is essential to compare raw cow's milk, pasteurised milk, and human milk, both as regards their chemical composition and as regards their suitability as foods for the human species.

In making such a comparison we have to bear in mind the fact that both human and cow's milk vary widely in composition under the influence of different conditions. These differences cannot therefore be conveniently set out in tabular form. It is only necessary to consider in detail those constituents which are affected by pasteurisation.

Average human milk is rather poorer in fat than cow's milk, while there is no evidence of important quantitative differences. Lactose is more abundant in human milk. Since these constituents are not affected by pasteurisation they do not require further discussion.

The proteins show wide differences. In cow's milk caseinogen is approximately 3 per cent., lactalbumin about 0·5 per cent., and lactoglobulin about 0·05 per cent. In human milk the caseinogen is about 1 per cent., and lactalbumin about 0·5 per cent. or rather higher, but various figures are given by different authors. Lactalbumin is richer than caseinogen in the two amino-acids, cystine and lysine, both specially important for growth.

The quantity of ash is about three times as high in cow's milk as in human. The mineral constituents of cow's milk have recently been exhaustively reviewed by Allen (1931), but only some of them need to be discussed. Allen shows that there are considerable differences between individual cows in the calcium and magnesium content of the milk, both as regards the total quantities present and also for those portions present in true solution. Taking average figures, calcium varies from about 0·17 to 0·19 per cent. as CaO, phosphorus from 0·21 to 0·25 per cent. as P_2O_5. The stage of lactation has a definite influence. In human milk there are also considerable fluctuations. Lane-Claypon[6] gives many figures with averages about 0·04 per cent. CaO and 0·04 per cent. P_2O_5.

Telfer (1930)[11] finds the following figures for human milk CaO 0·045, MgO 0·006, P_2O_5 0·048, Fe 0·0001, and in cow's milk CaO 0·16, MgO 0·018, P_2O_5 0·21, Fe 0·00008 g. per cent. The concentration of these minerals showed no appreciable variations at different lactation periods.

Golding, Mackintosh, and Mattick (1932)[12] studied the milk of a typical herd of shorthorn cows over a period of three years. During 1928–29 the highest and lowest percentages of calcium were 0·136 and 0·122, with an average value of 0·127. For 1929–30 the figures varied between 0·140 and 0·115, the average being 0·124. For 1930–31 the figures varied between 0·141 and 0·124, the average being 0·131.

Of other mineral constituents iron is of importance, and Allen remarks "the quantity of iron in cow's milk is approximately one-quarter of that in human milk, and it appears to be independent of the nature of the feed." Davies (1931)[13] found that in fresh cow's milk the iron content ranged from 1·50 to 2·40 parts per million. In ten samples of pasteurised milk it ranged from 1·7 to 3·8 parts per million.

Vitamin A is abundant in both human and cow's milk. The B vitamins are usually adequate in amount in both milks, but in the Medical Research Council Report[7] the authors quote results from Detroit dealing with the amount of human milk required to prevent anti-vitamin symptoms in rats, and state "these results give an indication that human milk may easily be poor in vitamin D and in the B-vitamins. In point of fact there is good evidence that infants at the breast may in some cases suffer from lack of these vitamins." According to Outhouse, Macy, and Brekke (1928),[14] the ratio of calcium to phosphorus is a factor in rats as well as lack of

The insistent demand for calcium by the growing rat is clearly shown by the work of Sherman and MacLeod (1925).[25] They found for the rat that

> "in round numbers the percentage of calcium in the body is found to increase from 0·25 per cent. at birth, to about 0·6 per cent. at 15 days; about 0·7 per cent. at 30 days, 0·75 to 0·85 per cent. at 60 days; 0·95 to 1·1 per cent. at 90 days, and 1·0 to 1·2 per cent. in the adult animal."

While pregnancy does not make such great demands on the rat owing to the little bone in the new-born rat, lactation, owing to the need to supply a milk so rich in calcium, causes a serious drain, as is evident from other results of Sherman and MacLeod, and more specifically in the work of Macomber (1927),[26] who fed rats on a diet intentionally low in calcium. Under these conditions he found that the mother rapidly lost calcium from her body to supply the needs of the growing young, but the young were not able to get all they required and showed signs of lack of calcium by stunting, weakness, and often death.

The same fact is brought out from another angle by Sherman and Muhlfeld (1922)[27] when they showed the superiority of a diet of one-third whole-milk powder, two-thirds ground whole-wheat over one of one-sixth whole-milk, five-sixths ground whole-wheat, measured by increase of young and percentage successfully suckled.

The importance of adequate calcium in the food for young production applies to other animals. For example, Hart and Steenbock (1919)[28] found that lack of calcium in the ration of pigs and cows caused premature births of dead or weakly young.

Since stress is laid by the opponents of pasteurisation upon the diminished fertility of rats fed with boiled milk and upon the allegation that similar results occur when pasteurised milk is used, it is worth while to refer to the considerable literature showing the unsuitability of cow's milk in any form for the rat.

Sherman, Rouse, Allen, and Woods (1919–20)[29] found that young rats on a bread and milk ration, with milk comprising one-fifth of the total calories, made normal growth, but the females usually failed to breed and no young were raised. When the food was altered so that the milk formed two-fifths of the total calories and the rest by ground whole-wheat the young were suckled without undue loss. Mattill and Conklin (1920)[30] found that on fresh milk rats made good initial growth but, beginning between the 50th and 100th day of life, especially in the females, there was a decided retardation, while there was no reproduction. The addition of iron citrate improved growth but reproduction was not successful. With dried milk (a heated milk) and 1 per cent. yeast they obtained normal growth and partially successful reproduction. Mattill, Carman, and Clayton (1924)[31] found this inability to reproduce associated with a milk diet high in fats. Waddell, Steenbock, Elvehjim, and Hart (1928)[32] used as a basal diet whole cow's milk fed fresh every morning, *ad libitum*. Their results showed good growth for four to six weeks, then the weight became stationary, then declined rapidly. With cessation of growth was a marked anæmia with a marked reduction of hæmoglobin. In a later paper (1928)[33] they showed that ashed residues of beef liver and other substances fed with milk cured the anæmia. Waddell, Steenbock, and Hart (1931)[34] found that young rats when kept on a diet of whole unheated milk develop a severe anæmia in the course of a few weeks. While the addition of small amounts of the salts of iron and copper effectively prevented the anæmia, it was found that even with these additions growth and reproduction were still subnormal. Waddell (1931)[35] remarks that total sterility in male rats has been observed on a diet of cow's milk supplemented with small amounts of iron and copper salts. This sterility is characterised by the complete disappearance of the germinal epithelium, great loss in the amount of testicular tissue, and pronounced œdema. He concludes that this sterility is not due to lack of vitamin E.

These experimental results are quoted merely to show how complicated is the problem of anæmia and faulty reproduction in the rat in relation to milk feeding, and the absurdity of basing conclusions as to pasteurisation effects upon slight differences as regards these factors with rats fed upon milk. It is obvious that new unheated milk is unsuitable as a diet for an animal like the rat which grows with great rapidity and reaches maturity at a very early age. Cow's milk does not supply the essential substances in sufficient quantities.

On the general question of the suitability of these animal experiments to obtain findings applicable to man the position is, I believe, clear-cut. When feeding experiments are made with any animal whose normal calcium requirements are equal to or in excess of the calf, the slight diminution in the available calcium of the milk which pasteurisation effects is likely to show itself by diminished growth and other symptoms. To suggest, however, that such results are applicable to man is to ignore the essential fact that the human infant needs much less calcium and phosphorus than are present in cow's milk as shown by the composition of human milk. There is nothing in any of these experiments to indicate that any unknown substance is destroyed by pasteurisation. All the results (such as they are) are explainable on a diminution of calcium and phosphorus fed to experimental animals whose need of these substances is much greater than man. They offer no evidence which can be applied to man.

[In the remaining sections of his paper, which will appear next week, Dr. Savage relates what direct evidence is available on the question whether the value of milk is diminished for the child by its pasteurisation, and discusses the practical bearing of the ascertained changes due to pasteurisation. References are given to all the work quoted.]

MEDICINE AND THE LAW

Liability for Shock without Physical Impact

In the High Court last week a plaintiff was awarded £700 damages for nervous shock due to the fall of a quantity of window glass from a firm's premises. The firm admitted that the glass fell and that it constituted a nuisance; but it did not admit that the plaintiff had suffered nervous shock in consequence, as she alleged. The brief report leaves the facts obscure; the case, however, seems to have been one where personal injury consisted of shock without physical impact. Not every startling accident, of course, gives a right of action; there must be some breach of duty by the defendant (some negligence, for instance) if the plaintiff is to succeed. The damage, moreover, must not be too remote.

In the nineteenth century the courts were disinclined to allow damages for mere shock. It was difficult to prove the incidence of the invisible injury, and there was perhaps what Lord Atkin has called "a belated psychology which falsely removed mental phenomena from the world of physical phenomena." The law was reluctant to give a right of action for the days. The addition of a soluble calcium salt to the diet of cereals enabled the animals fed on it to remain in a thriving condition for 60 days. Under experimental conditions the retention of calcium, phosphorus, and nitrogen was lower with heated milk than with either fresh or sour milk. On the other hand, the addition of calcium chloride to the pasteurised milk caused an increase in the amount of calcium retained which was more than twice the amount added, so that the calcium retention was greater than when fresh or sour milk was given.

ON CALVES

Orr, Crichton, Crichton, Haldane, and Middleton (1926)[10] carried out a series of feeding experiments with calves. The pasteurised milk was from the same source as the raw but pasteurised in one experiment by the "flash" method and in two by the "holder" procedure. They found a lessened increase of weight with pasteurised as compared with fresh milk, but this could be entirely obviated by the addition of calcium lactate to the pasteurised milk. All the calves receiving either fresh milk or pasteurised milk plus the soluble calcium salt remained in perfect health. Those receiving pasteurised milk were not in such good condition as the others, while in one experiment the animals showed definite signs of malnutrition.

ON GUINEA-PIGS

Schroeder (1913)[21] used 467 guinea-pigs, removed from their mothers immediately after they were born and divided into three groups.

Group 1.—155 guinea-pigs fed raw milk.
„ 2.—156 „ „ pasteurised milk.
„ 3.—156 „ „ boiled milk.

The *pasteurisation temperature was 60° C. for* 20 minutes. The experiment extended over a period of ten months. Weight and mortality were the two signs measured (Table II.).

TABLE II.—*Percentage Mortality among the Guinea-pigs*

Mortality.	Young with mothers. Per cent.	Young fed artificially on cow's milk.		
		Raw. Per cent.	Pasteurised. Per cent.	Boiled. Per cent.
First 10 days	4·0	27·74	30·13	27·56
„ 20 „	5·0	40·00	46·16	39·74
„ 30 „	6·0	45·62	51·28	42·95
First year	14·0	52·90	53 85	46·79

The percentage death-rate for the guinea-pigs left with their mothers is based on the young born alive, weaklings as well as others, but no weaklings were selected for the artificial tests. As regards weight, the boiled milk weight record is distinctly better than that of either the raw or the pasteurised milk and the pasteurised drop a little behind the raw.

Schroeder makes the suggestion that possibly the better records with the boiled milk is due to the fact that the milk of a foreign species may contain objectionable elements for another species, and that these are eliminated by the heating. It is an interesting suggestion, but in view of the fact that there was evidence of *Brucella abortus* being present in the raw milk it cannot be accepted as more than a possibility.

THE QUESTION OF THEIR VALIDITY

These animal experiments (particularly with the rat) are so frequently cited by opponents of pasteurisation as evidence that this process damages milk as a food for the human child, that it is necessary to discuss some of the nutritional factors involved which bear upon the validity of these experiments as applied to man.

The needs of the growing animal for proteins, calcium, and phosphorus (to consider *only* certain elements) are conditioned by the rate of growth and by the relative development of bone and of soft tissues. These needs are reflected in the composition of the milk, and Sherman (1927)[22] gives Table III., mainly from the work of Bunge and Abderhalden.

TABLE III

Species.	Days required to double birth weight.	Percentage composition of the milk.			
		Protein.	Ash.	Calcium.	Phosphorus.
Human .	180	1·6	0·2	0·02	0·02
Horse ..	60	2·0	0·4	0·09	0·06
Cow ..	47	3·5	0·7	0·12	0·09
Goat ..	22	3·7	0·78	0·14	0·18
Sheep ..	15	4·9	0·84	0·18	0·11
Swine ..	14	5·2	0·80	0·18	0·14
Rabbit .	6	14·4	2·50	0·65	0·43

The slowly growing human child shows a very low calcium and phosphorus content in its milk as compared to the cow.

Not only is this the case for different species, but we get similar fluctuations in the composition of the milk during lactation to meet the requirements of the young. For human milk this is brought out in *Table IV. from Holt, Courtney, and Fales (1915)*[23]

TABLE IV.—*Human Milk During Different Periods of Lactation*

Stage.	Protein.	Ash.	CaO.	P_2O_5
Colostrum (1–12 days) ..	2·25	0·31	0·0446	0·0410
Transition (12–30 „) ..	1·56	0·24	0·0409	0·0404
Early mature (1–4 mths.)..	1·15	0·21	0·0486	0·0342
Middle mature (4–9 „)..		0·21	0·0458	0·0845
Late mature (10–12 „)..	1·07	0·20	0·0390	0·0304

These facts apply to the cow and other animals but are particularly striking as regards the rat, and as this animal is so much used in nutrition experiments it is important to realise their cogency in relation to pasteurisation.

The rat is an animal which is born largely cartilaginous, and which arrives at sexual maturity when only about 60 days old. It grows at a great rate, and its call upon a very rich milk with abundant calcium and phosphorus is insistent. Hatai (1927)[24] gives the figures for the milk shown in Table V.

TABLE V

Species.	Water.	Percentage composition of solids.			
		Protein.	Fat.	Lactose.	Ash.
Man	87·58	16·22	30·1	51·28	2·39
Cow	87·17	27·68	28·76	38·03	5·53
Rat	54·12	22·11	69·13	5·31	3·50

Unfortunately he does not give the calcium or phosphorus content, but the figures show the enormously high proportion of solids.

a concomitant invader. Rich suggests that this organism, the Bordet-Gengou bacillus, and the influenza bacillus tend to localise in the cilia of the trachea and bronchi, and provoke coughing by the irritative effect of their presence in this sensitive site. Whether or not *Hæmophilus pertussis* is the causal organism, Gardner and Leslie were able to detect it in at least three out of four cases in the early stages of the disease by a single examination, using the cough-droplet or cough-plate method and the Danish modification of the original Bordet-Gengou medium; these results are comparable with those of H. Madsen (1924) and Sauer and Hambrecht (1930) in a much longer series of cases. A. R. Thompson,[4] on the contrary, with the same method and the same medium, freshly prepared, obtained only 7 positive results out of 64 cultures taken during the catarrhal and early spasmodic phase. A. Sundal[5] commonly uses two plates for each child, since he has found that colonies may develop upon one and not upon the other.

With the proviso that a negative result is not conclusive, the cough-droplet method may be accepted as a valuable means of diagnosis of the disease at a period of great infectivity, and when signs and symptoms present nothing characteristic. It is true that leucocytosis, with relative lymphocytosis, occurs quite early in whooping-cough, but even if facilities are available, a high lymphocyte count in very young children may be no more than suggestive, whereas recovery of the *H. pertussis* is conclusive of infection. In the spasmodic phase the diagnosis can hardly be in doubt, but R. Neurath[6] draws attention to the difficulties in infants and adults in whom the disease may remain quite atypical but nevertheless infective.

PROPHYLAXIS

There is difference of opinion as to the prophylactic value of vaccines prepared from *H. pertussis.* H. Madsen and his co-workers have reported a considerable measure of success upon a large scale, and R. Steindler[7] mentions a number whose experience has been similar; others, however, have had no success at all. Gardner and Leslie point out that unless the vaccine is prepared from organisms in the correct antigenic phase it is useless, and it is noteworthy that those who have reported favourably upon vaccine prophylaxis have either obtained the products of certain laboratories or have taken great care to see that they used freshly prepared vaccines from suitable strains. Old stock vaccines are valueless. Sundal gives an instructive account of vaccine prophylaxis in a children's home at Oslo. There were 32 children in the home, of whom 10 had a previous history of the disease. Two children began to cough; the plates were positive. From the organisms so recovered a vaccine was prepared (1000 millions per c.cm.) and injected both into these two children and into the remaining 20 susceptibles in a first dose of 0·5 c.cm. and two succeeding doses of 1·0 c.cm. at intervals of four days. The two children were not isolated, but played and ate with the others. These two developed marked cough with vomiting shortly after the last injection. Four others, between one and two weeks after the last injection, developed conjunctivitis and a cough without whoop. The other 16 children remained free from symptoms. Sundal thinks that it is not reasonable to suppose that without the vaccine these children, with no previous history of infection, could have remained exposed to massive infection without evident whooping-cough developing. L. Sauer,[8] using only vaccines prepared from recently isolated strongly hæmolytic strains grown upon human blood and the like, has injected, during the last four years, about 300 non-immune children without any untoward symptoms. Sauer finds that the vaccine, like the disease, produces a high lymphocytosis. Discussing results, he distinguishes carefully between "certain" and merely "probable" exposure. Only when the patient disseminates the bacilli, and the exposed child in the immediate environment (within a foot or two) aspirates the germ, does actual exposure occur. Sauer gives details of eight injected children of five families and six non-immune controls. All six controls (and a mother) "developed unquestionable whooping-cough from two and a half months to three years after their brothers and sisters had been injected." With one possible exception none of the injected children developed any sign or symptom, although they were daily exposed to the patients throughout the incubation, catarrhal, and paroxysmal stages. Amongst 127 injected children who experienced transient or accidental exposure none developed whooping-cough. Further work with suitable vaccines under adequately controlled conditions is clearly called for.

THERAPEUTICS

A sure sign of the weakness of the therapeutic case is the employment of a multiplicity of dissimilar remedies for the same disease. In the therapy of whooping-cough, counsel is darkened by premature enthusiasm for this specific or that. Steindler recalls the advice of Reitschel, that judgment of any whooping-cough remedy should only be based upon the results obtained in infants and children up to 2 years of age observed under proper clinical conditions, older children and ambulant cases being excluded from consideration. Several recent writers stress the psychological effect of injections in older children. W. Kaupe,[9] like Steindler, is favourably impressed with the therapeutic value of vaccines, and thinks that any psychological influence is purely secondary, since he has obtained good results in infants. W. Bayer asserts, upon the same page, that he has seen equally good results follow injections of distilled water. H. Steurnthal[10] has had such marked success with intramuscular injections of quinine combined with a small amount of oil of turpentine that he has not found it necessary to try vaccines. Some years ago J. Audrain advocated intramuscular injections of ether, and undoubtedly some cases respond temporarily, but ether injections are not only painful, but are generally held to be liable to cause abscesses, although this is not the experience of Sundal. E. Lorenz[11] tried Goldbloom's method of rectal injections of ether in olive oil (2 c.cm. of anæsthetic ether in 15 c.cm. of oil twice daily). He obtained no significant results after a fortnight's treatment of a series of 21 children. Others however have had partial and temporary success with this method, but, in order to be effective for more than a day or two, it is necessary steadily to increase the dose of ether.

As Neurath remarks, the pharmacology of the treatment of whooping-cough fills volumes. It is clear that the last volume has not yet been written. The mere sensation of fright lest, as was said in Victorian Railways Commissioners *v.* Coultas (1888), a wide field should be opened to imaginary claims. Mrs. Coultas saw a train approaching at a level crossing; being put in peril by the railway's negligence, she thought she was going to be killed. The Privy Council held that damages arising from mere sudden terror, unaccompanied by any actual physical injury but occasioning a nervous or mental shock, could not be deemed legally to flow from the railway servant's negligence. A different view was taken in Pugh *v.* London and Brighton Railway (1896) where a signalman was incapacitated through shock due to the excitement and alarm of successfully averting a train smash. He was never in personal danger himself but he was held to have been incapacitated from employment by reason of accident. In 1901 the decision in Dulieu *v.* White awarded damages to a woman who was sitting behind the bar in a public-house when a horse-van, negligently driven by defendant's servant, dashed into the premises. She was untouched, but she sustained shock and gave birth to a child prematurely. She succeeded in her claim though there was still a hint that she would have failed if she had proved no more than a "merely transitory mental emotion." There may be other faulty conduct on the part of a defendant, apart from negligence. Wilkinson and Wife *v.* Downton (1897) was a case of a silly practical joke. Defendant, as the jury found, falsely and maliciously told a woman that her husband had met with a bad accident and broken both his legs; she suffered a severe shock on hearing the news, and was held entitled to succeed. Somewhat similar was the decision in Janvier *v.* Sweeney and Barker (1919). Sweeney, a private detective, instructed Barker to endeavour to induce Mlle. Janvier to show him certain documents. Barker tried to achieve his object by threats and false statements. He pretended he came from Scotland Yard. "You are the woman we want," he said; "you have been corresponding with a German spy." Plaintiff said she had so bad a shock that she suffered from neurasthenia and shingles. She sued for damages and succeeded, the judges definitely discountenancing the decision in Victorian Railways Commissioners *v.* Coultas, on which the defendants relied.

[11] Deutsch. med. Woch., 1932, lviii., 1443.

We see therefore that A may owe a duty to B not to inflict a mental shock on him or her and, if A nevertheless inflicts the shock on B and physical damage ensues, B may have a legal right of action even though (in Lord Phillimore's words) "the medium through which the damage has been inflicted is the mind." One interesting case raises wide questions. In Hambrook *v.* Stokes Bros. (1925) a lorry had negligently been left on a slope at Folkestone with the wheels straight and the engine running. It started off by itself and injured a little girl. Her mother knew the girl was in the road; the mother did not see the accident but she heard the progress of the lorry, which eventually came to a stop close to her; when told by a by-stander of the little girl's injury she knew it was her child. The mother became hysterical through shock and died ten days later in hospital. The judge told the jury that unless death was due to shock caused by fear of harm for herself as contrasted with fear of harm for her child, damages were not recoverable. The Court of Appeal, by a majority decision, held that this was a misdirection. The husband could recover damages if he could prove that his wife's death resulted from shock caused by the lorry running away, that the shock came from something she either saw or realised by her unaided senses and not from something which someone told her, and that the shock was due to a reasonable fear of immediate personal injury either to herself or to her children. It was, we must suppose, natural that a mother should be anxious for her child; the mother's shock would be a reasonable consequence of the lorry-driver's negligence. Atkin, L. J., went further. He was prepared to allow a right of action even to a passer-by on the road "who receives injury in the same way from apprehension of, or the actual sight of, injury to a third party." This opens a wide prospect indeed. A negligent motorist whose driving leads to a gruesome accident at Charing Cross might be sued by dozens of spectators on a crowded pavement. This extension of the law was not necessary to the decision in Hambrook's case, and it must not be taken as an established principle.

PREVENTION AND TREATMENT OF WHOOPING-COUGH

IN a recent communication P. Stocks,[1] discussing the epidemiological features of whooping-cough, expressed the opinion that in London it must now be regarded, in terms of mortality, morbidity, and loss of school attendance, as the most expensive epidemic disease of childhood. Since the disease is only notifiable in certain of the London boroughs its real ravages can only be surmised, but, even so, it is noteworthy that at the present time, as the weekly returns show, considerably more than 600 cases are at present under treatment in the infectious hospitals of the London County Council. Among the common acute specific infections the case-mortality of whooping-cough is rivalled only by that of measles, and for the same reason, the frequency of the secondary infection of broncho-pneumonia. In an address delivered to the Royal Statistical Society on Feb. 21st Mr. A. Bradford Hill, D.Sc., called attention to the heavier mortality of female children, and to the unexplained fact that the death-rates of illegitimate children of 3 months and under are less than those of legitimate children.

THE CAUSAL ORGANISM

What is the primary infection? Most workers accept the Bordet-Gengou bacillus (*Hæmophilus pertussis*) as causal. A. D. Gardner and P. H. Leslie[2] consider that there is "no longer any room for doubt" that it is the true and sole cause, and they give several reasons for this conclusion. Others are not so sure. A. R. Rich[3] does not think that the bacillus represents the whole story, and in this he is not alone. Rich points out that interstitial pneumonia which is characteristic of whooping-cough occurs also in measles and influenza, diseases in which there are strong reasons for suspecting the ætiological rôle of filtrable viruses, and further, that the mononuclear-cell infiltration of the bronchial walls which is to be seen in sections of interstitial pneumonia also occurs in pertussis uncomplicated by pneumonia. He thinks that the true cause of whooping-cough may be a filtrable virus, the Bordet-Gengou bacillus being a secondary invader, and supports his view by adducing distemper in dogs which pertussis "resembles in an extraordinary manner." Distemper is now held to be caused by a filtrable virus, the *B. bronchisepticus* being merely complain that vermin come from her room and that an offensive smell is noticeable. The room is crammed with furniture and bundles of newspapers and it is feared that she will cause a fire. Her mattress is obviously the cause of the smell and the room and the furniture are badly infested with bed-bugs. She is not easy to reason with but I try to make it clear that unless she allows the disinfecting staff to rid the room of vermin, and unless she allows herself to be properly nursed, I shall get a magistrate's order for her removal to a municipal hospital. I am reluctant to interfere with adult persons who deliberately choose to live in a state of filth, but here other persons are affected and she herself is likely to die from inattention. She has lived in this miserable room for 20 years and dreads the idea of leaving it. My next visit is to a delicatessen shop in a residential neighbourhood, the proprietor of which has decided to fry fish for sale, in the basement. Fish-frying cannot be forbidden in London, but is strictly regulated by by-laws, and the difficulty here is the ventilation of the frying room. It will be necessary to have pavement light and ventilation and this will spoil the appearance of his attractive shop-front. I must, however, consider what effects an unventilated room may have on the health of his staff, and I am quite obdurate on the matter. I instruct the sanitary inspector that ventilation must be enforced, by legal proceedings if necessary.

[2] Ibid., 1932, i., 9.

[3] Bull. Johns Hopkins Hosp., 1932, ii., 346.

Next I proceed to a small but expensive flat in the best quarter of my area, whose occupant, a professional man, is dissatisfied with what the sanitary inspector tells him. His complaint is that his wife finds the kitchen dark and badly ventilated. I find that he is using a gas-oven and cooker without a flue and that the kitchen quickly becomes overheated. It is impossible to construct a flue, and I therefore inform him that the ventilation will only be sufficient if he substitutes an electric cooker and fan. As for light, the situation absolutely prevents the access of natural light. From his remarks I gather that he has a tenancy agreement which is proving irksome and he wishes no doubt to enlist my support in his dispute with his landlord. He will be disappointed.

My borough is one of contrasts and after driving half a mile I find myself in a slum area. It is necessary that a sanitary inspector should devote his whole time to supervising these few acres, in a war waged against indifference and squalor. Many of the landlords are willing to do their best for their tenants, but a certain number can only be made to do their duty in removing sanitary defects by formal notice and the threat of legal proceedings. The inspector gets me to referee any cases which he proposes to take to the police-court. The commonest defect is "premises in such a state as to be a nuisance." I have to see two such cases. The rooms to which he takes me first have not been redecorated for some three years. The walls and ceilings are darkened and impregnated with smoke, dirt, and exhalations. Things are even worse than they appear to be, since on scraping away the wallpaper an older and even dirtier one is seen to lie underneath.

Next I am taken by the inspector to a basement tenement where dampness has shown itself on the walls. It can be seen and felt with the hand. There are various legal procedures for dealing with such a defect. It is for me to decide what is to be done. We may be able to make a closing order, prohibiting the use of the rooms for human habitation, or else for use as sleeping-rooms. We may serve a notice to repair, do the work ourselves if the owner defaults and recover the cost. We may regard the dampness as a nuisance. I advise the inspector that the latter procedure will be the most practicable, and we then proceed to discuss the details of the structural work which is necessary. Whilst in the basement I learn that the occupants are newcomers to the borough and have a baby. I make a note of the name and address so that the health visitor may pay a call. The inspector takes the opportunity of asking me to see a house near by, as regards water-closet accommodation. The law requires that one closet be provided for every 12 occupants of a house. This house contains 14 occupants, the majority being small children. I am not disposed to put the landlord to the expense of providing another closet under these circumstances, but I tell the inspector that the matter must be reopened in two years' time.

THE AFTERNOON

After the lunch interval I return to the town hall, intending to spend the afternoon reading and writing at my desk. There are always papers accumulating which have to be dealt with. Later on, I remember that there are two infant consultations in session this day of the week and that I have not put in an appearance lately. At each welfare centre I interview the superintendent, say a word or two to the voluntary helpers, and put my head into the doctor's room. Everything appears to be going smoothly. On returning to my office there is a message waiting for me that a doctor would like me to see a case of suspected scarlet fever. I go out at once in order to get the advantage of the daylight. The patient is a child with a punctate erythema and a slight rise of temperature, but with no other distinctive signs, such as one might expect in the throat or tongue. My advice is to keep the child isolated and under observation. Fortunately, this is possible as the child is an only one and in a comfortable home.

There is a public health committee meeting early next week and the committee clerk comes up to see me. He is the link between me and the town clerk; he keeps me in touch with all official correspondence and drafts the agenda and minutes of the committee. We discuss which of my matters are to be brought before the committee. The public health committee is the one to which I am mainly responsible. There is also a maternity and child welfare and a housing committee. The monthly meetings of the committees loom large on my horizon. Each lasts an hour or so, but into that time a good deal is compressed. A large number of reports and letters are placed before the committee and its decision taken on various matters of detail and policy. Once a month the council meets in public. It is very rarely that I am called upon to speak at a council meeting, but I have to be there to prompt my chairman if he is interrogated on any public health matter.

SOME PERSONAL MATTERS

The foregoing is only a sketch of my duties, which are extremely varied. In addition to being a medical man I have to know something about law, sanitary engineering, and other sidelines. One drawback in my position is that I do not get much clinical experience, but London is fortunately a place where there are plenty of post-graduate facilities. Men in my position have to make up for lack of clinical work by doing plenty of general medical reading. I am a whole-time officer and am therefore debarred from engaging in practice. Apart from this, no undue restriction is placed on any activities which I may wish to pursue out of office hours, such as writing or the teaching of public health. My working week extends from Monday morning to Saturday midday, but it is quite possible for me to take Saturday off from time to time. I am allowed one month's holiday a year, which, subject to arrangement with my deputy, who is a local practitioner, I can take at any time. For one week of the year I attend one of the medical congresses, for which I get special leave of absence. A London M.O.H. is bound to live within his borough or close to it, unless he obtains permission to reside elsewhere, which is not often refused. My evenings and week-ends are usually my own, the only interruptions being occasional telephone calls and requests to see cases of infectious disease. I meet my fellow practitioners at the local medical society or at B.M.A. meetings and committees.

I have left to the last the question of remuneration, and need only say that London boroughs differ somewhat in this matter. Generally speaking, we experienced practitioner realises that there is as yet no specific, and falls back, as he must, upon such symptomatic treatment as, in his experience, has procured alleviation in some at least of his cases. There are only two sheet anchors—sunshine and an abundance of fresh air—but, for only too many children, neither of these is obtainable. For others these conditions are not even sought, because whooping-cough, like measles, is considered as a disease which can be treated without medical advice, or this may be enlisted only at a stage when it can be of little avail.

IRELAND

(FROM OUR OWN CORRESPONDENT)

REFORM IN NATIONAL HEALTH INSURANCE SYSTEM

THE approved societies are concentrating their forces in opposition to the proposals for reform in the National Health Insurance Scheme which are expected to come before the *Dáil* in the near future, and the daily press has been giving expression to their views. The change to which most grave objection is taken is the amalgamation of all the existing approved societies—65 in number—into one "National Health Insurance Unified Society." It is stated that the Bill will provide for equal benefits for equal contributions for all insured persons between the ages of 16 and 70, who are not earning an income exceeding £250 a year, and all such employed must be insured. Manual workers must be insured, irrespective of income. It is pointed out that 43 of the 65 approved societies give additional benefits at present, the additional benefits being of varied nature. It is suggested that these additional benefits which the better managed societies have been able to provide will disappear in the future, and that, in fact, the stronger societies will be compelled to carry the worker on their backs. Despite the protests of the approved societies, it is unlikely that the Government will alter its intention concerning insurance. The concentration of the manifold, but, at present, scattered influences of the several approved societies into one society is not attractive to the medical profession, whose interests up to the present have received little respect from the societies.

THE DOCTOR'S DAY

"Come, tell me how you live," I cried,
"*And what it is you do!*"

XVI.—METROPOLITAN HEALTH OFFICER

THE medical officer of health of a metropolitan borough shares responsibility for the health of a large and populous area with the chief medical officer of the London County Council. The latter is responsible amongst other things for the provision of institutional medical treatment and the medical inspection and treatment of school-children. My borough is a fairly typical one, but administrative arrangements differ greatly in the London boroughs. I live about a mile from my office, which opens at 9 A.M.; it is not necessary for me to arrive before 9.30 A.M., by which time my correspondence has been opened and sorted, all letters of importance being ready for me to read. Amongst those requiring immediate attention are the "complaints," that is, information as to insanitary conditions requiring to be investigated. Some complaints are anonymous; these are not ignored, but entered with the others in a register, so that they may all be accounted for in due course. Notifications of infectious diseases are entered in a register and handed to the sanitary inspectors, unless I decide to visit personally.

I ring for the typist and dictate some letters. Others will be drafted for me by my chief clerk. By this time there is ready for me a report on the disinfections performed on the previous day. I also read over a summary of each health visitor's and sanitary inspector's previous day's work and interview any of these officers that wish to consult me. This will be for the purpose of seeking my advice or to arrange for me to visit premises. I am well isolated from telephone interruptions, but here is a doctor put through to me. He saw a woman yesterday with a sore-throat which he diagnosed as tonsillitis; before leaving the house he decided to take a throat swab; he informs me that the swab has been reported positive to diphtheria but that he said nothing to the patient about this possibility and feels in a difficulty. My obvious course is to visit the patient, advise as to diagnosis, and smooth away any difficulties. It is sometimes forgotten that to swab a sore-throat is to suspect diphtheria, and that a suspect diphtheria must be treated as such until the contrary is proved.

SOME CALLERS

It is now after 10 o'clock and there are persons waiting for interview. The first is a boarding-house keeper. It appears that rats are reported in the neighbourhood and that an inquisitive borough council workman has been creeping along the sewer. He reports that the drain from her house is an old brick one, which has collapsed, thus enabling rats to leave the sewer. She has learnt to her dismay that she is responsible for the repair of the drain, not only on her premises, but as it proceeds under the road to the sewer. The estimated cost of the repair is £50, but she has fallen on lean times and cannot find the money at once. After some discussion it is agreed that the council will do the necessary repairs and that she will repay the cost by instalments. The next caller is an irate father who complains to me about a call paid to his house by a uniformed N.S.P.C.C. inspector. He cites one of my health visitors as being responsible for this invasion of his privacy and appeals to me to protect him from further molestation. The *corpus delicti* is produced, in the person of little Henry. He is pale and flabby, and has bandy legs. His mother, under my cross-examination, admits that the child has not been to hospital about his legs for two months. I speak forcibly to the parents and approve of the health visitor's action. I think I have done Henry a good turn.

Next my old friend Councillor —— comes in. He is retired and has plenty of time to spare. He is much concerned about the welfare of his fellow men, and 20 minutes of my valuable time pass by pleasantly. I next find that a mother and her child with a running nose are waiting to see me. This child was in hospital for three months with scarlet fever. Seven days after its return another child in the family sickened with the disease. I called to see the mother yesterday but she was out, so that she is asked to call here by appointment. There is nothing apparently wrong with the child except the nasal condition. I advise the mother to keep it to itself as much as possible and to take it to the local children's hospital. She is too poor to go to a private doctor. This child is probably a carrier of scarlet fever infection and I detail a woman sanitary inspector to keep it under observation.

OUTDOOR VISITS

It is now 11 A.M. and I have several visits to pay. My first visit is to a room in a respectable working-class street. Here I meet a woman sanitary inspector and see a very old woman more or less confined to bed with some form of paralysis. The neighbours suspected to be suffering from the five major diseases, or to have come from an area declared by the Minister to be infected with any of these. He has also to carry out such disinfection as he thinks necessary and see that the cleaning is done by the master or by the sanitary authority at the master's expense. In the fourth schedule full details are given of the measures to be taken against these diseases, with the exception of yellow fever, which is subject to the International Sanitary Convention (Paris) of 1926. The regulations are issued with an explanatory circular, No. 1296.

County Statistics

The issue of the separate county volumes setting out the results of the 1931 census of England and Wales is proceeding apace. Some sixteen have now been published, two of the latest of which refer to Stafford and Bedfordshire. Both these counties, it is shown, increased between 1921 and 1931 at a slightly faster rate than the country as a whole; though Bedfordshire has gained, Stafford has lost, by migration during the ten years. The only novel feature introduced at the 1931 census provided for a specific return of the "usual residence" of each person, irrespectively of the address at which he or she was enumerated. In neither of these counties did the resident population differ materially from the enumerated. In Stafford, in 44 areas out of 51, and in Bedfordshire, in 12 areas out of 14, the difference—usually a deficiency of enumerated—was less than 10 per 1000. Both counties agree in showing a considerable fall in the average size of family, and accompanying it, a substantial reduction in both the numbers and proportions of persons scheduled as living in the "overcrowded" category (more than two persons per room), the rate of reduction, it is to be noted, showing great improvement over the increases recorded in the previous decade. On the other hand, it must be observed that, in Stafford, of families of six or more persons in size at the recent census there were as many as 2604 housed in but one or two rooms each, so that there is still scope for much improvement in this respect. The average age of the population in these counties has risen by about two years between 1921 and 1931, and in consequence, and in spite of the economic depression, there has been an increase in Stafford of the proportion of the population enjoying the married state.

These county volumes, of which there will be between 40 and 50, comprise the statistics which are of predominantly local interest—viz., populations and acreages of local government, Parliamentary, and certain judicial areas; statistics of private families and the rooms and dwellings in which they live; and distributions of the local populations according to sex, age, and marital condition. Upon completion of the series national volumes will be issued dealing with such subjects as occupations and industries, and summarising the county statistics.

Influenza

There was a further big decline in the number of deaths from influenza last week, the total being 630, compared with 1306 in the previous week. In London there was a corresponding fall from 261 to 130. In Scotland the outbreak is now almost over, for only 44 deaths were registered in the 16 principal towns. Fifteen of these were in Edinburgh.

Details of the number of deaths in particular towns will be found under the heading of Infectious Disease, and the following Table shows the death-rates from influenza (per 1000 per annum) in various groups of great towns during the week ended Feb. 11th. It will be seen that the mortality was reduced in every area except the south-west.

INFECTIOUS DISEASE

IN ENGLAND AND WALES DURING THE WEEK ENDED FEB. 11TH, 1933

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 25 (last week 18); scarlet fever, 1696; diphtheria, 844; enteric fever, 12; acute pneumonia (primary or influenzal), 4106 (last three weeks 3781, 4821, 5151); puerperal fever, 41; puerperal pyrexia, 125; cerebro-spinal fever, 84 (last three weeks 61, 66, 90); acute poliomyelitis, 10; encephalitis lethargica, 17; dysentery, 16; ophthalmia neonatorum, 82. No case of cholera, plague, or typhus fever was notified during the week.

The number of cases in the Infectious Hospitals of the London County Council on Feb. 14th–15th was as follows:—Small-pox, 60 under treatment, 6 under observation (last week 56 and 4 respectively); scarlet fever, 1583; diphtheria, 1572; enteric fever, 8; measles, 291; whooping-cough, 669; puerperal fever, 28 (plus 11 babies); encephalitis lethargica, 231; poliomyelitis, 1; "other diseases," 323. At St. Margaret's Hospital there were 13 babies (plus 9 mothers) with ophthalmia neonatorum.

Deaths.—In 118 great towns, including London, there was no death from small-pox, 1 (0) from enteric fever, 28 (1) from measles, 10 (5) from scarlet fever, 70 (20) from whooping-cough, 38 (7) from diphtheria, 44 (8) from diarrhœa and enteritis under two years, and 1306 (261) from influenza. The figures in parentheses are those for London itself.

The towns which reported the largest number of deaths from influenza were as follows, last week's figures being given in parentheses: Bradford 43 (38), Manchester 41 (87), Hull 40 (49), Liverpool 33 (49), Swansea 30 (25), Sheffield 28 (63), Bristol 27 (62), Birmingham 24 (21), Stoke-on-Trent 24 (34), Norwich 21 (26), Blackburn 20 (16), Bolton 20 (21).

Hull reported 1 death from enteric fever. Five fatal cases of measles were reported from Liverpool, 4 from Birmingham, 3 from Burnley. Deaths from whooping-cough were still widely distributed, 6 being reported from Leeds, 5 from St. Helens, 4 from Wolverhampton, each 3 from Leicester and Liverpool. Diphtheria claimed 6 victims at Liverpool, 4 at Hull.

The number of stillbirths notified during the week was 314 (corresponding to a rate of 47 per 1000 total births), including 38 in London.

WEST HARTLEPOOL INFECTIOUS DISEASES HOSPITAL. Alderman Clarkson, chairman of the health committee, last week opened an infectious diseases hospital at West Hartlepool which has cost £40,000. The scarlet fever block provides accommodation for 22, and the diphtheria block for 16 patients, and provision has been made for 16 sisters and nurses.

receive enough to live in reasonable comfort and have other compensations. Our pay is steady, we have few professional outgoings, and we lose nothing by taking a holiday. When we are ill we receive full pay, perhaps for as long as a year, and after ten years' service we receive a pension if disabled. At the retiring age, which is usually 65, the pension amounts perhaps to half or two-thirds of one's previous salary. In my somewhat detached position I often receive confidences, and whilst I may feel a twinge of envy on hearing of the earnings of the big men of the profession, I know that many men, no worse than myself, have a hard struggle to carry on. I am therefore content to pursue my interesting work for a modest reward, but I could not be happy unless I was an enthusiast for preventive medicine.

PUBLIC HEALTH SERVICES

Economy at Wigan

AT a meeting of the Wigan Education Authority on Jan. 25th reference was made to a special report submitted by Dr. H. Whitehead, medical officer of health, to a joint meeting of the committees charged with child welfare at home and at school, which asked for certain increases of staff and facilities. One of the aldermen remarked that while no doubt it was the duty of the medical officer to submit suggestions to lead to an ideal medical system, some at any rate of the members of that authority were there to think of the people who had to find the money. He mentioned the good average attendance at schools in the town, and thought they could deduce therefrom that the medical services must be sufficient and the authority ought to be extremely reluctant to make the ratepayers spend more money on reorganisation. "I may be a voice bleating in the wilderness," the *Wigan Observer* reports him as saying.

It is indeed true that the percentage attendances at the Wigan schools, for which the alderman paid a generous tribute to the school medical service and attendance officers, has been good for some years past, but this is not a criterion of the adequacy of medical organisation. Children may attend school regularly and yet have defects of serious import for their future health and efficiency. A more valid sign of the need for extension of medical care at Wigan is an infantile mortality-rate of 109 for the period 1921–30, compared with 72 for the whole country. Another that the routine medical inspections are never completed in the year, and even to get through the numbers actually done the work has to be rushed. There are few areas in England where the position is as bad, and no one who has kept a watch on this column from year to year has been in doubt that in health matters Wigan has much leeway to make up. For instance :—

> "Dr. W. Whitehead and his assistants are fighting an uphill battle. Though the report describes good progress made with orthopædic and dental schemes, yet the facts and figures show a great deal more to be done in many directions. . . . The dental staff is much too small, there is one dentist for 13,327 children, while the Board of Education recommended one for each 5000. Dr. Whitehead's statement that there is ample scope for two full-time dental surgeons is on the modest side " (THE LANCET, 1931, i., 1427).

It is for one additional dentist, two altogether, that Dr. Whitehead is now asking. These are only examples to show that what is now sought is not an "ideal" organisation, but one which makes a reasonable approach to the average of progressive areas.

The matter however goes far beyond the local needs of Wigan. If there is there one voice bleating in the wilderness, elsewhere there is a full-throated chorus calling out for reduction of "non-productive" expenditure, and the school medical service is talked of as a luxury and as an "unimportant frill" of education. But surely any practical person would say that the results obtained by coöperation of teachers with school medical service in producing children who are clean, alert, and healthy in mind and body are more important than mere academic attainment. From a financial aspect is it not a sound proposition to lessen the number of those who will be burdens on the community ? An untreated untrained deaf person is rarely self-supporting, and many cripples have to be helped by the ratepayers for the period of life. All these sources of financial loss to the community, with many others, such as rheumatism, causing loss of working time greater than that of industrial disputes, can be minimised by an efficient school medical service at a cost which is relatively trifling. But the work is of little use unless it can be done properly; rushed inspections are almost valueless. Children can be inspected and records made at a rate of 25 or more a session ; but such examination will fail to notice those early signs of disease in the stage when it is most easily cured. Gross defects usually cause the parents to seek advice of their own medical attendant, or at hospital; the less obvious signs, whose detection may mean so much need skilled and careful investigation. No shrewd business man would think it true economy to send out damaged goods; when things are going badly the maintenance of sound quality in the output is a primary consideration for the recovery of prosperity.

Port Sanitation

The new port sanitary regulations which come into operation on May 1st amend and consolidate the measures now in force for preventing sea-borne infection. The master of a ship arriving from abroad is required to ascertain the health of all persons on board and to complete a "declaration of health," countersigned by the ship's surgeon (if any), stating that there have or have not been on board cases suspected to be infectious. For the master who has no surgeon to help him half a dozen clinical signs of serious infectious diseases are mentioned. The master is advised in his own interest to send a wireless report in advance. The declaration of health comes into the hands of an officer of customs who, on finding no infectious disease on board and no epidemic among the rat population, gives free pratique, or, if he suspects either, detains the ship for 12 hours to give time for inspection by a medical officer of the port sanitary authority. Precautions are to be taken not only against cholera, plague, and yellow fever, but against typhus, small-pox, and all epidemic or acute infectious diseases, not including venereal disease. Standing permission may be given to the master of a daily passage boat to disembark passengers on arrival, provided he undertakes to report any suspicion of infectious disease to the medical officer by wireless. Apart from this no unauthorised person may board or leave a ship arriving from a foreign port till the ship is freed from control. Only in special circumstances do tuberculosis and the commoner infectious diseases call for the isolation of the ship. Control is now so complete and confident that mooring stations for detained ships are to be established in the docks. Powers are given to the medical officer to prevent the embarkation of persons removal) of local sources of infection, of unsuspected ocular defects, and of a few other remediable but unobtrusive troubles; occasionally, if the examination were very complete, some actual systemic disease might be discovered in its early stages and checked, but I think not very often. No doubt a proportion of those examined would be relieved of fears which they would not have had the courage to carry to their doctor, and it is to be hoped a fair amount of good advice on personal hygiene would be spread abroad.

But on the debit side would have to be placed the unfortunate and unprofitable discovery of cardiac murmurs, tachycardias and innocent arrhythmias, impaired percussion notes at the right apex, movable kidneys, unconventional blood pressures, pallors simulating anæmia, retroversions of the uterus, tendernesses in the right iliac fossa—all the familiar props of invalidism, all inviting misinterpretation, all capable, if probed too long or too often or mentioned a thought too earnestly, of spoiling a useful life. If the account were cast in terms of human health and happiness is it not doubtful on which side the balance would be found?

But this, Mr. Donaldson might say, is going far beyond what he advocates. He only suggests that women who have reached an age when cancer may begin should be encouraged to visit their doctors regularly to be overhauled.

The difficulties still seem to me great. How often is the examination to be made? How far is it to be carried? What does the doctor undertake to do for the patient? An ad-hoc examination, directed only to the likeliest cancer sites, guarantees nothing and must, I should suppose, be for any patient of ordinary courage cumulatively alarming, and for a timid or introspective one completely demoralising. True, at the last examination the doctor saw nothing abnormal through the vaginal speculum or the proctoscope, but he is to look again in six months or three. How long can this fortunate immunity last? What will he see next time? What kind of reassurance is that which lasts at most six months? On the other hand an examination professing to be a general overhaul must cover a wide and undefinable field. To be worth anything it must be carried at least to life insurance limits, and yet as the patient approaches the age at which the irreversible and final degenerations begin to show themselves the humane examiner will find it harder and harder to decide how far to go, what to reveal, what to reserve, and what advice to give; nor will he easily banish from his own mind the fear of a day on which at some six-monthly examination of a faithful patient he will discover not an early but an inoperable growth.

Let it be conceded at once that we should examine, thoroughly and sympathetically, any patient whom we know or guess to be afraid of cancer. From my own experience I should have supposed we all do so, time and again; carcinophobia is a very widespread disorder, commonest perhaps in healthy young men, and surely it must be uncommon for a patient to be laughed at by his or her own family doctor for an honest if fantastic fear. But periodic examination should, I submit, be confined to the young, should on no account be promoted by propaganda, and should not be directed to a single issue.

The case of London school-children is perhaps worth considering. They are submitted to periodic general examinations in school, which are accepted as a matter of routine, and by general consent do good. But many of them have lately been submitted to repeated examination, accompanied by vigorous propaganda and directed solely to the detection of early rheumatism or even "pre-rheumatism." The arguments used are almost precisely those used concerning cancer, though perhaps they are more insecurely founded. Little stress is laid on the difficulties of diagnosis, none on the dangers of diagnosing rheumatism where none exists, and it is implied that there is some efficacious treatment which would "save the heart" if only it could be applied early.

No one will ever be able to balance the accounts of this campaign, for all its effects can never be known; but those of us who work in schools and in children's hospitals see enough to be sure that there are very big items on the debit side.

I am, Sir, yours faithfully,

Hampstead, Feb. 15th, 1933. LINDSEY W. BATTEN.

MALIGNANCY IN RADIO-ACTIVE PERSONS

To the Editor of THE LANCET

SIR,—In a recent leading article (Dec. 31st, 1932, p. 1439) you say that in 1926 Dr. Martland was the first to publish observations on this important occupational affection. For the sake of historical accuracy, I desire to call your attention to the fact that at the annual meeting of the industrial medicine and public health section of the American Medical Association held in Atlantic City in May, 1925, I presented unmistakable evidence of this fact on the basis of my own investigation which, as far as I know, was the first made public on that question.

My investigation was an original study of the facts of the disease as it appeared in a number of girls employed in the radium plant in Orange, near Newark, New Jersey. The reprint of my paper contained all the essential facts, establishing the occupational origin of this disease to which I gave the name radium (mesothorium) necrosis. But it requires to be said, as pointed out in my address, that as early as September, 1924, Dr. Theodore Blum, a dentist in New York City, in an address before the American Dental Association referred to it in an obscure footnote reading as follows:—

> "During January, 1924, there came under my observation a case of osteomyelitis of the mandible and maxilla, somewhat similar to phosphorus necrosis, which, however, was caused by some radio-active substance used in the manufacture of luminous dials for watches. The condition has been termed 'radium jaw.'"

This note, however, attracted no attention, and has not, as far as I know, been referred to by anyone writing on the subject.

I concluded my paper with the remark:

> "In any event, however, we are dealing with an entirely new occupational affection demanding the utmost attention on the part of those who are in a position to render the necessary technical assistance, but at the same time it is a safe assumption that if the insanitary habit of wetting the brush with the lips is done away with the disease itself will probably tend to disappear, or in any event become extremely rare."

This conclusion has been fulfilled since there have been no entirely new cases in the meantime, although old cases have increased as the facts have come to public notice. I recently had a call from the first case seen by me, a young woman about 32 years of age, who is now in reasonably good health and free from all pain, suffering only from a shortened limb after the disease had settled in the pelvis.

Dr. Martland has done outstanding service in giving technical attention to the true nature of this affection, and his papers on the subject are classics in medical

CORRESPONDENCE

CONTROL OF INFECTIONS IN CHILDREN'S WARDS

To the Editor of THE LANCET

SIR,—The leading article in your last issue should remind those on whom rests the responsibility of sending or receiving children into institutions how serious the risks and consequences of infections may be in such places. There can be no doubt that we are groping towards a partial solution of the problem through the coöperation of medical staffs, administrators, and architects in the planning and building of newer hospitals with smaller ward units. But mere structural arrangement, vitally important though it be, deals with only one aspect of it. In hospitals it may be necessary to do away with large wards and to restrict the number of cots in each room to two, as is suggested in your description of Wieland's new children's hospital in Basle, but this will not be found practicable for all institutions even if it were desirable.

It is of first importance to appreciate which particular infections are most dangerous and what age and type of child most likely to be affected. Most of us with experience of the hospital treatment of children will readily agree with your view that it is the introduction of non-specific infections such as the virus of the common cold or of "influenza," and the mixed flora of broncho-pneumonia, amongst children already ill, that is to be feared more than infection with so-called specific fevers such as measles, diphtheria, and scarlet fever, outbreaks of which are relatively easy to avoid or control. But this view needs reinforcing by recognition of the fact that it is mainly towards the infants that the danger is directed, and that a respiratory or tonsillar infection may be harmless in a 5-year-old child and "of serious clinical consequence" when transmitted to an adjacent infant.

The immediate social importance of this state of affairs is that there is now astir an increasing interest in diseases of infancy, and that this will probably lead to the opening of new hospitals and infants' wards by municipal authorities and other public bodies. This is a matter which should not be contemplated lightly. If this be doubted the recent words of one of the most eminent of the world's pædiatricians should be read: "The herding of infants in separate wards where the individualisation and mothering of the home are wanting, where exposure to infections of the respiratory tract leads to more institutional casualties than one can contemplate with serenity of mind and of heart, is fraught with such danger that one often wonders if it were not better to abolish them altogether . . ."[1] If this be the opinion of one whose hospital appears to the visitor to leave nothing to be desired, well may others search their hearts and question themselves concerning ward infections in hospitals to which they themselves send or receive children for treatment. This danger to infants is well illustrated by the results of the treatment for pyloric stenosis, for which the stay in hospital is usually limited to as short a period as possible. In private practice a mortality of 10 per cent. is expected. In hospitals a mortality of 30 per cent. is frequently exceeded. The risks in other diseases requiring a more prolonged stay can be suspected.

While it is my object to emphasise the danger of ward infections particularly in young infants, I am no advocate of the defeatist policy of closing the infants' wards. My hospital experience—formerly bitter, now less so—convinces me that with thought and care on the part of the staff and nurses, and with proper structural and administrative arrangements, these dangers can be avoided and hospital treatment rendered as safe for the infant as for patients of other ages. Moreover, the study in hospital and the ultimate mastery and avoidance of these infections will throw light on the various disorders so rife amongst the children of the ill-housed classes.

It is difficult to cite brief rules by the application of which ward infections can be avoided. Small ward units with adequate milk kitchen arrangements; facilities for nursing mothers to be admitted with their babies; the segregation of infants into groups of approximately the same ages; the realisation that a sudden loss of weight due to "gastro-enteritis" or "acute intoxication" appearing while the child sojourns in hospital is probably due to a ward infection; the limitation of a nurse's services to one or two babies; the use of lay help if necessary; the recognition of the danger of tonsillitis or septic sores in a nurse; the safeguarding of the nurses' health by adequate holidays and recreation; the recognition of the danger of a discharging empyema infecting another child; the necessity for spare wards so that a ward may be completely emptied once a month for cleansing—these are some of the important points which rise to the mind. But when all this is done, when all techinical details have been ordered and obeyed, success will still wait upon the enthusiasm of the nursing staff, and the interest of a medical staff capable of recognising how little of disease in infancy is due to "feeding disorders," and how much to infection. I am, Sir, yours faithfully,

Newcastle-upon-Tyne, Feb. 19th, 1933. J. C. SPENCE.

EARLY DIAGNOSIS OF MALIGNANT DISEASE

To the Editor of THE LANCET

SIR,—Your annotation and Mr. Donaldson's letter raise the question of the expediency of periodic medical examinations which Mr. Donaldson advocates so warmly and so persuasively. May I be allowed to comment as one generally interested?

The most sceptical of pessimists will scarcely have the hardihood to urge that we should not try to discover malignant and other more tractable diseases in their early stages if we can, and our chances of doing so would no doubt be increased by examining our patients frequently and regularly without waiting for symptoms. A good theoretical case can be made out for the periodic examination of everyone from birth to the onset of old age, and a generation which regarded the human body with the reverence we reserve for our machines would probably arrange for it to be done. Our own generation, however, seems to have more fear of disease than love of health; we ourselves are not free from the belief that it is our sole function to search out abnormalities, to declare them and to correct them if we can, and we are still far from the day when the reproach of having imagined a pathological condition will be esteemed as great or greater than the reproach of having overlooked one. In consequence periodic examination, if it were now instituted, might prove to be a mixed or doubtful blessing.

To the credit of its account could be placed the gradual extension and diffusion of knowledge and understanding of the normal, the discovery (leading to extension or breaking down of the atelectatic area. To await a clear picture of cavity is to risk adherence of the lung to the thoracic wall. The second radiogram on which the decision as to collapse must be made is not to be delayed longer than ten days, because breaking down of the area may occur with terrifying rapidity.

---

[1] Brennemann, J.: Amer. Jour. Dis. Child., 1930, xl., 1.

2. The interesting case described by Dr. Hudson well illustrates the teaching of Turban[1] that natural healing of a cavity, if it is to occur at all, takes place quickly. Conservative treatment is only justified if successive radiograms taken at very short intervals show diminution.

3. The prognosis of the patient with cavitation of the lung is bad; Lydtin[2] traced 771 such patients and found that there was a mortality of 98 per cent. within a few years. Modern methods have rendered the accurate diagnosis of a cavity possible, but an accurate prognosis is a contradiction in terms. It would therefore seem unwise to assure any given patient suffering from this condition that he will survive 10, 20, or 30 years—free to distribute, if only intermittently, tubercle bacilli to his immediate circle.

4. The performance of a partial thoracoplasty to produce collapse of the lower lobe of the lung in phthisis is an operation for which there is no justification, and in no informed European centre is it even contemplated. It is therefore a little surprising to find the recent work of Charrier and Loubat described as giving a balanced view of the modern surgical treatment of pulmonary tuberculosis because in their comparatively small experience these authors appear to have carried out the operation with some frequency.

I am, Sir, yours faithfully,

LAURENCE O'SHAUGHNESSY.

Inn-fields, W.C., Feb. 19th, 1933.

LYMPHO-GRANULOMA INGUINALE

To the Editor of THE LANCET

SIR,—Will you permit me to make clearer a statement in the paper in your last issue by my friend Dr. Stannus? As it stands it might be taken to mean that among 10,000 examinations at the Albert Dock Hospital venereal diseases clinic only two doubtful cases of lympho-granuloma inguinale had been recognised. In fact, since 1920 and up to date, 93 cases of climatic bubo (Scheube), occurring in men of European, Asiatic, and African race, have been recognised in the clinic.

The condition, therefore, has been known and looked for at the hospital. The two doubtful cases have been—one, a young white seaman who had not been away from the coasts of Britain, where the clinical doubt was whether it was climatic bubo; and another, a white seaman, where, although the diagnosis was confirmed by positive skin reaction (Mr. A. H. Walters) and by reproduction of bubo in the guinea-pig by Dr. Marshall Findlay, there could be no reliance on the patient's varying statements as to when and where he had acquired the infection. All the other 92 cases were seafarers, and had acquired their infection in the tropics or sub-tropics. For comparison it is interesting to note that of the many landsmen from the district who have attended the hospital V.D. clinic, none has yet been seen with climatic bubo.

I am, Sir, yours faithfully,

H. M. HANSCHELL,

Hon. Medic[illegible] dical Officer, i/c
V.D. [illegible] Royal
Feb. 20th, 1933.

NON-TROPICAL SPRUE

To the Editor of THE LANCET

SIR,—Unfortunately, my attention has not been called till now to a review of my book "Non-tropical Sprue" which appeared in THE LANCET of Dec. 3rd, 1932, p. 1221. It appears to me that the reviewer has misunderstood my comments and views on some very essential points, and this has occasioned an unjustified criticism of my work. I may add that, as far as I know, no other reviewer of my book has misunderstood me in this manner, so that the fault can hardly altogether lie in my presentation of the subject.

Evidently the reviewer does not realise exactly what is meant by the terms "non-tropical sprue" and "idiopathic steatorrhœa," and he fails to grasp the main purpose of my book. Non-tropical sprue is a sprue-like disease occurring in adult persons who have never been in the tropics. Idiopathic steatorrhœa comprises cœliac disease in children, tropical sprue and non-tropical sprue as near-related, probably identical, diseases. The term "idiopathic steatorrhœa" was introduced in the literature by me in a paper published in THE LANCET (1929, i., 1086) under the title "The Cœliac Affection—Idiopathic Steatorrhœas." The purpose of my monograph is given on the first page in the following words: "The purpose of this work is then to describe the clinical picture of non-tropical sprue, to demonstrate that non-tropical sprue is identical with sprue occurring in the tropics. . . ."

The reviewer says: "Dr. Thaysen has for many years been interested in idiopathic steatorrhœa or, as he prefers to call it, non-tropical sprue." This is not correct, as the terms idiopathic steatorrhœa and non-tropical sprue are not synonymous. Nor is the reviewer correct in saying: "His (Thaysen's) main thesis, as was apparent in his earlier papers, is that non-tropical sprue is identical with tropical sprue and probably with Gee-Herter's or cœliac disease." As cited above, the purpose of my book is to demonstrate that non-tropical sprue is identical with the sprue occurring in the tropics, so that when the reviewer states that "unfortunately his analysis of cœliac disease in children is far from complete," his remark is entirely off the track, as I have not aimed at giving any complete analysis of cœliac disease in children. I have included only those clinical features that might elucidate certain points in the symptomatology of non-tropical sprue.

The reviewer further writes: "He fails to appreciate the striking fact that the majority of adult patients with idiopathic steatorrhœa have a history of diarrhœa and bone deformity during infancy." In saying this the reviewer demonstrates that he does not know the meaning which the term "non-tropical sprue" holds for others and for me. The cases he refers to are described by Parsons and others under the name "cœliac rickets," and they are cases of cœliac disease in children with production of rachitic bone deformity; some cases of such patients live to become adults. Non-tropical sprue, on the contrary, develops in adult persons, and consequently these patients will not present rachitic bone deformities but osteoporosis and a slight degree of osteomalacia. This capital difference seems to have gone quite unnoticed by the reviewer; yet he might have found it peculiar that among the authors describing cases of non-tropical sprue none has demonstrated rachitic bone deformity in this disease.

The reviewer says: "On the other hand, the difference between these two conditions (cœliac literature. By a fortunate coincidence his services were available to the girls since he is city physician in Newark, New Jersey.

MIGRAINE AND PREMENSTRUAL HEADACHES

To the Editor of THE LANCET

SIR,—The difference between Dr. A. P. Thomson and Drs. Macdonald Critchley and Ferguson is of general as well as special interest. It seems a pity that we should spend time in discussing, even nominally, what may be "the" cause of "a" disease. It should be clear by now that "diseases" are what Bentham called "fictitious entities"! And whether the kind of premenstrual headache described by Dr. Thomson is a "migraine variant" or not, is a question best answered according to the "taste and fancy" of those concerned with it. It has no objectivity. A fortiori, when we speak of "the" cause of any fictitious entity we mean, as Mercier said, that factor which most interests us for the purpose. In seeking such "causes" we are really seeking defining-correlatives (for nosological purposes) which may be of singularly little clinical importance, unless making an academic diagnosis of the label-sticking variety be considered important. But, when dealing, in the world of clinical realities, with, say, the complaints of Mrs. Smith about her premenstrual headaches, we have to do, not with defining-correlatives, but with such departures from the fictive normal, present to Mrs. Smith, as experience shows us are germane to the matter. Amongst these a bridged sella turcica is very likely to be prominent. But its relevance is not in the least impugned by the fact that Mr. Smith, who also has a bridged sella turcica, neither menstruates nor has headaches. For, as the theory of organ-inferiorities helps us to understand is the case, a bridged sella, like many another abnormality, may assume importance, or have importance thrust upon it, in times of psychological stress, which it would not otherwise achieve.

Dr. Thomson's original paper[1] does suggest to me that his patients are the subject of what is compendiously called the "masculine protest." Indeed, the woman who is satisfied with her position, *qua* muliebrity, does *not* suffer premenstrual headache; Dr. Margaret Jackson's patient,[2] I am sure, is not one of these. *In the dissatisfied women the pituitary* seems to play, premenstrually, the kind of special rôle that the error of refraction or of muscle balance does in "ocular" migraine, and that conditions of Oddi's sphincter and Vater's ampulla do in the more "bilious" variety.

There is, therefore, much to be said from the psychological point of view in relevance to the whole problem of migraine. Unfortunately, although Drs. Macdonald Critchley and Ferguson do hint that psychical stresses are sometimes obvious, and do use—*not quite correctly—the "rage and humiliation"* cliché for which I must take responsibility, they do not set out the psychological "case," and give no reference other than to Dr. Hilda Weber's capital paper, in which no complete presentation was, I fancy, intended. But, as Dr. Weber does, in some sense, base her remarks on a reference to my views, I will be glad if I may very briefly restate these.

In "Migraine and other Common Neuroses" (1926) I wrote that the man or woman who complains of migraine or of trigeminal neuralgia is, I think, without exception, placed in some situation which gives rise to an unexpressed or unrecognised emotion of, to use Adler's words, rage and humiliation. And again, that if the present psychological state of anyone who seeks relief from migraine be investigated, it will be found that, *although the patient himself will at first deny the fact,* yet always the mental content, in the neighbourhood of the paroxysms, or *during their* persistence, is one that, in Adler's phrase, is coloured by repressed "rage and humiliation" (pp. 48, 78). These statements imply no *theory;* they are based upon many observations and are open to corroboration or refutation. Those who know how to examine, usually agree with me; those who don't often do not. (A little while ago a medical man strenuously disputed with me, for an hour, that *his* inveterate migraine had any such psychological significance. The next day a friend told me, incidentally, that the doctor in question had "always a grievance and never a bob.")

But, although insistent on the *necessity* of the psychological factor, I have always stressed the importance of a complete assessment of the *whole individual* (pp. 64–66) and that it is vital in treatment that the organ-inferiority be remedied or compensated, so far as in our power. If I say that, however meticulous the general treatment, even though relief from paroxysms be obtained, the patient does not become *well* unless the psychological situation is elucidated or *adjusted (p. 77), I am as far from disparaging* general treatment as I am from disparaging psychotherapy in saying (what I believe to be true) that that *alone* does not give the best results.

In a word, the plea overlooked by Drs. Macdonald Critchley and Ferguson (as, inferentially by Dr. Thomson) is one (not found, I think, in Dr. Weber's paper) for examination, diagnosis, and treatment of the *individual as an individual, a whole, a psycho-somatic unity.* Believing that men and women are best dealt with, clinically as well as socially, *as* psycho-somatic unities and not as mind-body-dualities, I find no difficulty in tracing, in every case, in some degree, not only what is called a psychical, but a somatic element, whether or not the latter be organic and morphological or functional and neuro-humoral. Surely it is time we turned away from the dregs of theologico-scholastic Aristotelianism lurking in our muddy talk about clinical entities and specific causes! D. H. Lawrence has put the matter once and for all in his "Last Poems."

> "When I went to the scientific doctor
> I realized what a lust there was in him to wreak his,
> so-called science on me
> and reduce me to the level of a thing.
> So I said: Good-morning! and left him."

The key to understanding migraine and premenstrual headaches and their "variants" lies, not in neurology and in biochemistry—though these play their parts—but in remembering that the sufferers are men and women in this world.

I am, Sir, yours faithfully,
F. G. CROOKSHANK.

Wimpole-street, W., Feb. 11th, 1933.

SURGICAL TREATMENT OF PULMONARY TUBERCLE

To the Editor of THE LANCET

SIR,—Your last issue, with its several references to the active treatment of pulmonary tuberculosis, prompts me to the following comments.

1. The "Fruh-infiltrat" has a *bad* prognosis. The indication for collapse by air is not cavitation but

OBITUARY

SIR GEORGE BEATSON, K.C.B., K.B.E., M.D. Edin.

CONSULTING SURGEON, GLASGOW WESTERN INFIRMARY

We regret to announce the death of Sir George Beatson, which occurred on Thursday, Feb. 16th, at his house in Glasgow in his 85th year.

George Thomas Beatson was the son of Surgeon-General Beatson, an honorary physician to Queen Victoria, who held distinguished appointments in India and saw service in the Crimean war. The son was born in Trincomalee and received his preliminary education at King William's School, Isle of Man, whence he proceeded to Clare College, Cambridge, in 1870. He graduated in arts at Cambridge and went on to Edinburgh for his medical training, taking the M.B., C.M. in 1874, and the M.D. three years later. His professional progress was rapid. House surgeon to Lord Lister, then professor of clinical surgery at Edinburgh, he moved to Glasgow and promptly acquired a professional reputation which led to his appointment as assistant to the Regius professor of surgery. At this time he became attached to the staff of the Western Infirmary, where after long service as assistant surgeon he became full surgeon in 1900. This post he occupied for 13 years, and on his retirement was elected honorary consulting surgeon.

SIR GEORGE BEATSON

[Photograph by Lafayette

During his active work in the wards of the Western Infirmary Beatson became deeply interested in the pathology of cancer as well as a successful exponent of the methods of surgical relief. He grew convinced that the rôle of fat in the ætiology and progress of malignant disease had not received proper attention. Both at operations and at autopsies he believed that he could observe a pigmented condition of the fat in cases of carcinoma. He continued his researches at the Glasgow Cancer Hospital, where he was surgeon, and in a paper in THE LANCET of 1911 he set out his theory, supported by the results of a collaborator. He admitted in that communication that to connect the fat of the body with the causation of cancer was far fetched, but submitted that there was chemical justification for the theory. Since that time much work has been done on the connexion between fatty acids and cancer, but Beatson's special treatment based upon his own theory received no general endorsement.

As quite a young man Sir George Beatson was interested in military affairs. He was an officer in the old Volunteers, and had an administrative medical post with the Territorial Army, during the formation of which he was constantly consulted, and was finally appointed administrator of the Lowland Division. At the same time he began to take an active part in Red Cross organisation, and at the outbreak of the South African war was largely responsible for the fact that the Scottish National Red Cross Hospital of 520 beds played so prominent a part. For these services he was gazetted C.B. in 1902, and five years later K.C.B., receiving also the V.D. and the decoration of the Order of St. John of Jerusalem. In the European war he played a similarly important rôle. He acted as chairman of the Scottish Branch of the Red Cross Society throughout the struggle, did invaluable work in that capacity, and received official thanks, the order of K.B.E. and the decoration of the Legion of Honour, and the Crown of Belgium. It will be remembered that the Scottish Red Cross Society was responsible for the construction of the famous bungalow hospital at Bellahouston, where 1200 beds ministered during the war to the needs of 15,000 sick and wounded, while its construction cost only £100,000.

By the death of Sir George Beatson we have lost a great medical organiser and one whose work had a special influence during critical situations in national affairs.

THEOPHILUS BULKELEY HYSLOP, M.D., M.R.C.P., F.R.S. Edin.

LATE PHYSICIAN-SUPERINTENDENT, THE BETHLEM ROYAL HOSPITAL

The death occurred on Sunday, Feb. 12th, of Dr. T. B. Hyslop, the well-known psychiatrist, in a nursing home after a prolonged illness at the age of 69. He received his medical education at the University of Edinburgh where he graduated M.B., C.M. in 1886, and proceeded to the M.D. in 1890, being already an M.R.C.P. Edin. He early elected to specialise in medical psychology; he studied his subject on the continent, especially in Paris, and at the age of 25 became assistant medical officer at the Bethlem Hospital. He was Gaskell scholar of the Royal Medico-Psychological Association, and took a prominent part in educational questions connected with psychology, and was for a time senior examiner of the Association. In 1909 Hyslop was appointed physician-superintendent to Bethlem, while he was also at different times lecturer on psychological medicine at St. Mary's Hospital medical school and at the London School of Medicine for Women. As a lecturer he was a great success, for his well-informed teaching abounded with witty illustrations of the various phases of his subject, while his great versatility made it easy for him to vary his academic discourses with references to sport and art.

DR. T. B. HYSLOP

[Photograph by Russell

Hyslop wrote a text-book on mental physiology disease and non-tropical sprue) and tropical sprue appears more significant than he suggests." As it is the main purpose of the monograph, however, to demonstrate that non-tropical sprue is identical with tropical sprue, it seems to me the reviewer might reasonably have emphasised his criticism on this particular point by informing me of the differences between these diseases, but he does not—evidently because he has misconstrued the aim of my book. In this connexion I may mention that in his review of my monograph the well-known sprue investigator, Harold H. Scott, says: "Certain small points of distinction exist between cases of tropical and non-tropical sprue, but whether those are sufficiently marked to warrant separation into two entities is doubtful." (*Tropical Diseases Bulletin*, 1933, xxx., 59.)

It seems to me that the possibility that sprue might be due to a disturbance of absorption is discussed clearly enough in the chapter "pathogenesis"; the significance of vitamin D is also mentioned there. Certainly the reviewer must have failed to notice that I recommend (on page 213) the employment of vitamin D in the treatment of non-tropical sprue.

I am, Sir, yours faithfully,

TH. E. HESS THAYSEN.

Amagerbrogade 31, Copenhagen S., Feb. 15th, 1933.

*** The nomenclature of the conditions discussed by Dr. Thaysen in his book which bears the title Non-tropical Sprue: a Study in Idiopathic Steatorrhœa, is not yet common ground. Dr. Thaysen states in his introduction: "In a paper published in THE LANCET (1929), I have tried to show that tropical sprue, '*non-tropical sprue*' *and* Gee-Herter's *disease* (cœliac disease, intestinal infantilism)—grouped together under the term idiopathic steatorrhœa—are very nearly related, probably identical conditions. Subsequently, my work with these symptom complexes has convinced me, not only that these three diseases are nearly related, but that it is the same disease which occurs in the tropics as sprue, and outside the tropics as '*non-tropical sprue*' *in adults and* as Gee-Herter's disease (cœliac disease) in children." A series of cases recently described in this country (Bennett, Hunter, and Vaughan, *Quart. Jour. Med.*, 1932, n.s., i., 603) under the name of "idiopathic steatorrhœa" suggests that most adult patients with idiopathic steatorrhœa have a history dating back into childhood. Two of these cases are included by Dr. Thaysen in his list of cases of *non-tropical sprue occurring* in the literature. The only reference on p. 213 to vitamin D therapy is where, having made the comment on another form of treatment that "it has to be kept up for a long time and of course the bowels have to be watched carefully" Dr. Thaysen adds "the same applies to the ergosterol treatment; irradiated ergosterol is given in doses up to 30–40,000 units a day."—ED. L.

BRITISH EMPIRE CANCER CAMPAIGN

RECEPTION AT DOWNING-STREET

THE Prime Minister and Miss Ishbel MacDonald held a reception at Downing-street on Tuesday evening last, when the guests were invited to see the ingenious film prepared by Dr. R. G. Canti in demonstration of the value of cinematography as applied to the study of tissue culture and cancer research. The cost of the film, whose educational lessons have been explained in the medical press on more than one occasion, was defrayed by the British Empire Cancer Campaign. It displays through microphotography the phenomena attending the cultivation of the living cells of normal and malignant disease, and the action of radium upon them. Through the exhibition the ever-changing condition of living cells could be observed by means of a series of pictures taken at frequent and close intervals over a long period, and subsequently speeded up. The value of such a record depends much on the fact that it can be referred to whenever desired to illustrate and illuminate phenomena observed under different conditions. The original tissue cultures were made at the Strangeways Research Laboratories in Cambridge, Dr. Canti having been associated at the commencement of the work with the late Dr. Strangeways. The apparatus used had to be specially constructed to Dr. Canti's designs, and the film was originally meant for the instruction of scientific workers. Since then its value for exhibition to public audiences has been fully recognised.

H.R.H. the Duke of York was present at the reception, which was largely attended by well-known members of the public who have shown special interest in scientific medicine, and by a representative group of the medical profession.

THE SERVICES

ROYAL NAVAL MEDICAL SERVICE

Surg. Comdr. G. P. Adshead is placed on the retd. list with the rank of Surg. Capt.

Surg. Comdr. H. E. Perkins is placed on the retd. list at own request with rank of Surg. Capt.

Surg. Lt.-Comdr. J. W. Tighe to be Surg. Comdr.

Surg. Lt. R. A. Graff to be Surg. Lt.-Comdr.

ROYAL ARMY MEDICAL CORPS

Col. E. W. Powell, late R.A.M.C., having attained the age for compulsory retirement, is placed on retd. pay.

Lt.-Col. and Bt. Col. G. A. D. Harvey to be Col.

The undermentioned relinquish their appts.: Maj. and Bt. Lt.-Col. J. M. Weddell, R.A.M.C., relinquishes his appt. as Asst. Professor of Military Surg. at the R.A. Med. Coll.

Maj. T. S. Eves to be Lt.-Col.

Lt. A. F. Kennedy to be Capt.

ARMY DENTAL CORPS

Maj. A. K. Macdonald, having attained the age for compulsory retirement, is placed on retd. pay.

The undermentioned Lts. (on prob.) are confirmed in their rank: W. A. O. Roe and C. A. Pank.

ARMY RESERVE OF OFFICERS

Maj. J. A. W. Webster, having attained the age limit of liability to recall, ceases to belong to the Res. of Off.

TERRITORIAL ARMY

Maj. W. G. Shakespeare, R.A.M.C., to be Divl. Adjt., 54th (E. Anglian) Div., vice Maj. A. R. Barlas, R.A.M.C., vacated.

Maj. J. H. Bayley, R.A.M.C., to be Divl. Adjt., 55th (W. Lan.) Div., vice Maj. C. L. Emmerson, R.A.M.C., vacated.

Maj. W. H. Kerr to be Lt.-Col. and to comd. 158th (Welsh) Fd. Amb.

Capt. C. de W. Kitcat resigns his commn.

Supernumerary for service with the O.T.C.—Maj. C. H. Carlton to be Lt.-Col. and to comd. the Med. Unit, Univ. of Lond. Contgt., Sen. Div., O.T.C.

Lt. J. M. F. Whitby (late Essex R.) to be Lt. with seniority.

INDIAN MEDICAL SERVICE

D. K. L. Lindsay to be Lt. (on prob.).

Capts. A. N. Narang, R. Labhaya, and N. C. Ramchandani relinquish their temporary commissions.

FOREIGN DECORATION

The King has given Brevet Colonel Philip Henry Mitchiner, T.D., F.R.C.S., R.A.M.C. (T.A.), His Majesty's Royal licence and authority to wear the Insignia of the Third Class of the Order of St. Sava, which has been conferred upon him by the King of Yugoslavia in recognition of valuable services rendered by him.

of the results as soon as might be for the guidance of His Majesty's Government and the information of the health committee of the League.—Mr. H. Ramsbotham replied: My noble friend is aware of the memorandum and inquiry in question. The effect of the economic depression on the health of school-children is being carefully watched by the Board and the local education authorities, as part of the ordinary work of the School Medical Service, and special measures to safeguard the health of the children are being taken in the areas where the depression is most acute. As stated in the latest annual report of the Board's Chief Medical Officer, the depressed state of industry does not appear to have exerted any measurable physical ill-health upon the child population. In these circumstances my noble friend does not think it necessary to institute a comprehensive inquiry on the lines suggested.

In reply to a similar question addressed by Mr. Gordon Macdonald to the Minister of Health, Sir E. Hilton Young replied: I am aware of the memorandum and inquiry. I do not think it necessary to attempt to supplement by means of another inquiry such as is suggested in the question, which might be both prolonged and costly, the substantial body of information available from official and other sources as to conditions in England and Wales which has, as the memorandum referred to shows, already been communicated to the health section of the League of Nations.

Maternity and Child Welfare

Mr. Hicks asked the Minister of Health whether he was aware that the maternity and child welfare centre in Cumming-street, Finsbury, had been given up, and the municipal midwifery scheme had been abolished on grounds of economy; and whether, in view of his pledges to set the maternal mortality-rate in the forefront of national health services, he would inquire into this reduction of the services of Finsbury.—Sir E. Hilton Young replied: I am informed that the facts are that early last year the borough council decided not to proceed with the erection of a proposed maternity and child welfare centre, and to substitute for the services of the municipal midwives a midwifery service provided by arrangement with the hospitals and nursing associations which serve the borough. I am not aware that there has been any reduction of maternity and child welfare services in this borough, but I have arranged that in ordinary course a review should be made of the working of the midwifery scheme recently instituted.

Changing Ambulance at Boundaries

Mr. Doran asked the Minister of Health if he was aware of the risks involved by the practice of transferring sick patients from one hospital ambulance to another at the various metropolitan and other town boundaries throughout the country; if he would issue a circular to metropolitan and other authorities asking them to discontinue the practice and establish a through service between the hospital and the patient's home; and, if in the absence of compliance with this request, he would introduce a Bill to sanction measures for the enforcement of such a service throughout the country.—Sir E. Hilton Young replied: The working of ambulance arrangements is a matter for the responsible local and hospital authorities, and such arrangements throughout the country as a whole naturally vary in different districts. I shall be glad to consider any evidence with which my hon. friend may desire to furnish me as to injurious effects resulting from existing practices.

Impure Imported Tinned Foods

Sir Mervyn Manningham-Buller asked the Minister of Health whether his attention had been drawn to the recent discovery by a county analyst of harmful bacteria in imported tins of Russian herrings and in condensed milk; and whether periodical analysis of such imported goods were undertaken by his department, or what steps were taken to check the imports of impure tinned goods.—Sir E. Hilton Young replied: I understand that certain brands of herrings and condensed milk have recently come under suspicion, and I am making urgent inquiries into the matter. In answer to the second part of the question, imported foods are examined by the local authorities at the ports of entry, and together with home produced articles also by inland local authorities.

Mr. Drewe asked the Minister of Healther whether, in view of the fact that recent samples of Russian condensed milk had been found to contain staphylococci, he would prevent the importation of Russian condensed milk in the future.—Sir E. Hilton Young replied: I understand that certain brands of imported condensed milk have recently come under suspicion, and I am making urgent inquiries into the matter. I may add that the presence of staphylococci in condensed milk does not necessarily make it injurious to health.

Death from Generalised Vaccinia

Mr. Groves asked the Minister of Health whether his attention had been drawn to the inquest held at Liverpool on Jan. 20th upon the body of an infant named Donald Hardy, whose death was attributed by the verdict of the jury to vaccination; and whether his medical officers had any explanation to offer as to why Government lymph, which was used in this case, should have led to this result.—Sir E. Hilton Young replied: Yes, Sir. I have made inquiries into this case and I am advised that there is no doubt that this child died from generalised vaccinia, a very rare sequel of vaccination, which is explicable only on the assumption of a peculiar susceptibility of the individual to the vaccine. The same batch of lymph had been used for at least 1200 other vaccinations without ill-effect.

MONDAY, FEB. 20TH

Notification of Leprosy

Major Procter asked the Minister of Health why leprosy had not been made a notifiable disease; and if he was prepared to make it notifiable.—Mr. Shakespeare (Parliamentary Secretary to the Ministry of Health) replied: My right hon. friend is advised that in the conditions which exist in this country leprosy is very unlikely to be conveyed from one person to another. The number of imported cases is very small, and no instance is known in which infection has resulted from contact with them. My right hon. friend is advised accordingly that compulsory notification is not required in the interests of the public health.

TUESDAY, FEB. 21ST

Health Insurance Benefit in Scotland

Mr. Duncan Graham asked the Secretary of State for Scotland if he was aware that regional medical officers in the employment of the Department of Health were in the habit of recommending disallowance of health insurance benefit in cases of persons who had not fully recovered from their illness but who were described as being fit for some form of light employment; and if he would state the number of persons whose benefit had been stopped on this ground during the years 1931 and 1932.—Sir Godfrey Collins replied: It is not the function of the regional medical officers of the Department of Health for Scotland to make any recommendation with regard to the stoppage of National Health Insurance benefit in the case of insured persons who have been examined by them, and in no case do they do so. The duty of these officers is to furnish the insured person's approved society with an opinion as to his capacity for work. The decision as to the continuance or stoppage of benefit rests with the approved society from whose decision the insured person has a right of appeal. I have no information regarding the matter referred to in the latter part of the question.

Mr. Duncan Graham asked the Secretary for Scotland whether he was aware that a letter had been sent to the insurance committee of the burgh of Glasgow, from the Department of Health for Scotland, to the effect that medical practitioners were signing certificates entitling persons to payment of health insurance benefit who were sufficiently recovered from their incapacity to enable them to resume their ordinary employment; whether this letter was issued by his authority; and, if so, would he state the grounds upon which it was sent.—Sir Godfrey Collins replied: In the ordinary course of administration an annual circular letter on the subject of the issue of certificates of incapacity for work to insured persons was recently sent by the Department of Health for Scotland to each insurance committee in Scotland. With the letter were enclosed statistics showing (1) the extent to which such certificates had been issued during the year ended June 30th, 1932, by each insurance practitioner in the insurance committee's area, and (2) the results of re-examinations by the Department's regional medical officers of insured persons to whom certificates of incapacity had been issued. The letter, of which I am sending a copy to the hon. Member, asked insurance committees to inquire into the problems presented by the statistics both as regards their area as a whole, and in respect of individual practices, and called attention to the importance of correct certification and to the unfortunate results accruing from laxity in this respect.

Royal Devon and Exeter Hospital.—The annual report states that at the end of September last 17 cases of fractured femur, the result of road accidents, were being treated, and that the average stay of these patients was between three and four months. The average stay of the 3122 in-patients was 20½ days, and the average cost per occupied bed was £129 14*s.* 7*d.* Out-patients made 57,700 attendances.

PARLIAMENTARY INTELLIGENCE

NOTES ON CURRENT TOPICS

Accused Persons and Medical Certificates

On Monday, Feb. 20th, the House of Commons went into Committee of Supply on Civil Service Estimates. Captain BOURNE, Deputy-Chairman of Committees, was in the chair.

On a supplementary vote of £7500 for the salaries and expenses of the Lord Advocate's Department and other law charges in Scotland,

Mr. HORE-BELISHA (*Financial Secretary to the Treasury*) said that this increased expenditure was in regard to criminal prosecutions in Scotland. It arose from the Scottish Amalgamated Silks case.

Mr. McGOVERN said that one of the circumstances which arose in connexion with this Amalgamated Silks case was that Mr. John Gardiner, on the production of a medical certificate, was discharged. It was alleged that prominent members of the House of Commons did a considerable amount of interviewing and appealing in connexion with Mr. Gardiner when he was released. He was 57 years of age, and to his (Mr. McGovern's) knowledge had fairly decent health. Two other persons were also discharged. The accused were sent for trial and one man was discharged from the dock—again on the production of a medical certificate. It seemed to him that the judicial régime in Scotland at the moment was pursuing a policy of recognising the production of medical certificates in cases of people of substance and wealth, and that such persons were being discharged fairly readily on production of certificates of ill-health. The result of this great trial, involving about a dozen people, was watered down by the production of medical certificates and in various ways. He wanted to know if the production of medical certificates was part and parcel of the policy being pursued by the Lord Advocate and the Scottish Office in order to allow people of substance to evade their responsibilities.

Mr. NORMAND (*Solicitor-General for Scotland*) said he regretted that the Lord Advocate was prevented by illness from being present to reply to the attack which had been made upon him. For the suggestion that there had been some differentiation in favour of those who were well-to-do, and that others who were less well-off had been placed on trial, there was no shadow of reasonable ground whatever. It would be impossible for one to conduct the criminal administration of the law in Scotland if it were to be supposed that everybody originally charged must be brought to trial. He repudiated in the most emphatic terms the suggestion that the administration of justice in Scotland was open to suspicion by any reasonable man on the assumption that a man who was well-off would receive more favourable treatment than anybody else.

Mr. BUCHANAN said that he believed sincerely that the Lord Advocate's Department, presided over by the present Lord Advocate in Scotland, was corrupt at the present time. As soon as the Lord Advocate returned he would be prepared to face him in the House of Commons and say that his Department was corrupt, and that he himself was not capable of conducting his Department in a way that any business man would allow his department to be conducted. John Gardiner was liberated on the grounds of ill-health, and the evidence of that was a doctor's certificate. But the doctor was not examined on oath as to its correctness or otherwise. The certificate was sent to the Lord Advocate who was the sole custodian.

Mr. ALBERT RUSSELL: Does the hon. Member accuse the doctor of giving a false certificate?

Mr. BUCHANAN: No, but I say that he should go into the witness-box and be examined.

Mr. RUSSELL: A doctor gives a certificate on his soul and conscience, and he stakes his reputation on it.

Mr. BUCHANAN said that even if the doctor did that he had his duties as a citizen, and he should be examined on his medical evidence. When a doctor gave a certificate under National Health Insurance that a man was sick, he did it upon his soul and conscience, but it was not taken as final, and the man had to go to the regional doctor.

Mr. SKELTON (Under Secretary of State for Scotland) said it was most unfortunate that these attacks upon the professional conduct of the Lord Advocate should be made in his absence through illness. He did not propose to reply to them, but he most emphatically registered his protest.

After further debate,

The supplementary vote was agreed to by 178 votes to 2.

HOUSE OF COMMONS

THURSDAY, FEB. 16TH

The Children Act, 1932

Mr. LEES-JONES asked the Home Secretary when the whole of the *Children Act, 1932*, would be put into operation.—Sir J. GILMOUR replied: It was my original intention to bring this Act into operation on April 1st, but I hope to be able to introduce shortly a Bill to consolidate this Act with other enactments relating to children and young persons. It will be greatly for the convenience of those responsible for the administration of these Acts that the provisions of the Act of 1932 shall not come into force until the Consolidation Bill has passed into law. This may mean a short delay, but I intend that these provisions shall be brought into force in any case before the Summer Recess.

Privacy at an Inquest

Mr. COCKS asked the Home Secretary whether he was aware of the anxiety concerning the circumstances of the death by poisoning on Dec. 25th at St. Stephen's Hospital, Chelsea, of Madame Zeinep Vlora, an Albanian subject; whether permission was granted by his department to dispense with the usual public coroner's inquest, and, if so, for what reason and by whom was the request made; for what reason the death of Madame Vlora was kept secret for a month; whether any report on the case was made by the police; whether he could state its nature; and whether he would make a statement with a view to relieving the anxiety aroused by this affair.—Sir JOHN GILMOUR replied: I am not aware of the existence of any anxiety in this matter. Questions of diplomatic privilege arose in connexion with the attendance of witnesses at this inquest, and it was as a result of this being communicated to the coroner that, in the exercise of his discretion, he decided not to hold the inquest in public. The death was registered in the ordinary way on the day after the inquest.

Open-air Nursery Schools

Viscountess ASTOR asked the Parliamentary Secretary to the Board of Education the total number of children who entered school at the age of 5 last year after attending open-air nursery schools; and what proportion of these were free from mental or physical defects.—Mr. HERWALD RAMSBOTHAM replied: I am afraid no information is available which would enable me to give the figures in question, but I am aware that certain data may be obtained by individual authorities in the course of their administration of the School Medical Service, and I should be happy to send the noble lady any information on the subject which may be available.

Viscountess ASTOR: Is it not true that of the children entering in the ordinary way 37 per cent. are physically defective in some way or other, while of those who come from open-air nursery schools only 7 per cent. have any physical defect; and would it not be a very good thing for the Government to go on encouraging open-air nursery schools during this terrible depression?

No further answer was given.

Economic Depression and Public Health

Mr. RHYS DAVIES asked the Parliamentary Secretary to the Board of Education whether his attention had been called to the memorandum prepared by the health section of the League of Nations on economic depression and public health, and to their inquiry into the effects of the crisis on public health; and whether he would institute a comprehensive inquiry on these lines in Great Britain in respect of children of school age, with a view to the publication

NORTH-WEST LONDON MEDICAL SOCIETY.

TUESDAY, Feb. 28th.—9.30 P.M. (at the Willesden Constitutional Club House, 110, Walm-lane, N.W.), Dr. J. Stanley White: Recent Advances in Biological Therapy.

HUNTERIAN SOCIETY.

MONDAY, Feb. 27th.—9 P.M. (in the London Mansion House), Sir T. Crisp English: The Language of Facts. (Hunterian oration.)

WEST LONDON MEDICO-CHIRURGICAL SOCIETY.

FRIDAY, March 3rd.—8 P.M. (at West London Hospital, Hammersmith-road, W.), Clinical and Pathological Meeting.

LONDON ASSOCIATION OF THE MEDICAL WOMEN'S FEDERATION.

TUESDAY, Feb. 28th.—8.30 P.M. (at B.M.A. House, Tavistock-square, W.C.), Miss F. M. Huxley: American Experience.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

ROYAL COLLEGE OF PHYSICIANS, Pall Mall East, S.W.

TUESDAY, Feb. 28th.—5 P.M., Dr. R. Cruickshank: Pneumococcal Infections. (Second Milroy lecture.)

THURSDAY, March 2nd.—5 P.M. (Last Milroy lecture).

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, W.

MONDAY, Feb. 27th, to SATURDAY, March 4th.—MEDICAL SOCIETY OF LONDON, 11, Chandos-street, Cavendish-square. Practical Problems in Medicine and Surgery. Tues., lecture by Mr. J. P Lockhart-Mummery on the Causes and Treatment of Incontinent Anus, at 4 P.M. (Free to Members and Associates of the Fellowship.)—NATIONAL TEMPERANCE HOSPITAL, Hampstead-road, N.W. Evening M.R.C.P. Course. Mon. and Fri., at 8 P.M.—PRINCE OF WALES'S HOSPITAL, Tottenham, N. Post-graduate Course in Medicine, Surgery, and the Specialties. All day instruction.—HOSPITAL FOR CONSUMPTION, Brompton, S.W. Post-graduate Course in Practical Pathology dealing with Laboratory Methods and the Interpretation of Results. Mon. and Thurs., 11.30 A.M. to 1 P.M.—NEW GENERAL HOSPITAL, Southend-on-Sea. Week-end Course of Practical Demonstrations in General Medicine and Surgery. Sat. and Sun., all day.—(Courses, &c., open only to Members and Associates of the Fellowship of Medicine.)

ST. MARK'S HOSPITAL, City-road, E.C.

THURSDAY, March 2nd.—4 P.M., Dr. Norman Henderson: The Value of the Opaque Enema in the X Ray Diagnosis of Pathological States of the Large Intestine.

CENTRAL LONDON THROAT, NOSE, AND EAR HOSPITAL, Gray's Inn-road, W.C.

FRIDAY, March 3rd.—4 P.M., Mr. W. A. Mill: The Diagnosis of Acute Mastoiditis.

SOUTH-WEST LONDON POST-GRADUATE ASSOCIATION, St. James's Hospital, Ouseley-road, Balham, S.W.

WEDNESDAY, March 1st.—4 P.M., Dr. H. C. Cameron: Demonstration of Children's Ailments.

ROYAL NORTHERN GROUP OF HOSPITALS.

WEDNESDAY, March 1st.—3.15 P.M. (at the Royal Chest Hospital, City-road), Dr. J. Maxwell: Empyema.

LONDON SCHOOL OF DERMATOLOGY, St. John's Hospital, 49, Leicester-square, W.C.

TUESDAY, Feb. 28th, and THURSDAY, March 2nd.—5 P.M., Dr. W. Griffith: Eczema. (Chesterfield lecture.)

ST. PETER'S HOSPITAL FOR STONE, Henrietta-street, W.C.

WEDNESDAY, March 1st.—3 P.M., Mr. A. C. Morson: Relation of Genito-urinary Symptoms to Diseases of the Nervous System.

NATIONAL HOSPITAL, Queen-square, W.C.

MONDAY, Feb. 27th.—2 P.M., Dr. Riddoch: Out-patient Clinic. 3.30 P.M., Dr. Hinds Howell: Vascular Diseases of the Nervous System.

TUESDAY.—2 P.M., Dr. Walshe: Out-patient Clinic. 3.30 P.M., Dr. Martin: Demyelinating Diseases of the Nervous System.

WEDNESDAY, March 1st.—2 P.M., Dr. Martin: Out-patient Clinic. 3.30 P.M., Dr. James Collier: Clinical Demonstration.

THURSDAY.—2 P.M., Dr. Kinnier Wilson: Out-patient Clinic. 3.30 P.M., Dr. Walshe: Cerebral Tumours.

FRIDAY.—2 P.M., Dr. Adie: Out-patient Clinic. 3.30 P.M., Dr. James Collier: Virus Diseases of the Nervous System.

KING'S COLLEGE HOSPITAL MEDICAL SCHOOL, Denmark-hill, S.E.

THURSDAY, March 2nd.—9 P.M., Dr. J. L. Livingstone: The Treatment of Lobar Pneumonia.

LONDON JEWISH HOSPITAL, Stepney Green, E.

THURSDAY, March 2nd.—4 P.M., Miss M. Landau: Sterility.

NATIONAL COUNCIL FOR MENTAL HYGIENE.

WEDNESDAY, March 1st.—5.30 P.M. (at 11, Chandos-street, Cavendish-square, W.), Dr. J. A. Hadfield: Anxiety.

ST. MARY'S HOSPITALS, Manchester.

FRIDAY, March 3rd.—4.15 P.M. (at the Whitworth-street West Hospital), Dr. Dougal and Dr. Brentnall: Antenatal Demonstrations.

MANCHESTER ROYAL INFIRMARY.

TUESDAY, Feb. 28th.—4.15 P.M., Mr. A. H. Southam: Thyrotoxicosis.

FRIDAY, March 3rd.—4.15 P.M., Dr. A. Ramsbottom: Demonstration of Medical Cases.

GLASGOW POST-GRADUATE LECTURES.

TUESDAY, Feb. 28th.—3.30 P.M. (in the Faculty Hall, St. Vincent-street), Dr. W C. Macartney: Some Diagnostic Points in the Complications of Otitis Media.

WEDNESDAY, March 1st.—4.15 P.M. (at the Lock Hospital), Dr. D. Watson: Venereal Diseases (Female).

Vacancies

For further information refer to the advertisement columns

Aberdeen University.—Lecturer in Medicine. £400.

Bolingbroke Hospital, Wandsworth Common, S.W.—Hon. Surgeon to Ear, Nose and Throat Dept. Also Part-time Pathologist.

Bradford Municipal General Hospital, St. Luke's House.—Phys. and H.S.'s. Each at rate of £150.

Brighton, Royal Sussex County Hospital.—H.S. £150.

Brighton, Sussex Maternity and Women's Hospital.—Res. H.S. £130.

Burnley, Victoria Hospital.—H.P. At rate of £150.

Cambridge, Addenbrooke's Hospital.—Two H.S.'s and Res. Anæsthetist and Emergency Officer. Each at rate of £130.

Cambridge, Papworth Village Settlement.—3rd Asst. M.O. £300. Also H.P. At rate of £150.

Charing Cross Hospital, W.C.—Med. Reg., Surg. Reg. Each £150. Registrar to Nose, Throat and Ear Dept. £100. Also Part-time Medical Registrar. £50.

Chester, East Lancashire Tuberculosis Colony, Barrowmore Hall, Great Barrow.—H.P. At rate of £100.

Connaught Hospital, Walthamstow, E.—Res. H.P. At rate of £100.

Coventry and Warwickshire Hospital.—Res. H.S. £125.

Dover, Royal [illegible] M.O. £180.

Farnborough [illegible] *Kent.*—Asst. M.O. £250.

Guernsey Stat[illegible]—Mental Officer. £800–£1000.

Hendon Isolation Hospital.—Res. M.O. and Asst. M.O. £500.

Lenham Sanatorium.—Asst. M.O. £400.

Liverpool, David Lewis Northern Hospital.—Cas. O. At rate of £120.

Liverpool Royal Babies Hospital, Woolton.—Res. M.O. At rate of £90.

Liverpool, Walton Hospital.—Res. Asst. M.O. £200.

L.C.C.—Temporary District M.O.'s. £140–£200. Pathologist at Group Laboratory, Mile End Hospital. £1100. Also Asst. Pathologist to Group Laboratories. Each £650.

London Homœopathic Hospital, Great Ormond-street, W.C.—Phys. Also M.O. for X Ray Dept.

Manchester [illegible] s. H.S. £120.

Manchester [illegible] *s of the Throat and Ch*[illegible] torium. £200.

Manchester [illegible] *le-street.*—Two Asst. M[illegible] t rate of £150.

National Te[illegible], *N.W.*—Hon. Asst. Physician.

Northampton General Hospital.—H.P. and H.S. Also H.S. to Ear, Nose and Throat Dept. Each at rate of £150.

Nottingham General Hospital.—H.P. At rate of £150.

Oswestry, Shropshire Orthopædic Hospital and Agnes Hunt Surgical Home.—H.S. At rate of £200.

Oxford County and City Mental Hospital, Littlemore.—Asst. M.O. £400.

Plymouth City General Hospital.—Med. Supt. £1000.

Portsmouth, St. Mary's Hospital, &c.—Third Asst. Res. M.O. £250.

Preston, Sharoe Green Hospital.—Res. Asst. M.O. At rate of £150.

Queen's Hospital for Children, Hackney-road, E.—H.P. and Cas. O. Each at rate of £100.

Radium Institute, Ridinghouse-street, W.—Res. Surg. Reg. At rate of £250.

[illegible] . H.S. At rate of £100.

[illegible] *ast, S.W.*—Membership.

[illegible] *Southwark, S.E.*—H.S. At rate of £150. Also Asst. H.S., Clin. Bacteriologist, and Pathologist. Each £100.

Royal National Orthopædic Hospital, 234, Great Portland-street, W.—H.S. At rate of £150.

St. Albans and Mid-Herts Hospital and Dispensary.—Res. H.S. £150.

St. John's Hospital for Diseases of the Skin, 49, Leicester-square, W.C.—Out-patient and In-patient Med. Regs. Each £50.

St. Mary's Hospital, W.—Director of V.D. Clinic. £400.

St. Peter's Hospital for Stone, &c., Henrietta-street, W.C.—H.S. At rate of £75.

Salford Royal Hospital.—H.P. and H.S. Also Cas. H.S. Each at rate of £125.

Shrewsbury, Royal Salop Infirmary.—Res. Surg. O. £250. Also Cas. O. and Res. Anæsthetist. At rate of £160.

Stafford County Mental Hospital.—Temp. Asst. M.O. £400.

Sutton and Cheam Hospital.—Res. M.O. £150.

Swindon and North Wilts Victoria Hospital.—Res. M.O. At rate of £125.

West [illegible] *ital.*—Res. H.P. At rate of £200.

West [illegible] *mmersmith-road, W.*—H.P. Two [illegible] Also Res. Anæsthetist. Each [illegible]

Weston-super-Mare General Hospital.—Res. H.S. £150.

Whipps Cross Hospital, Whipps Cross-road, Leytonstone, E.—Specialist Consultant Gynæcologist. £50, and £5 5s. per visit.

The Chief Inspector of Factories announces vacant appointments for Certifying Factory Surgeons at Droitwich, Worcester; Wells, Norfolk; Almondbank, and Methven, Perth.

MEDICAL NEWS

University of Oxford

In a congregation held on Feb. 11th the degree of Bachelor of Medicine was conferred upon Charles Hilton Fagge.

University of London

On Tuesday, March 14th, Dr. C. Bruce Perry will read a lecture, which was prepared by the late Dr. Carey Coombs, on Thirty Years' Progress in the Study of Rheumatic Heart Disease. The lecture will be given at 5.30 P.M., at University College Hospital medical school, Gower-street, W.C., and Dr. F. J. Poynton will take the chair.

Royal College of Surgeons in Ireland

The Mary Louisa Montgomery lecture was delivered in the hall of the college on Feb. 17th by Mr. Maurice H. Whiting, who took as his subject Modern Developments in Cataract Extraction.

Gresham College

Four lectures on Health and Industry will be given by Sir George Newman at this college, Basinghall-street, London, E.C., at 6 P.M. on Feb. 28th and March 1st, 2nd, and 3rd. Admission without ticket.

A High Mental Recovery-rate

Reporting on his annual visit to the Stirling District Mental Hospital at Larbert, Dr. H. C. Marr, senior commissioner of the Scottish Board of Control, states that 76 patients were discharged as cured, a recovery-rate of 53·9 per cent., which is much above the average in Scottish mental hospitals. Dr. Marr suggests that the rate may have some relation to the use of physical therapy.

International Congress of Hydrology

The 14th International Congress of Hydrology, Climatology, and Medical Geology will be held at Toulouse from Oct. 4th to 8th, under the presidency of Prof. Paul Sabatier and Prof. E. Abelous. The subjects of discussion will be the thermo-mineral waters of the French Pyrenees and their geological grouping; the rare gases of mineral waters; climatic cures and pulmonary tuberculosis; indications for bracing cures for children; primary non-suppurative infections of the nervous system; utilisation of the French spas by the army medical corps; and the legal control and survey of mineral waters. Sir James Purves-Stewart will introduce the English report on nervous infections. Further particulars of the congress may be had from Prof. Serr, hon. general secretary of the congress, at the Faculté de Médecine, Toulouse, Haute Garonne, France.

Moorfields Hospital Dinner

The annual dinner of past and present students of the London Royal Ophthalmic (Moorfields) Hospital was held at the Langham Hotel on Feb. 9th, with Sir Arnold Lawson in the chair.

Mr. Charles Goulden, dean of the medical school, stated that the school was in a flourishing state. During the year 1931–32, 117 students had attended the practice of the hospital, and of these 67 were new students. A total of 328 lectures had been given. The school still prepared by far the largest proportion of students who sat for the diploma of ophthalmological medicine and surgery. During the past year, of 31 candidates who were successful in the first part of the examination for this diploma, 21 received their instruction at Moorfields, and of the 31 who were successful in the second part, 25 were students of the hospital. Rebuilding of the out-patients' department and the medical school will begin in March, and when it is completed the facilities for clinical instruction and laboratory teaching will be greatly improved.

Radium in West Sussex

On behalf of the Sussex council of the British Empire Cancer Campaign, Lord Leconfield, Lord-Lieutenant of the county, at a meeting at Chichester on Jan. 20th, handed over a gift of 75 mg. of radium for the Royal West Sussex Hospital. Fifteen months ago a campaign was launched whose objects were: (1) the provision of radium for the treatment of cases in West Sussex; (2) a supply for East Sussex; and (3) the establishment of a deep ray therapy plant in a central place in the county. The first object has now been achieved by the distribution of over 75,000 leaflets and the collection of over £4000. In receiving the gift the Mayor of Chichester said that heretofore the nearest place where radium treatment could be obtained was Southampton, and travelling north from Chichester there was nothing to be found between it and London. The hospital had possessed since 1930 some 36 mg. of radium, the cost of which was £513.

London Jewish Hospital

A surgical ward has been given to this hospital by Mrs. Dickman. It will be known as "The Esther Mohnblatt Ward"—from the donor's maiden name.

Heating and Ventilation

A paper on Recent Developments in the Warming and Ventilation of Buildings will be read by Mr. J. L. Musgrave, past president of the Institution of Heating and Ventilating Engineers, at a meeting of the Royal Society of Arts which will be held at its premises in John-street, Adelphi, London, W.C., at 8 P.M. on Wednesday, March 8th.

Enlargement of Sale War Memorial Hospital

Last week Mr. Cyril Atkinson, M.P. for Altrincham, opened a new wing of this hospital containing 20 beds entirely for women. The ground floor is occupied by a maternity ward of eight beds, one private ward, and the necessary labour ward, bathrooms, and kitchen. On the first floor there are an eight-bedded ward, three private wards, and a theatre. The old building has been so rearranged as to afford a children's ward of six beds.

Waltham Joint Hospital Inquiry

The result of the Ministry of Health's inquiry into complaints regarding the deaths of two boys in the Waltham Abbey Infectious Diseases Hospital, and into its general administration, is completely to exonerate the institution. It is found in the case of one boy that treatment was unsuccessful because of the patient's very serious condition when he had only partially recovered from scarlet fever. The other boy "died from hæmorrhage following scarlet fever, which hæmorrhage could not have been foreseen or prevented, and was not caused by a previous traumatic injury," as had been suggested. In reply to the complaint of the Chingford urban district council that the number of "return" cases is abnormal, it is pointed out that in 1931 there was a larger number than usual on account of the heavy incidence of scarlet fever. The Ministry promises, however, to make suggestions calculated to minimise the number of return cases. In the meantime it is suggested that in times of pressure medical officers should advise isolation in hospital only of patients who cannot adequately be treated at home.

Medical Diary

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

SOCIETIES

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

MONDAY, Feb. 27th.—8 P.M., ODONTOLOGY. Mr. F. N. Doubleday: Evidence Regarding the Different Types of Periodontal Disease.

WEDNESDAY, March 1st.—5 P.M., HISTORY OF MEDICINE. Papers: Mr. James Kemble: The History of Occupational Diseases. Dr. E. Stolkind: The History of Allergy and Allergic Diseases (Bronchial Asthma, Hay-fever, Migraine, &c.).

THURSDAY.—8.15 P.M., TROPICAL DISEASES AND PARASITOLOGY. Discussion: The Diagnosis of Chronic Diarrhœas. Opening papers: [illegible] The Differential Diagnosis of t[illegible] Diarrhœas. Dr. P. H. Manson-[illegible] Chronic Diarrhœas as Seen in the Tropics. [illegible] Lionel E. C. Norbury: Chronic Diarrhœa from the Surgical Aspect. Other speakers will take part. Members of the Section of Medicine are specially invited to attend.

FRIDAY.—4.45 P.M., *LARYNGOLOGY*. (Cases at 4 P.M.) Discussion: Acute and Chronic Inflammatory Disorders of the *Ethmoidal and* Sphenoidal Sinuses. Openers: Prof. Lemaitre (Paris), Dr. Aubin (Paris), and Mr. A. Lowndes Yates. 8.30 P.M., ANÆSTHETICS. Discussion: Anæsthesia in Intracranial Surgery. Openers: Dr. Norman Dott, Dr. Z. Mennell, Dr. J. F. Ryan, and Dr. J. H. T. Challis. Other speakers will take part.

MEDICAL SOCIETY OF LONDON, 11, Chandos-street, Cavendish-square, W.

MONDAY, Feb. 27th.—*8.30 P.M., Discussion on the Increased* Frequency of Fevers of the Undulant Type in Non-tropical Countries and its Relationship to Infection by Cow's Milk; to be introduced by Dr. P. H. Manson-Bahr, Prof. G. S. Wilson, and Dr. Theodore Thompson.

WEDNESDAY, March 1st.—9 P.M., Mr. V. Zachary Cope: Pathology of Acute Abdominal Disease. (Second Lettsomian lecture.)

particular type of paroxysmal tachycardia. The drug is necessary and efficacious—no other remedies have any action—in paroxysmal tachycardia of ventricular origin. In the other types of paroxysmal tachycardia quinidine is of doubtful value and often useless, but vagal compression is successful in a certain proportion of cases. The determination of the site of origin of paroxysmal tachycardia without electrocardiographic survey is pure guess-work.

There is room for considerable further instrumental research on the action of adrenaline on the myocardium and conducting tissues. The drug has a specific and peculiar action in effecting regularity and acceleration of the heart in nodal rhythm, but the deductions to be drawn from this clinical curiosity and applied to conditions like Stokes-Adams disease are not yet clear.

FURTHER INVESTIGATION OF DISTURBANCE OF KNOWN CARDIAC NATURE

Such illnesses include tachycardia, precordial pain, cardiac irregularity with suspected block, suspected toxic cardiac myopathy, and fibroid or senile cardiac degeneration.

Tachycardia may be of a nature easily and usually determined by ordinary clinical examination, but the diagnostic value of an electrocardiograph in determining the site of origin of true paroxysmal tachycardia is of unique importance.

Precordial pain of known cardiac origin may be anginal or due to coronary thrombosis. The treatment and prognosis of these two conditions are very widely different; for example, the administration of amyl nitrite to a patient suffering from coronary thrombosis may be definitely harmful or even fatal. The drug may lower pressure and permit further thrombosis. Distinction between angina pectoris and coronary thrombosis is often possible without electrocardiographic review, and obviously such review is frequently impracticable or inconvenient. When practicable, however, differentiation is clear. There are curves pathognomonic of angina pectoris, and these differ substantially from those of coronary thrombosis. Moreover, the cardiac scars and infarctions of coronary thrombosis can be detected with certainty long after the subsidence of the acute process, and such detection aids in diagnosis and treatment.

Cardiac irregularity with suspected block should always recall the aid of instrumental scrutiny. Ordinary clinical examination in these conditions is sometimes very uninformative.

Toxic cardiac myopathy may be brought about by digitalis, as already mentioned, but there are many other causes. Not very much evidence of value about the myocardium can be instrumentally obtained in cases of ordinary toxic goitre, but decidedly important data are sometimes secured in conditions like pyorrhœa. In the latter case repeated cardiac infarctions have been demonstrated, followed by amelioration under dental treatment.

Not much evidence of value is obtained by the examination of merely senile and fibroid hearts, except that occasionally bundle branch block is unexpectedly revealed in such cases and materially alters the prognosis. The electrocardiographic signs of bundle branch block are decisive, and there is no other means of detecting the lesion. It is especially important in the matter of prognosis that serial records be taken of this condition.

FURTHER INVESTIGATION OF PAINFUL OR CONSTITUTIONAL ILLNESS OF OBSCURE ORIGIN

Myocardial disease often mimics disease elsewhere. The conspicuous difficulty in angina pectoris when the pain is referred to the abdomen or the trunk is well known. Paroxysmal auricular fibrillation may offer great difficulties by its power of simulating abdominal catastrophe. Sundry forms of heart-block mimic apoplexy; epilepsy and Stokes-Adams disease will be recalled in this connexion. In all these difficulties electrocardiographic study will often—not always—yield data of diagnostic value. In particular, the electrocardiographic changes during and immediately following an attack of true angina pectoris are pathognomonic and unlike those seen in any other condition. They serve to differentiate angina pectoris not only from coronary thrombosis but from other conditions of intense pain. Thanks to some exemplary research it is now known that pain, such as gall-stone colic, does not disturb the electrocardiograph. In passing, a possible fallacy must be mentioned: liability to angina pectoris may coexist in a patient with the presence of pain-producing lesions such as gall-stones.

AS A GUIDE IN PROGNOSIS

Prognosis depends on diagnosis, and in so far as an electrocardiogram assists in, or reveals, diagnosis it may indirectly be of surpassing value in prognosis. With one exception, however, electrocardiographic records are not, of conspicuous direct value in prognosis unless serial records are taken to determine the evolution or regression of a lesion such as myocardial gumma or infarct. The exception is auricular fibrillation, and in this common and important condition it has been found that the amplitude of the fibrillation waves is in general larger in the rheumatic cases and that a prolonged or aberrant Q R S notably diminishes the expectation of life.

CONVALESCENCE

Related to prognosis is convalescence, and here it may be stated dogmatically that in the determination of cardiac myopathy following acute fevers the electrocardiogram should be resorted to much more freely. This particularly applies to post-influenzal debility, but the most thorough survey has hitherto been made in diphtheria. The most serious cardiac disabilities, totally unsuspected under clinical examination, may be revealed by electrocardiographic scrutiny, and these include conducting lesions and focal myocardial lesions. Conversely, an electrocardiogram may sometimes reverse an unnecessarily gloomy prognosis based solely upon auscultation. As for diphtheria, so for scarlet fever and typhoid.

Obviously no case convalescent from rheumatic fever or chorea is fully assessed without electrocardiographic examination. One has a feeling, based on an insignificant few cases hitherto, that the tendency is to prolong convalescence in these diseases unnecessarily.

Conclusions

If ever an instrument was expressly capable of yielding massed statistical research and report of international scope, that instrument is the electrocardiograph. A beginning has already been made on such widely different topics as chloroform anæsthesia, tobacco poisoning, and athleticism, but one cannot but deplore the absence as yet of really large-scale collaboration in amassing data and comparing results. The great amount of work already done should stimulate wider and wider usage of the instrument and more pooling of reports. Such reports will emanate from individual workers, but their cumulative value in matters of diagnosis and prognosis could, if properly collected and examined in conjunction with long-term clinical data, add heavy and valuable volumes to the science of medicine.

FOLIA OPHTHALMOLOGICA ORIENTALIA

UNDER this title a new ophthalmological quarterly is intended to serve the southern section of the Mediterranean countries together with Mesopotamia and Persia. It is published in Jerusalem under the editorship of Dr. Aryeh Feigenbaum, and the articles are in one of three languages, French, English, and German, each article being accompanied by short summaries in all three languages. There are over 30 distinguished collaborators, mostly European, but some from the Eastern countries; the aim of the production being twofold, on the one hand to foster close collaboration between the ophthalmological specialists of the Middle East, and on the other to

NOTES, COMMENTS, AND ABSTRACTS

THE PLACE OF THE ELECTROCARDIOGRAPH IN MEDICINE

BY G. F. WALKER, M.D., M.R.C.P.

HONORARY PHYSICIAN TO THE SUNDERLAND ROYAL INFIRMARY AND THE CHILDREN'S HOSPITAL, SUNDERLAND; CONSULTING PHYSICIAN TO THE SUNDERLAND MUNICIPAL HOSPITAL

THE electrocardiograph is an instrument of precision in diagnosis and prognosis. Its utility is very wide but its usage singularly narrow. A fair number of patients are sent for electrocardiographic examination when this is superfluous, but a very large number are deprived of the benefits of diagnostic exactitude because the scope and powers of the instrument are not as yet sufficiently realised. The object of this paper is to survey as fairly as possible, and from the point of view of a general clinician, the place of the electrocardiograph in medical science.

A few disabilities and limitations of the instrument must first be admitted. It is costly and complex, and a peculiar knack is required for its handling. Records taken by it represent a very short sample of the heart's action, and if they show a lesion they give no clue to its pathological nature nor to whether it is active or quiescent. In certain cases small and clinically unimportant lesions cause conspicuous changes in the records and, conversely, a normal record is in certain circumstances possible from a diseased heart. There is a very wide range of normal in electrocardiographic records, and this applies especially to children. Moreover, many records tend to be vitiated or reduced in value by somatic tremors or visceral movements. Finally, in a few heart cases the electrocardiograph is totally superfluous, and a step-ladder will give better evidence of the presence of cardiac reserve or otherwise. Hence, as in all technical aids to clinical medicine, electrocardiographic reports must be considered alongside other data, as contributory to general diagnostic investigation.

But there are very many heart illnesses, some frank and some highly obscure, in which electrocardiographic examination yields valuable information. In a certain number of diseases and disorders the data secured by electrocardiographic examination cannot be secured in any other way whatever. It is notable that in those very cases the question of complete diagnostic precision is often of supreme importance to the patient in connexion with employment, life insurance, or travel.

The clinical utilities of the instrument may be considered under several heading, as follows:—

(*a*) In the investigation of the nature of cardiac arrhythmia.
(*b*) In the assessment of myocardial power and integrity, with special reference to medical or surgical treatment.
(*c*) In the determination of lack of ventricular balance.
(*d*) As a control in therapy.
(*e*) For further investigation of illness of known cardiac nature.
(*f*) For further investigation of painful or constitutional illness of obscure origin.
(*g*) In determination of prognosis of many diseases.
(*h*) As a guide to convalescence in many acute fevers.
(*i*) As an instrument of research.

Before considering these it is necessary to recall that the basis of the value of the electrocardiograph is its power to delineate separately auricular contraction, ventricular excitation, ventricular contraction, and ventricular relaxation. The records are obtained from three different angles of observation, and a timing mechanism enables time relationships of muscle activity to be determined with the greatest accuracy down to one-fifth of a second.

How the Electrocardiograph Helps the Clinician

In what follows there is no attempt to deal with the interpretation of the records nor the mechanism of production of the different types of curves. Th review is purely in answer to the question from general clinician: How can this instrument hel me?

INVESTIGATION OF CARDIAC ARRHYTHMIA

When the pulse is irregular the exact diagnos is often highly uncertain. The following are th common causes, and they will be recognised once as widely different, alike in ætiology, trea ment, and prognosis: sinus arrhythmia; extr systoles, including paroxysmal tachycardia; parti or complete heart-block at any point; auricul fibrillation; and auricular flutter.

The differential diagnosis in all these, and in the combinations and complications, is infallibly disclose by electrocardiographic examination.

ASSESSMENT OF MYOCARDIAL POWER AND INTEGRITY

Apart from ordinary clinical examination it often necessary to secure definite information to the myocardium in conditions such as diabete exophthalmic goitre, and prostatic hypertroph Subject to the limitations mentioned, the instrumen is often of value in delineating conditions such as diminution in auricular force, recent coronar occlusion, cardiac infarction, impaired myocardi nutrition, or diminished conductility.

Conversely, repeated normal electrocardiographi records add considerably to the data required f prognosis in conditions such as cholelithiasis; or i other cases they may fortify a clinician's opinio that symptoms ostensibly and even aggressivel cardiac may in fact be of other origin or exaggerate

DETERMINATION OF LACK OF VENTRICULAR BALANCE

The question of inordinate unilateral ventricula hypertrophy arises in conditions such as lea poisoning, hypertension, and long-continued physica stress. The extent of this hypertrophy can b ascertained with precision by instrumental method only. Sometimes such instrumental ascertainmen is strikingly at variance with the impressions gaine from ordinary clinical examinations.

Other conditions in which an accurate estimatio of unilateral ventricular hypertrophy is of hig value are exophthalmic goitre, adherent pericardium aortic disease, chronic bronchitis with emphysema bronchiectasis, and pulmonary stenosis.

CONTROL IN THERAPY

The chief utilities of the instrument in this respec centre round accurate diagnosis and the clinica employment of digitalis, quinidine, adrenaline, an drugs acting on the blood pressure. It is highl desirable to know the point at which the optimu effect of digitalis is being exerted. Beyond a certai point the drug exerts a toxic and blocking effec on the conductile and contractile tissues of th heart. By delicate and pathognomonic changes in the T-wave, unlike changes seen in any other known condition, it is possible to predict digitalis saturation and impending intolerance a considerable time before the better-known general constitutional signs of digitalis poisoning appear. Indeed, when these do appear, irreparable damage has probably already been done to the conducting tissues of the heart, and therefore every patient requiring to take digitalis for long periods should be periodically examined by electrocardiograph with particular scrutiny of the T-wave. Digitalis is probably over-prescribed, and for two reasons. Firstly, there may be erroneous diagnosis, as for example when extrasystoles mimic auricular fibrillation; secondly, the signs and symptoms of ordinary heart failure may pass insiduously into those of toxic heart failure from digitalis.

The utilities of quinidine depend on a completely accurate diagnosis of fibrillation or flutter, or a

THORACIC SURGERY

BY H. MORRISTON DAVIES, M.D., M.CHIR. CAMB., F.R.C.S. ENG.

MEDICAL SUPERINTENDENT, VALE OF CLWYD SANATORIUM; CONSULTING SURGEON TO UNIVERSITY COLLEGE HOSPITAL, KING EDWARD VII. WELSH NATIONAL MEMORIAL ASSOCIATION, LANCASHIRE COUNTY SANATORIUMS, AND CHESHIRE JOINT SANATORIUM

LECTURE I[*]

THE two lungs are completely separated from each other by the mediastinum; the two pleural cavities are independent. But when the question of surgical intervention arises, the two halves of the thorax cannot be considered individually. The effect or the complications of disease on the one side may materially influence the physiological state of the opposite lung; treatment of the one side may so embarrass the other that death ensues. The crux of the whole situation is the mediastinum and, to a lesser extent, the heart.

The mediastinum is not a rigid vertical partition; it must be regarded rather as a veil, comparatively taut in some people but surprisingly lax in others. Disease which causes thickening of the pleura will stiffen and even immobilise the mediastinum. Except under these pathological conditions, it is a mobile structure, but so balanced by the perfect elasticity of the lungs on either side that it is, in health, practically devoid of movement. Deprived, however, by disease of this equipoise, it loses its apparent stability and yields to every displacing force, being either pushed away or drawn towards the affected side, carrying with it, among other structures, the heart.

Displacement of the Mediastinum

The heart is extremely tolerant of certain movements, but most intolerant of others. A slow progressive displacement up to an inch, or even more, produces no disturbance recognisable either by clinical or electrocardiographic examination. A rapid displacement is not well tolerated, but as such change is associated usually with a rapid diminution of lung volume, it is difficult to assess to the heart displacement and to the diminished lung volume their correct responsibility in the production of change in the rate and quality of the pulse and in the dyspnœa.

A mediastinum and heart which have been deprived of their normal balance and have become displaced will show some recovery towards the normal position during inspiration, but an increased displacement on expiration. The to-and-fro movement is slight during quiet respiration, but becomes greatly increased with deep respirations. Provided no especial call is made for deep breathing, this slight though constant to-and-fro movement is of little consequence so long as the thoracic walls are rigid and complete. Once, however, an opening is made through the chest wall or the wall itself is made mobile by resection of lengths of rib, the mediastinum and heart may flap constantly to-and-fro with every respiration. This, together with the associated disturbances of the normal physiological condition, produces a state of affairs which, if unchecked, has a rapidly disastrous ending.

Changes in the position of the mediastinum in a closed chest cannot take place without alterations of the lung volume. Pathological conditions, such as an effusion or a pneumothorax, produce a positive intrapleural pressure, and take up space in the hemithorax. This necessitates a partial collapse of the lung on the same side, a displacement of the mediastinum towards the sound side, and, of necessity, therefore, a diminution in the volume of the opposite lung also. If the volume of the lung on the affected side is diminished rapidly, as with massive collapse, and, to a slight extent, with pneumonia, the mediastinum is drawn across to that side, and the opposite lung must expand to fill up the enlarged hemithorax. Such increase in size, when produced acutely, is partly by dilatation of the alveoli, but partly by increased engorgement of the vessels and by œdema. This doubtless contributes to the breathlessness seen in massive collapse. The mediastinal displacement associated with chronic fibroid contraction of one lung is of such gradual onset that the contralateral lung can compensate by a pure emphysema. In such cases, moreover, the mediastinum resists the drag, being to a great extent fixed by the thickened and adherent pleural membranes.

These changes in the position of the mediastinum, if of slow onset, can be, and often are, symptomless, but, if abrupt, are always accompanied by symptoms. Reference has already been made to the cardiac manifestations and to the dyspnœa; especial reference must be made to one other symptom, pain. The mediastinum has its fascial attachments front and back. The lungs are attached to it by their roots. In addition, it is surrounded by the parietal pleura, which has certain pouch-like protrusions which reach up to or across the midline. These incursions doubtless account for the mobility of the mediastinum, and also for its fixation when there has been intrapleural inflammation. Displacement of the mediastinum cannot occur without dragging on its attachments to the surrounding structures, including the parietal pleura. This drag affects equally the attachments both to the right and left, irrespective to which side the displacement is. In a case with unilateral disease in which the mediastinum is either drawn over to the affected or displaced to the opposite side, pain may, therefore, occur in the interscapular or parasternal regions on the sound side, thus causing anxiety as to the possibility of extension of disease to that side.

The most important of the pleural reflections in relation to the mediastinum is the approximation of the membranes of either side, in front of the mediastinum, and behind the sternum from the first to the third rib. To the anatomist there is no particular asymmetry at this point, but to those who practise artificial pneumothorax the comparative frequency of a hernial protrusion of the left sac to the right, and the rarity of a similar protrusion of the right sac to the left is very striking. Another important deviation is of the right pleural sac behind the mediastinum, including the heart and œsophagus, in front of the bodies of the eighth and ninth dorsal vertebræ—the vertebro-mediastinal pleural sinus.

These pleural reflections, when the pleural cavity is filled with an effusion or air, may become stretched and form herniæ, which bulge across the middle line and encroach on the opposite lung. This herniation is always combined with displacement of the mediastinum and the two combined cause a considerable reduction, especially during expiration, in the volume of the contralateral lung on which the patient depends bring to the notice of their colleagues in the West the special peculiarities of ophthalmic practice in that part of the world. The first number, published in November last, contains much interesting matter, and includes articles by Max Meyerhof, of Cairo, on fifty years of ophthalmological progress in Egypt, and by R. H. Elliot (London) on the special features of ophthalmological practice in Eastern countries. I. Taborisky (Haifa), Rowland P. Wilson (Giza), R. Peters (Basra), and A. Sinai (Tel-Aviv) write on different aspects of trachoma; A. Trantas (Athens) on the location of foreign bodies in the ciliary and post-ciliary regions; Moh Sobhy Bey and E. J. Attie (Cairo) discuss Barraquer's method of cataract extraction; N. Shimkin (Caiffa) the bitemporal hemianopsia of pregnancy; and Aryeh Feigenbaum (Jerusalem) the origin of lenticonus anterior. If succeeding numbers keep up the standard of the first issue they will be more than worth the modest subscription.

---

[*] The first George Haliburton Hume lecture for 1933, delivered before the Newcastle-upon-Tyne and Northern Counties Medical Society on Feb. 2nd. The second lecture will appear in a forthcoming issue of THE LANCET.

DR. MARY WALKER

Mrs. C. W. M. Poynter, 1306, South Thirty-fifth-avenue, Omaha, Nebraska, U.S.A., is working on a biography of the late Dr. Mary E. Walker, of Oswego, New York, and would be glad of any information about her visit to this country in 1866–67, when she went the round of the London hospitals and gave many lectures in England and Scotland. It appears from our own columns of the time that Dr. Walker had practised medicine in New York for five years before the war between North and South broke out, when she volunteered for the Federal Army Medical Service, and served through a campaign of four years, being taken prisoner and exchanged after a few months for a male surgeon. Her visit was largely occupied with controversy on the dress appropriate for women. Dr. Walker herself was of opinion that, from a physiological point of view, the great weight of clothes then carried from the waist was open to objection, and her own garments were suspended from the shoulders, which she described as "a physiological dress with moral bearings." THE LANCET, although hesitant about the advisability of Dr. Walker's example being generally followed by her sex, commended her to the courtesy of hospital authorities and the medical profession; but a lecture which she gave at St. James's Hall on Nov. 20th, 1866, on the experiences of a female physician was, we are told, "marred by the singing of Rule Britannia and the more familiar but less refined Slap Bang," until police assistance was secured. There was, we gather, no impediment put in the way of Dr. Walker's visits to hospitals, for it is stated that she attended operative practice at the Middlesex Hospital, where she witnessed removal of dead bone from a jaw and the attempted reduction of an old dislocation of the humerus.

BROADCASTING THE LOSS OF DRUGS

THE British Broadcasting Corporation informs us that, while the S O S service is normally restricted to matters of life and death, the service has hitherto been extended to messages referring to the loss or theft from doctors' cars of bags containing dangerous drugs, with appeals to the public for help in tracing them. Five messages of this kind were broadcast from the North Regional transmitter, and two from other transmitters during 1932. The Corporation point out that, while assistance of this kind has been given in the past, the loss of a bag containing dangerous drugs hardly fulfils the condition of extreme urgency which justifies this service, since, in their view, it is unlikely that anyone who had stolen or found a doctor's bag would deliberately sample its contents and run the risk of being poisoned. This intimation must, it seems, be taken as a warning that such messages will in future be accepted for transmission with some reluctance, and may eventually perhaps be refused.

IODINE COMPOUNDS IN THYROID DISEASE.—In the report of a discussion at the Royal Society of Medicine, published in our last issue (p. 365), Prof. C. R. Harington is credited with saying that "the most suitable mode of administration of iodine was in the form of diuretyrosine." This last word should, throughout the report, be *diiodotyrosine.*

THE author of "Things to be Desired, or Daily Health Reminders," reviewed last week in this column, was Dr. W. W. Shrubshall. We regret the omission of the second letter "h" from his name as printed.

Appointments

GALLOWAY, T. M'LAREN, F.R.C.S. Edin., has been appointed Asst. Physician, Cumberland Infirmary.

JONES, NANCY LLEWELLYN, L.R.C.P., M.R.C.S., Resident Anæsthetist, Queen Charlotte's Maternity Hospital.

LAWSON, D. F., B.Chir. Camb., L.R.C.P. Lond., M.R.C.S., Hon. Asst. Radiologist, Leicester Royal Infirmary.

SMITH, F. W. G., M.D. Dub., D.P.H., D.O.M.S., Refraction Assistant, East Ham Memorial Hospital.

WEST, H. O., M.D., B.S. Lond., Medical Superintendent, St. Giles's Hospital, Camberwell.

St. Thomas's Hospital, London: GOADBY, H. K., M.D. Camb., M.R.C.P. Lond., Deputy Director of the Medical Unit; CHAMINGS, A. J. W., M.B. Camb., F.R.C.S. Eng., Chief Assistant in the Ear, Nose, and Throat Department; MARSHALL, E. H., M.R.C.S., Chief Assistant in the Physiotherapy Department.

Certifying Surgeons under the Factory and Workshop Acts: ADAM, D. C., M.B., Ch.B., D.P.H. Edin. (Ilfracombe); BLAKELY, A. D., M.D. Glasg. (Longton, Stafford); JOHN, A. H., M.B., B.S. Lond. (Stoke, Stafford), and PALMER, W. H., M.B., B.S. Lond. (Hayle, Cornwall).

Births, Marriages, and Deaths

BIRTHS

BENEY.—On Feb. 18th, at 3, Wilbraham-place, S.W.1, to Dorothea (née Pridden), wife of Charles Beney, 130, Harley-street, and Keston, Kent—a son.

MORTON.—On Feb. 19th, at a nursing home, the wife of Dr. Robert Morton, Ashbourne-avenue, Golders Green, London, of a daughter.

SELOUS.—On Feb. 17th, at a nursing home, the wife of Cuthbert F. Selous, M.B., of South Lawn, Clarence-road, Tunbridge Wells, of a daughter.

WALLACE.—On Feb. 1st, at Murrayfield, Horsham, Sussex, the wife of J. H. Wallace, L.D.S., of a daughter.

MARRIAGES

DOWLING—HEARN.—On Feb. 14th, at Brompton Oratory, Lieut.-Colonel F. T. Dowling, R.A.M.C. (retd.), to Jessie Florence, widow of Alfred Booth Hearn, of The Gleanings, Folkestone.

EVERETT—PERRY-GORE.—On Feb. 18th, at St. John's Church, Regent's Park, N.W., Leslie S. Everett, M.R.C.S., L.R.C.P., Penzance, to Joan M. Lucy Perry-Gore, Oxford.

DEATHS

BEATSON.—On Feb. 16th, at Woodside-crescent, Glasgow, Sir George Thomas Beatson, K.C.B., K.B.E., M.D., D.L., in his 85th year.

BENHAM.—On Feb. 14th, 1933, of pneumonia, Harold Walter Benham, M.B., M.R.C.P. Lond., second son of the late Dr. C. H. Benham and Mrs. A. Benham, 88, The Ridgeway, N.W.11, aged 24 years.

CORBOULD.—On Feb. 15th, at Coleherne-court, S.W., Victor Albert Louis Edward Corbould, M.D., M.R.C.S., L.R.C.P.

CURRIE.—On Feb. 19th, at Oxford-terrace, W., after a very short illness, Andrew Stark Currie, M.D.

ELLIOTT.—On Feb. 14th, at Osborne-road, Clifton, Bristol, Christopher Elliott, M.D., in his 84th year.

HYSLOP.—On Feb. 12th, at a nursing home in London, after a long illness, Theophilus Bulkeley Hyslop, M.D., C.M., M.R.C.P. Edin., F.R.S.E., late of Portland-place, W., and formerly medical superintendent of Royal Bethlem Hospital.

SMITH.—On Feb. 16th, suddenly, of heart failure, at Kilburn Park-road, N.W., Robert Montgomery Travers Smith, M.D., in his 76th year.

THATCHER.—On Feb. 13th, at N Charles Henry Thatcher,

WHITE-HOPKINS.—On Feb. 12th, at Regina Hotel, Nice, Major J. White-Hopkins, late R.A.M.C., aged 81.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

should be as painless as possible, lest the constant apprehension and anticipation further undermine the general health. Needles should not be inserted without anæsthetising the track with novocain. Aspiration of a large effusion without replacing the fluid by air is productive of pain, and this is the least of the risks to which the patient is exposed.

A small, recent effusion associated with little change in the lungs or pleural membranes is easily withdrawn. When an effusion has produced collapse of a lung, possibly extensively fibrosed, has caused a considerable displacement of the mediastinum, and led to a general thickening of the pleura, it is not possible to aspirate that fluid with impunity in a short space of time. The thickened membranes cannot stretch, and pain will result from the drag on the adhesions; the lung cannot re-expand to its old volume, and existing cavities will therefore be reopened; the mediastinum, previously pushed across to the opposite side, will be dragged over to the affected side; the contralateral lung will be forced to expand beyond its normal. A distressing cough, considerable pain, and possibly copious frothy sputum are the consequences of such an effort. In some cases, even, œdema and death may ensue. By replacing, by air or oxygen, part of the fluid as it is withdrawn these symptoms are all avoided. The effect of this replacement is to enable the maximum traction force to be applied on the lung and mediastinum which can be tolerated with comfort and safety. At the same time it is possible to aspirate as much of the fluid as is considered desirable. When the effusion conceals a malignant growth in the lower lobe, the advantage of being able to empty the pleural cavity of the fluid is obvious.

It is sometimes possible to disinfect an effusion which is loaded with tubercle bacilli, by injecting, after the aspiration, 5 or 10 c.cm. of a 2 per cent. solution of methylene-blue in absolute alcohol. If this fails, the effusion should be replaced by olive oil containing 5 per cent. oil of gomenol. This will be referred to later when considering oleothorax.

Airtight syphon drainage is indicated for those cases of tuberculous empyema in which the pus is too thick for aspiration, and in which a thoracoplasty is proposed; it is also indicated when there is considerable persistent toxæmia despite treatment as indicated above, and especially when there is a mixed infection.

We have already seen that with simple effusions the most important consideration is the effect of the fluid on the mediastinum; that with tuberculous pleurisies, the importance of the mediastinum has in no way faded, but a new factor has arisen, and the toxæmia may occasionally assume prime importance and necessitate intervention on its own account. When the empyema is a pyogenic one, the infection and the dangers associated with the mediastinum are of almost equally great importance, and disaster is likely to result if the fullest consideration is not given to both of them.

Empyema

The old line of treatment by thoracotomy in every case of empyema was associated with a heavy mortality. In streptococcal cases it was about 25 per cent., but during the influenza epidemic of 1917–18 it rose in some places in America to as high as 70 per cent. This led to the Empyema Commission being set up in America. As a result of their work and of that of Evarts Graham, a true appreciation of the physiology of the open pneumothorax was obtained. The immense value of this is shown by the drop in the mortality in cases of streptococcal empyema to 4·3 per cent.

If a large opening is made in the chest wall there are, in the absence of adhesions, certain inevitable changes. There is the collapse of the lung, which, except that it occurs suddenly, is, in itself, the least serious of the effects. The collapse of the lung is due to the substitution of the negative pressure, to which the lung is usually subject, by an atmospheric pressure. As the mediastinum is mobile, this yields to the pull of the negative pressure of the contralateral side, and to the force of the atmospheric pressure on the surface of the lung on the affected side. The displacement continues until the pressure in the contralateral hemithorax is approximately the same as that on the side of the open pneumothorax. In other words, the pressure in both sides of the chest becomes approximately equal, except at the height of inspiration. In order to get any air into the lung on the sound side, a very forceful inspiratory effort has to be made, since it is only at the height of inspiration that there is a negative pressure, and therefore a suction power capable of drawing air from the trachea into the lung.

During inspiration air will enter the lung through the glottis and trachea, and into the pleural cavity through the opening in the chest wall. Should the opening through the glottis be the larger a greater volume of air will be drawn into the lungs than through the opening into the pleural cavity. But if the pneumothorax opening is definitely larger than the glottis, the reverse is the case. The effort necessary for the increased inspiratory respirations is considerable. It is natural that the more seriously ill the patient, the greater the strain of the effort and the less the endurance capacity.

During expiration there is a partial expansion of the lung on the side of the open pneumothorax. The air which inflates this lung comes from the opposite lung, being driven out of it by the forceful expiratory action. During the inspiratory phase this air is drawn back again into the sound lung. This pendulum flow of air is immediately deprived of all its oxygen and is therefore valueless, and it occupies space, already greatly limited, which should be filled by air from the trachea.

There is furthermore a to-and-fro flapping of the mediastinum with each respiratory phase; inspiration draws it to the sound side while expiration forces it away again. This constant to-and-fro action causes serious cardiac embarrassment. Other difficulties are the loss of aspiration of the venous blood by the heart, leading to a venous stasis, and a loss of heat from the exposed pleural cavity. These dangers diminish and may almost cease to exist in proportion as the mediastinum is fixed by thickening of the pleural membranes, by the deposit of cellular debris and lymph, and by the formation of adhesions.

DIFFERENCE BETWEEN PNEUMOCOCCAL AND STREPTOCOCCAL EMPYEMA

The essential difference between a thoracotomy done for a streptococcal and a pneumococcal empyema in the earlier stages is that with a streptococcal infection it takes a considerable time for the mediastinum to become immobilised and, until that happens, thoracotomy means exposing a patient to all the dangers of an open pneumothorax. With a pneumococcal empyema, on the other hand, early fixation of the mediastinum is the rule.

A pneumonic empyema is a “meta-pneumonic” manifestation. That means to say that the pneumonic consolidation is usually over before the empyema is diagnosed. By this time resolution is taking place, for aeration. This herniation may occur with a negative as well as with a positive intrapleural pressure.

In the presence of an effusion there is yet another mechanical difficulty which will be encountered. This is the deposit of the cellular and fibrinous content of the fluid on the diaphragmatic pleura and into the phrenico-costal sinus. This becomes organised, fixing the diaphragm, the base of the lung, and the lower part of the chest. It is also responsible for the formation of adhesions between the pericardium and the base of the lung, which interfere with the free action of the heart, causing dyspnœa, tachycardia, and an irregular pulse. The deposit on and the irritation of the parietal pleura cause gradual thickening of the membrane and impede the re-expansion of the lung, should that later be required.

When trauma or disease is responsible for a spontaneous pneumothorax, or an effusion in the pleural cavity, the most frequent indication for surgical intervention is the mechanical disturbance produced by either of these complications; intervention is much more rarely necessitated by infection. In other words, when dealing with a pneumothorax a serous effusion, or with the great majority of tuberculous effusions, the only indication for active treatment is the excessive displacement of the mediastinum. When intervention is necessary on account of empyema, one of the most important considerations regulating modern treatment is again the mediastinum.

Spontaneous Pneumothorax

The dangers of a spontaneous pneumothorax are embarrassment of respiration and infection. This latter is surprisingly rare. Embarrassment of respiration depends on the freedom of the lungs from adhesions, and on the size and character of the opening in the lung. Adhesions preventing the collapse of the lung limit the extent of the pneumothorax and prevent excessive displacement of the mediastinum and so of collapse of the opposite lung. This advantage is sometimes offset by the adhesion dragging on one side of the lung-opening and preventing it from closing. When this condition persists it is necessary to divide the adhesion.

In the absence of adhesions the pneumothorax results in progressive collapse of the lung. This is usually sufficient to occlude the opening, which then becomes sealed by lymph. Before, however, the opening is closed the pressure may have risen sufficiently to distress the patient owing to the displacement of the mediastinum and its consequent influence on the contralateral lung, thereby curtailing the respiratory capacity. It is occasionally only that the resultant dyspnœa is sufficient to necessitate aspiration of some of the air. Should this be advisable, however, only sufficient air must be aspirated to make the patient comfortable. The positive intrapleural pressure is reduced, but not converted to a negative pressure lest the tear in the lung be reopened.

The spontaneous pneumothorax with a valve-like opening which allows the escape of air from the lung into the pleural cavity but not in the reverse direction is an urgent menace to life. Death from suffocation may be a matter of minutes only. There may be no time for refinements in technique. The largest available needle must be thrust through an intercostal space into the pleural cavity. A hypodermic injection of morphine gr. ¼ can then be given. This will ward off the imminent danger and allow time for the insertion with all aseptic precautions of a needle connected with a pneumothorax apparatus. Air can now be drawn off and the intrapleural pressure controlled. It occasionally happens that the necessity for aspiration is constantly recurring, or that the opening having apparently closed reopens. It is then necessary to introduce a catheter into the pleural cavity and to institute air-tight drainage.† This has many advantages. Provided the catheter is securely fixed the patient can be left with safety, as the intrapleural pressure is automatically regulated. Every forceful expulsion of air into the pleural cavity escapes immediately; should an effusion develop this is drained; at the same time it permits of a slight negative pressure being kept in the pleural cavity, which helps the re-expansion of the lung. The disadvantage is that the lymph which will form and which is so desirable, as it is this which seals the lung opening, will clog the catheter from time to time. It is, however, possible to clear the catheter with a stilette or, alternatively, to change it.

Pleural Effusions

All non-progressive effusions should be left alone unless there is a definite reason for intervening. An exploratory puncture with a syringe and fine needle should always be made to confirm the presence of fluid, if in doubt, and to ascertain the character of it. This can be repeated with impunity as necessary. There are three indications for the removal of the fluid. The most frequent and the most important is the appearance of dyspnœa and tachycardia due to excessive displacement of the mediastinum. A second and later indication is the persistence of pyrexia due to absorption of toxins, almost certain evidence that the effusion is an acute tuberculous one or is infected with pyogenic organisms. The third indication is when, after two or three weeks, the effusion is still undiminished in size. It is often found that absorption can be started and will continue satisfactorily once the intrapleural pressure is reduced by aspirating a part of the fluid.

The reason why delayed absorption is an indication for aspiration is that most effusions have some cellular or fibrinous content which is deposited in the dependent parts of the thorax. Becoming organised it produces thickening of the membranes, and will eventually interfere with the re-expansion of the lung and produce adhesions between the pericardium, diaphragm, and lung.

When dealing with tuberculous effusions there is an additional reason against repeated aspirations. Such an effusion is at first usually clear with little solid content, but after two or three aspirations it becomes more opaque, due to an increase in cells and fibrin, and after a time may become so thick with fibrin that it cannot be withdrawn through an ordinary cannula unless predigested. A tuberculous empyema occurring in a case with unilateral disease, and which shows itself to be unresponsive to treatment by aspiration, should not be allowed to reach the state of chronicity with thick pus and with thickened rigid membranes. An extensive, multiple stage thoracoplasty should be done while the membranes are still capable of satisfactory collapse, and the patient's general health is yet sufficiently good to justify this major operation.

It is not justifiable to inflict unnecessary pain; it tends, among other things, to destroy the morale and the confidence of the patient. When repeated explorations or aspirations are necessary, the puncture necessary to decorticate the lung—that is, to strip its thickened visceral pleura off the surface of the lung, thus allowing it to re-expand. Such an extensive operation has to be done in stages. The apex is the part most difficult to occlude, and it is essential that complete obliteration be obtained in that area lest the success of the whole treatment be spoilt.

---

† This will be described later.

Such is the seriousness of operations for chronic empyema that it behoves the physician to keep a constant watch in every case of recognised or possible pleural effusion, and, by repeated exploratory puncture, if need be, to ensure that at the earliest onset of pus the case is promptly and efficiently dealt with. It behoves the surgeon also to make certain that every available means to procure re-expansion of the lung and obliteration of the pleural space is secured, and to guard against reinfection and the presence of foreign bodies.

Suppuration in the Lung

Lung suppuration offers a variety of clinical pictures. At the one end of the scale there is the acute lung abscess which runs a rapidly progressive course to a fatal termination. At the other extreme there is bronchiectasis, which runs a slow, but usually a progressive course and tends also, in the end, to be fatal. Between these two there are many gradations; there is the less intense subacute abscess, the chronic abscess, abscess complicated by bronchiectasis, and bronchiectasis complicated by abscess. These last two vary in their origin and in the earlier stages of their development, but later produce a picture that is practically identical. The acute, subacute, and chronic abscesses are comparatively amenable to treatment, but abscess complicated by bronchiectasis and all varieties of bronchiectasis are most resistant because of the associated mechanical difficulties.

ABSCESS

An abscess starts as an acute or subacute inflammatory condition. There is a diffuse zone of change in the lung, consisting of a central focus of intense infection and a surrounding area of pneumonic change fading into normal lung tissue to form an irregular pus-containing cavity, which usually communicates and discharges through a bronchus. The change in the outer inflammatory zone varies with the intensity of the infection. In the acute case, no limiting barrier can be formed against the progressive spread of the disease, but in the subacute type a controlling barrier may become possible and the subacute abscess gradually merges into the chronic type. This, in turn, depending on the extent and character of the changes and the absence of active surgical treatment, may become complicated by bronchiectatic changes.

Treatment differs according to the character of the abscess, and, to a less extent, its position. Briefly stated, the surgical treatment most frequently applicable to the acute, subacute, and some forms of chronic abscess is pneumotomy and drainage. When abscess is complicated by bronchiectasis, treatment must be on the lines used for bronchiectasis, and not on those used for abscess. Surgical intervention is not indicated, however, until medical treatment has failed; but it should unquestionably not be postponed until the abscess has become chronic.

When a foreign body is suspected as the responsible factor, bronchoscopy and, if possible, the removal of the foreign body is a proceeding that should be undertaken with the minimum of delay. But in other cases in which the abscess is acute or subacute, medical treatment should be given a trial for a period of six to eight weeks in the hope that, if drainage is efficient, the abscess will clear up without other intervention. This is more likely to happen when the lesion is in the upper lobe.

Should this fail, and in all cases of chronic abscess which, by the very fact that they have become chronic have shown themselves incapable of healing by bronchial drainage, bronchoscopy with aspiration of the pus should be tried. It is only when this also is unsuccessful that operation is indicated. In the case of an acute abscess, however, which is obviously progressing rapidly, and in cases in which the inflammatory processes are associated with gangrene of the lung, delay is not justifiable; the abscess should be opened and drained at the earliest possible moment.

OPERATION FOR LUNG ABSCESS

The first step, when surgical intervention has been decided on, is the localisation of the abscess by antero-posterior and lateral radiograms, preferably taken stereoscopically. Exploration with a needle is absolutely unjustifiable until the parietal pleura has been exposed and the visceral pleura is found to be adherent to it. If the abscess is located with the needle and the pleural cavity is patent, it is almost certain that an empyema will result.

It is for this same reason that it is impossible to decide beforehand whether the operation of pneumotomy can be done in one or two stages. More often than not the pleural membranes are not adherent, and secure adhesions must be produced before the abscess is sought for or opened.

No general anæsthetic is required; the operation can be done without distress to the patient under nembutal-morphine and local anæsthesia. As a general rule the most suitable access for an abscess in the upper lobe is over the first interspace and the second rib in front; for one in the middle lobe, in the anterior axillary line; whilst for an abscess in the lower lobe, in the posterior axillary line or below the angle of the scapula.

A musculo-cutaneous flap is turned off the area of approach It should be of sufficient size to give adequate access, bearing in mind that as the wound later granulates up, this opening will tend to close more rapidly than is convenient. A piece of rib, at least 7 cm. long, is excised, and also the intercostal muscles in the space above. The parietal pleura is exposed. If there are no adhesions, the underlying lung will be seen moving beneath the pleura. Under these circumstances the whole wound is packed with dry gauze and the flap sutured in place. When the abscess involves the apex, it is justifiable to strip the parietal pleura very gently away from the first rib, thus doing a partial apicolysis, and to pack the gauze under the first rib also. If, however, the membranes are thickened and apparently adherent, a small incision should be made cautiously through the parietal membranes to confirm the adherence of the lung. The second stage can then be proceeded with at once; otherwise not till ten days later.

When doing the second stage as a separate operation, nembutal and morphia should be given; a local anæsthetic is usually not necessary. After removal of the stitches, the wound is opened, the gauze is removed, and the cavity swabbed clean. It is now possible to explore with a needle and syringe. When pus is found the syringe is removed from the needle without disturbing its position; the lung is incised with a knife or the cautery, and the abscess opened. The cavity must be explored with the finger and all subsidiary abscesses opened into the main one. A gauze plug moistened in saline is packed firmly into the abscess cavity, and the outer wound is plugged with gauze which has been well covered with warm vaseline to prevent it adhering to the surrounding tissues. In the subsequent treatment, the outer wound must be kept well open until the abscess cavity has become obliterated by granulation tissue.

Should the abscess not be found, a free incision is made into the lung in the hope that the abscess will find its way out through this area. Failing this, lipiodol is introduced into the depths of the lung wound and further X rays are taken from different angles.

the rate of metabolism is diminishing, and the vital capacity is increasing. A streptococcal empyema, on the other hand, is "syn-pneumonic," developing with the very onset of the pneumonia. These two empyemas differ, moreover, in the character of their pus. The pus in a pneumococcic case is rich in fibrin from the start, and forms a deposit which thickens the pleural membranes and fixes the lung and mediastinum. The hæmolytic streptococcal case is very different. At first the effusion is a brown, turbid fluid, producing little deposit and unable, therefore, to immobilise the mediastinum. Frank pus does not appear till after two or three weeks.

Early thoracotomy and drainage is not particularly dangerous in a pneumococcal empyema, but it is intensely dangerous in the streptococcal case. Yet treatment is urgent, partly because of the acute toxæmia which demands immediate evacuation of the pus, and partly because of the symptoms caused by pressure on and displacement of the mediastinum.

The first step in every case of empyema is to ascertain by exploratory puncture the character of the effusion and the nature of the infection. If thick pneumococcal pus is found, thoracotomy and airtight drainage can be instituted, but if the empyema is due to a hæmolytic streptococcus, unless diagnosis has been long delayed and frank pus is present, thoracotomy is absolutely contraindicated, but other steps must be taken immediately to evacuate the fluid.

ASPIRATION AND AIRTIGHT DRAINAGE

The two essential principles in treatment, the removal of the fluid responsible for the profound toxæmia and the release of the pressure displacing the mediastinum and compressing the opposite lung, can both be carried out effectively by aspiration with replacement by oxygen or air. The difficulty is that the relief of symptoms is a temporary one only, and the process must be repeated every two or three days, as indicated by the return of pyrexia and the recurrence of symptoms of respiratory and cardiac embarrassment. Very occasionally, both in cases of streptococcal and pneumococcal empyemas, patients have been cured by aspiration alone.

Once pus has formed and has had time to cause a deposit which thickens the pleura, aspiration can be abandoned for thoracotomy. Even then, however, it is not wise to resect a rib and to institute open drainage. Syphon or suction drainage through an airtight opening is in most cases sufficient to evacuate the pus and re-expand the lung. In the earlier stages lavage is not indicated but may be after the acute phase has passed off. Lavage with Carrel Dakin's solution is necessary in certain cases where the deposit is so think that re-expansion of the lung is difficult. Carrel Dakin's solution has a solvent action on the fibrin in addition to its antiseptic value.

The great advantage about airtight drainage is the comparative simplicity of the operation. Two precautions are necessary. It is important to be sure that the catheter and the cannula are the same size, so that when the cannula has been withdrawn the catheter fits tightly in the tissues. It is advisable to mark the catheter at a point 3 inches from the end, before insertion, as a guide to the length projecting inside the pleural cavity. The catheter will become loose in the course of the ensuing seven to ten days and cease to function efficiently. Another difficulty is that the opening may get constantly blocked by flakes of lymph. It may then be advisable to make a larger opening and to insert an open drainage-tube. By this time all danger from an open pneumothorax will have ceased to exist, and the patient should be in a better general condition to tolerate the more extensive operation. The pull on the lung exerted through the airtight drainage will now be lost; as soon, therefore, as the patient is in a fit state, blowing exercises must be instituted. The greatest care will have to be taken during the dressings to guard against the risks of reinfection. The importance of the care for the patient's general condition must not be overlooked. Plenty of glucose and large draughts of water are essential.

For patients who are delirious and children who are restless or difficult to control, airtight drainage is not advisable owing to the danger that the catheter may be pulled out of the wound. For them it is wiser to continue with aspiration and replacement until it is safer to do a thoracotomy and open drainage.

The choice between thoracotomy through an intercostal space or by rib resection depends very much on the case. The intercostal operation is the simpler and needs a less extensive infiltration with the analgesia. It is not, however, satisfactory when the ribs are in close apposition; it limits the size of the drainage-tube, and there is a risk that the pressure of the tube will produce rib necrosis. There is also the risk of rib necrosis from infection when rib resection is done. This can be guarded against by plugging the cut ends of the bone with paraffin wax.

CHRONIC EMPYEMA

A very large percentage of all cases of chronic empyema are due to the following preventable causes. There is delay in diagnosis until the organisation changes in the deposited lymph have rendered the pleura so rigid that the lung cannot re-expand nor the mediastinum return to its normal position. There is omission to use Carrel Dakin's solution when its solvent action might yet free the pleura of deposited but still imperfectly organised lymph. There is inefficient or wrongly placed drainage. There is reinfection, due most often to the discharge of the patient before the lung is fully expanded and the wound healed. There is the presence of a foreign body due to a drainage-tube lost in the cavity, to fragments of rib, or to osteomyelitis of the rib. A chronic sinus may be due to the drainage-tube being left in too long.

Chronic empyema may also be due to unavoidable causes, such as a persistent pleuro-bronchial fistula, or to disease of the pleural membrane, whether tuberculous or actinomycotic.

The first step in the treatment of a chronic empyema, having ascertained its extent, is to secure efficient, dependent drainage and to irrigate the cavity repeatedly with Carrel Dakin's solution, so as to disinfect the cavity and to strip the pleural membranes of all possible organising lymph. The use of this solution will be impossible if there is a fistula. Blowing exercises are carried out at the same time to encourage expansion of the lung.

The character of the subsequent operation will depend on the extent of the empyema cavity. A small one may be obliterated by removing all the overlying and adjacent ribs. A large cavity, but one in which the lung is not fully collapsed, will need an extensive decostalisation and, in addition, the removal of the overlying thickened parietal pleura, together with the periosteum of the ribs and the intercostal muscles. A cavity with a fully collapsed lung will require additional measures to ensure approximation of the outer and inner walls. To this end it will be peritoneum running upwards and outwards from the convexity of the curve described by the spermatic vessels in the iliac fossa, but the pull is felt far above this and even the kidney moves with it. The peritoneum, of course, moves with the shifting of the structures underneath it, but it is far too flimsy and extensible to withstand the strain; the structure which is sought must lie beneath it. To show this structure a second incision is made.

This incision divides the entire muscular abdominal wall from the lumbocostal angle to the scrotum, opening that line of cleavage which lies directly beneath the muscles and which the surgeon uses for the "extraperitoneal" approach to the ureter or iliac vessels. Dissection is carried on in this interspace over the entire side of the abdomen, leaving the muscles on the outer side of the cleft and the spermatic vessels, the ureter, and the kidney on the inner.

The cord is now freed from the opened inguinal canal, and at the point where it joins the main mass of abdominal contents the peritoneum is exposed by pulling the spermatic vessels and their accompanying tissues away from it. The true peritoneum is a membrane hardly thicker than a soap-bubble, but it is possible to carry a second splitting dissection between it and the tissues to its outer side over much the same extent as the first one.

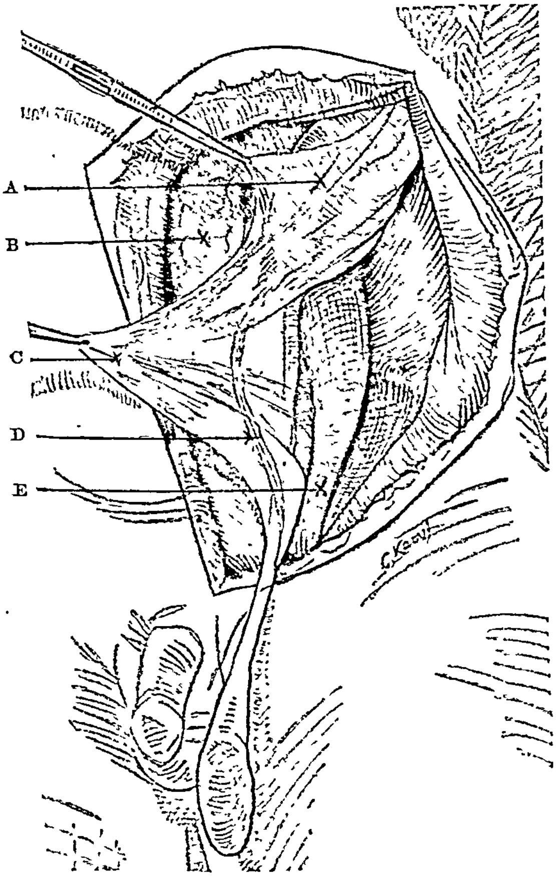

FIG. 1.—Dissection showing the layer of tissue in which the spermatic vessels run, isolated between the peritoneum on the inner side, and the muscle-sheaths of the abdominal wall on the outer. A fan-shaped prolongation of its fibres can be seen running down with the cord towards the testis, which has been pulled out of the scrotum. A = Kidney in its fibrous sheath. B = Peritoneum covering intestines. C = "Abdominal connective tissue." D = Spermatic vessels. E = Psoas muscle.

The final result is the isolation, between the two planes of dissection, of a layer of fibrous tissue which is apparently continuous around the whole extent of the abdominal cavity (Fig. 1). Above it becomes thick and fatty to ensheathe the kidney; below this the ureter and the spermatic vessels run in its substance; and at the internal ring a prolongation of its fibres accompanies the spermatic vessels through the inguinal canal down to the testis. It is this prolongation whose fan-shaped upper end was demonstrated through the intact peritoneum by pulling upon the cord, and which normally takes the weight of the testis off the vessels and the vas when the suspensory muscles relax.

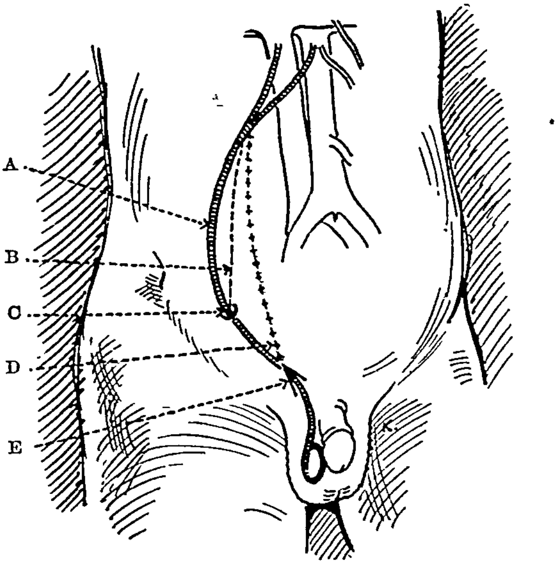

FIG. 2.—Diagram showing the three stages in lowering the testis. A = Normal course of spermatic vessels. B = Course of vessels after freeing them from abdominal connective tissue. C = Internal abdominal ring. D = Course of vessels after division of internal crus of internal ring. E = External abdominal ring.

The practical object of these investigations is to find out how to lower a testis as far as possible without destroying either of its two indispensable connexions with the body, the vas and the spermatic vessels. Obviously the next step is to divide the fibrous suspension that has been demonstrated and to observe the result. When this has been done and the spermatic vessels have been freed they straighten out both in their main curve and in those minor irregularities which they possess in common with all blood-vessels, so permitting a marked lowering of the testis. This straightening, however, makes the vessels meet the inguinal canal at a distinct angle of about 45°, instead of curving gently into it as they did originally (Fig. 2). There is normally a sharp turn at this point in the course of the vas, and investigation, either by dragging hard on the cord or by feeling with the finger, will make it clear that there is some firm structure here which maintains an angle in the constituents of the cord, and consequently prevents the maximum descent of the testis which that cord suspends.

Whatever this structure is, besides maintaining this angle it must form the boundary between oblique and direct inguinal herniæ, it must be capable of taking its part in the strangulation of a hernia at the internal ring, and it must raise that fold in the peritoneum which is always to be seen just internal to the point at which the testis originally left the abdomen. In text-books, of

Pneumotomy, in order to reach a deep-seated abscess close to the hilum, carries the serious risks that large vessels may be opened, and possibly large bronchi also. The patient is then exposed to the dangers of hæmorrhage from the wound, which is difficult to control owing to the depth from the surface; of hæmoptysis when both vessel and bronchus are opened, or of air embolus. This is just the case for which artificial pneumothorax is permissible and often very effective. Collapse by artificial pneumothorax is dangerous when the abscess is close to the surface, since the pleural cavity is apt to become infected from a superficial abscess.

Pneumotomy is contraindicated also in cases in which abscess and bronchiectasis complicate each other, unless the abscess is considerable and the bronchiectasis a mild secondary change. Extensive collapse by thoracoplasty is indicated in all these cases which involve more than one lobe. For the unilobar lesion, whether bronchiectasis alone or complicated by abscess, resection of the lobe is the operation of choice, despite the considerable mortality.

BRONCHIECTASIS

Bronchiectasis is a dilatation and thickening of the bronchi which, once it has developed, cannot be healed in the way that changes and even destruction caused by other inflammatory diseases can be healed. It is for this reason that the two great difficulties in the treatment of bronchiectasis are that the collapse of the dilated tubes must be complete and must be permanent.

Lobectomy, which eradicates the disease, is applicable to the unilobar lesion only. It is a difficult operation, and under the most favourable conditions has a mortality of 15 per cent. Lobectomy of more than one lobe has been done, but the mortality in these cases reaches 70 per cent. For the unilateral cases one or other method of collapse therapy offers some hope of improvement and even of success.

When a complete collapse of the lung can be obtained by artificial pneumothorax the immediate result is excellent, but the collapse of the lung must be maintained continuously else the symptoms will return. The substitution of the air by oil, once the collapse has been established, lessens very considerably the interval between the refills. Unless, however, the mediastinum is mobile, or a pocket of air is kept constantly above the oil, there are dangers associated with an oleothorax which may lead to serious complications. Hemidiaphragmatic paralysis is occasionally only successful in basal cases. When there is a bilateral basal bronchiectasis a bilateral phrenicectomy should be done, as considerable improvement may result.

Thoracoplasty has the advantage of producing a permanent collapse, but the collapse is not as complete as that obtained by artificial pneumothorax. The results depend on the type of bronchiectasis. If the dilatation involves the main tubes little benefit will follow a thoracoplasty, but if the smaller bronchi and bronchioles are the seat of the trouble, complete or almost complete abolition of the symptoms may result from the operation. When a thoracoplasty is done for bronchiectasis the amount of rib resected must be greater than is usual for a case of tuberculosis. It may also be necessary to supplement the posterior resection by an excision of the costal cartilages from the first down to and including the costal margin. If the supplementary collapse is needed over a localised area only, this may be effected by a further local rib resection or by a paraffin pneumolysis.

SOME ANATOMICAL POINTS IN THE OPERATION FOR UNDESCENDED TESTICLE

By Denis Browne, M.B. Sydney, F.R.C.S. Eng.

SURGEON TO THE HOSPITAL FOR SICK CHILDREN, GREAT ORMOND-STREET, LONDON

> "And rouse from sleep that fell anatomy."
> —King John, Act III., scene 4.

It is a useful platitude that the first step in trying to correct some congenital abnormality of the body is to define the normal structure and mechanics of the part concerned. In the surgical treatment of undescended testis therefore, before trying to shift the misplaced organ into its normal position, it is reasonable to investigate how exactly this normal position is maintained.

The suspension of the testis, like a weight at the end of a rope, is unique in the mechanics of the body, and it is not extremely obvious upon what structures the pull of gravity falls. The skin can be at once eliminated from any share in opposing this pull. Its behaviour in obesity, in large herniæ, or in the lips which certain African tribes stretch to the size of saucers, shows that it yields almost indefinitely to any persistent force, however small. To turn from analogy to experiment, it will be found that it is impossible to drag the normal testis downwards far enough to put a strain on the skin of the scrotum.

The dartos and cremaster muscles have of course a suspensory action; when they contract the testis is raised. But muscles are only fitted to exert force intermittently, and the body invariably backs them up by some arrangement of fibrous tissue to supply a passive but permanent safeguard when there is any danger of displacement of structure. A good instance of this is the relation of muscles and ligaments around joints.

The probability is then, that there is a secondary fibrous suspension of the testis. To counteract the force of gravity its direction must be straight up and down, and so it must run with the spermatic vessels and the vas, which lead directly downwards to the organ. These structures can be ruled out as being themselves the weight-bearers by virtue of another of the fundamental principles of the body: the principle that to one structure there shall be one function alone. (It is a rule whose wisdom the human inventor has usually to find out for himself; the combination tin-opener and mouse-trap is rarely a success.) The slackness and tortuosity of the blood-vessels, which enables them to convey fluid through all changes of pressure and position, completely unfit them for resisting tension. The same applies to the vas, which has many points of resemblance to an artery.

DISSECTION OF THE SUSPENSION OF THE TESTIS

To find out whether there actually exists the structure which has been deduced from the combination of the habits of the body and the mechanics of the problem, two incisions are needed. The first is an ordinary midline one that opens the peritoneal cavity and lays bare its posterior wall. Then, when the action of gravity is imitated and exaggerated by dragging downwards on the testis, it is seen that the strain of this drag passes up along the cord past the internal ring, to radiate over the exposed posterior abdominal wall. The main stress comes on fibres which can be seen and felt beneath the

This opinion is less startling than it looks, as it is held, though without any exact formulation of it, by almost every surgeon. The "peritoneum" sewn up in any abdominal operation contains the three layers of the anatomist welded to the endothelial lining of the abdominal cavity, but no surgeon ever refers to these layers as separate entities.

My own belief in the infallibility of the present systematic anatomy departed permanently after my investigations on the tonsil, an anæmic scrap of lymphoid tissue upon which the classical account concentrates some half a dozen arteries. But to anyone who doubts the possibility of gross misdescriptions being copied from one anatomy book to another, I would recommend consideration of the state of mind shown by the use of one term in the name of the structure under discussion, the word "fascia." The first essential in the scientific description of any subject is a narrow and sharply defined meaning to any terms that are used. In spite of this structures which are different developmentally, morphologically, and functionally are all lumped together under this one heading. Consider the absurdity of using the same term for a tendon like the fascia lata, and for a vague concentration of fibrous tissue like the fascia of Camper. Or why should the expansion of the tendon of the palmaris longus in the palm be an aponeurosis, and the precisely similar expansion of the hamstrings in the leg be fascia ? This confusion is at its maximum in the pelvis, where the muscle sheaths and tendons on the one side and the packing material between the viscera on the other, are described as the visceral and parietal layers of the same fascia. I feel diffident about attacking the mystery of the pelvic fascia. What student has not been reduced to a wholesome state of modesty by his complete failure to understand it ? What professor of anatomy is not rumoured to be writing a book upon it ? And yet I must confess that I believe the whole doctrine, like certain ones of the early Alexandrian theologians, to be founded upon the double meaning of a single word.

The difficulty of identifying the fibrous suspension of the testis with the internal spermatic fascia is paralleled by the difficulty of finding an exact anatomical name for the condensation of fibres which has been described at the upper end of the inguinal canal. It is, of course, the band which Hesselbach[4] described as the internal crus of the internal abdominal ring. In his drawings he shows with great clearness that it is this structure, and not the deep epigastric vessels, which actually forms the inner border of the gap through which an indirect hernia emerges. But I cannot see it as he draws it, directly continuous with the sheath of the rectus. It is quite different in texture from the tissues that transmit muscular force, and a strong argument against this band belonging to the muscular system is that the contraction of the abdominal muscles must slacken it by bringing the arch of the conjoint tendon near to Poupart's ligament; fibrous tissue which really belongs to muscles only serves the purpose of applying the force of the contractions, which invariably tighten it.

To me this band appears to be a typical condensation of the extraperitoneal fibrous tissue which may possibly have been originally produced by the emergence of the testis. If one imagines a loose fabric lining the abdominal cavity, the thrusting through it of a finger at the internal ring in the direction of the inguinal canal would produce just such concentration of fibres at this point. However, this is an unimportant speculation.

The "interfoveolar ligament," which is described in some books as crossing the floor of the inguinal canal between the sites of direct and indirect herniæ, appears to consist of aberrant strands of muscle which not infrequently stray from the transversalis in this region. Quain[5] shows it as superficial to the tissues bounding the internal ring and flooring the inguinal canal, but adds to the confusion by showing these tissues as continuous with the sheath of the transversalis and calling them the "iliopubic tract."

Most of the modern text-books simply describe the floor of the inguinal canal as being formed of transversalis fascia and let it go at that. It may be noted that though it is always stated that the cord carries with it prolongations of each of the layers of the abdominal wall, the extraperitoneal tissue and the fibrous layer of the peritoneum are never mentioned in the catalogue of these.

SUGGESTIONS FOR A DESCRIPTION OF THE FIBROUS TISSUE OF THE ABDOMEN

As a target for retaliatory criticism I offer the outline of a description of the abdomen in which a layer, "the abdominal connective tissue," is described as forming a complete investment for the abdominal contents, between the osteomuscular box on the outer side and the peritoneal sac on the inner. Only

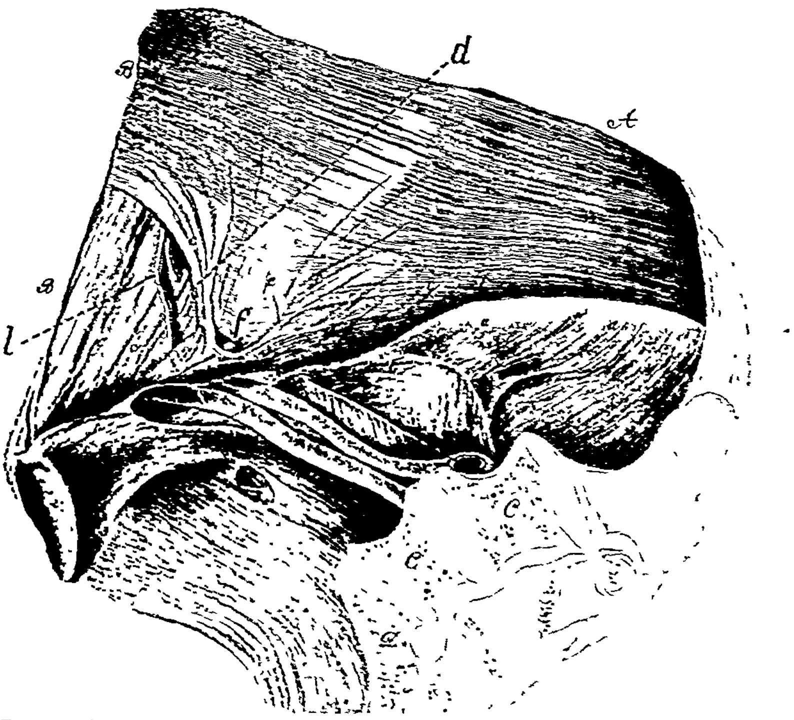

FIG. 4.—One of Hesselbach's original drawings, showing that it is the band of fibres which he calls the internal crus, and not the deep epigastric vessels, which bounds the internal abdominal ring. *d* = Internal crus of internal abdominal ring. *l* = Deep epigastric vein. *f* = Internal abdominal ring.

course, the dividing structure between direct and indirect herniæ is always described as the deep epigastric vessels, but it has been already pointed out that unsupported blood-vessels have not the tenseness and rigidity which would enable them to act in this way. Once again fibrous tissue should be expected, and *once again* it is found as an irregular but extremely tough band which defines the median half of the internal abdominal ring. Its fibres are usually arranged as several sharp-edged crescentic folds, blending behind with the sheath of the iliac vessels and in front with the general extraperitoneal fibrous tissue. In its shelter run the deep epigastric vessels, and once it has been divided it will be found that these vessels are so slack that they can be moved with ease downwards and inwards to the level of the external ring. This allows the complete straightening of the spermatic vessels, and as in almost all cases this straightening still leaves a definite amount of slack in the vas, nothing further can be done to allow the testis to descend.

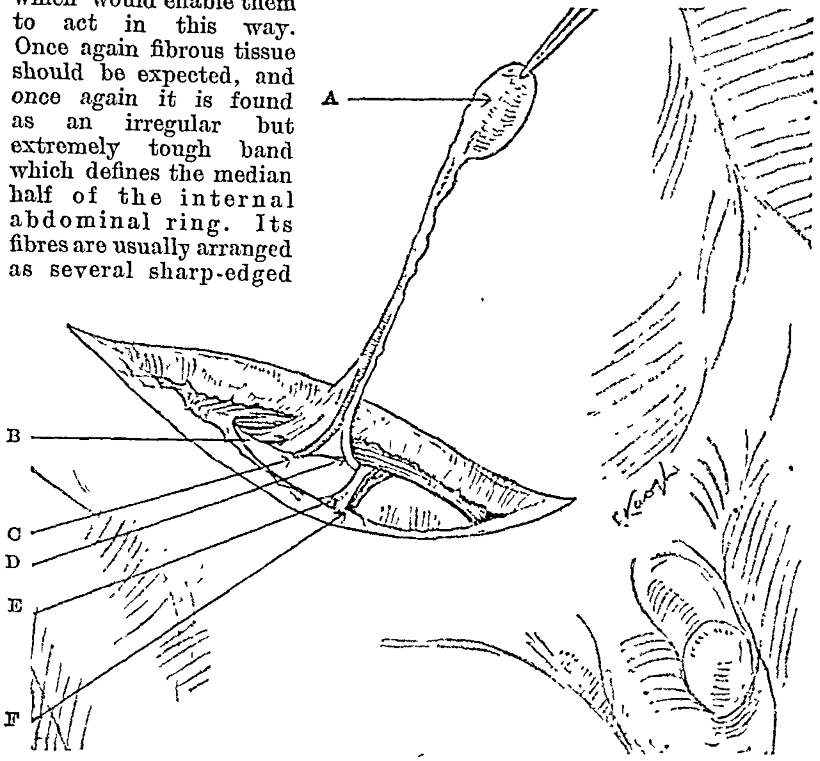

FIG. 3.—Drawing of an operation, showing a fan-shaped band of fibres spreading outwards and upwards from the spermatic vessels at the internal inguinal ring. The vas is seen turning at a sharp angle to join the cord, this angle being maintained by the fibrous internal crus of the internal ring. The deep epigastric vessels are running in the shelter of the internal crus, and take no part in bounding the ring. A = The testis. B = Fan-shaped expansion of suspensory fibres. C = Spermatic vessels. D = Vas deferens. E = Edge of internal crus of internal abdominal ring. F = Deep epigastric vessels.

SURGICAL IMPORTANCE OF THE STRUCTURES DESCRIBED

In the operation for undescended testicle the suspensory fibres must be deliberately and delicately isolated where they spread out in a fan shape from the spermatic vessels at the internal ring (Fig. 3). This fan can be felt running upwards free between the peritoneum on the inner side and the muscles on the outer; the veins are carefully defined on its inner edge, and it is divided piecemeal.

The final step in lowering the testis is a similar cautious division of the band which maintains the angle of the vas and the spermatic vessels at the internal ring. As has been already stated, when this is done the deep epigastric vessels are no obstacle to the complete shifting inwards of the cord, and consequently there is no need to divide them as Davison[1] recommends.

In the radical cure of an inguinal hernia, again, one of the main points in avoiding recurrence is to obliterate completely any dimple at the site of the original neck of the sac. In consequence the band which defines the inner edge of both the neck of the sac and of any dimple which may remain after the sac's removal is probably worthy of more attention than it usually receives.

There is also some surgical interest in the possible importance of the suspensory fibres in the production of varicocele. If the primary muscular suspension is put out of action for long periods, for instance by general debility or by residence in the tropics, the ensuing tension on the fibres must tighten them across the veins and so impede the return flow of blood. It is possible that an operation planned to relieve this might be more satisfactory than the present technique; it could scarcely be less so.

A CRITICISM OF THE DESCRIPTION OF THE FIBROUS TISSUE OF THE ABDOMEN

The interest of the fibrous bands described does not, however, end with their surgical division; they have still to be identified with structures in the systematic anatomy of the textbooks. These describe a funnel-shaped fibrous sheath to the elements of the cord, the infundibular fascia, as descending from the transversalis fascia. The transversalis fascia is described in its turn as an aponeurotic layer inserted below into the crest of the ilium and the outer third of Poupart's ligament, and continuous above with the fascia that surrounds the kidney.

I am not particularly concerned with the difference between the bundle of fibres running with the spermatic vessels which I have described, and the funnel-shaped infundibuliform fascia that encloses both vessels and vas. But the tissues into which the vessels and their accompanying fibres run lies over the iliacus, and so cannot be the transversalis fascia. And if it were the transversalis fascia, it has certainly no insertion into the iliac crest, though it does split above to enclose the kidney.

When I first met this difficulty I began to investigate the transversalis fascia. I sought it in books, where its descriptions were vague and unconvincing; in anatomy departments, which had no dissections of it to offer; and in the human body, where I failed entirely to find it. The only result of my search was a suspicion which hardened into a heresy. The orthodox teaching is that the layer between the filmy true peritoneum and the muscles of the abdominal wall, that layer whose isolation by dissection I have described, consists of three distinct structures: the fibrous layer of the peritoneum, the extraperitoneal connective tissues, and the transversalis fascia. My heresy is that these three are one and indivisible.

success obtained in the prolonged narcosis treatment of many cases of mental disorder has warranted a search either for new drugs which will produce sufficiently deep narcosis without the demonstration of toxic by-effects or for a modification of present methods of narcosis which will diminish or eliminate the toxic action.

The toxic effects of narcotic treatment, particularly by somnifaine, have been described by A. M. Meerloo [2] and M. Müller.[3] These include bulbar symptoms, such as derangements of swallowing mechanism, indistinct speech, ataxia, tremor of the lips, and vasomotor paralysis. A frequent accompaniment of prolonged narcosis is the development of ketonuria, which becomes more marked as the narcosis proceeds. The amount of ketonuria varies from person to person; in certain patients there is little or no ketonuria after seven days' narcosis under somnifaine, whereas in others the ketonuria may become very marked 48 hours or less from the commencement of the treatment. Doubtless the effect has much to do with the actual dosage of the narcotic, certain patients responding more vigorously than others, so far as ketosis is concerned, to a given dose. In the past it has always been considered advisable in this hospital to cut short treatment with somnifaine (the drug most frequently used) as soon as a definite ketosis has been produced. This has militated greatly against the success of narcotic treatment.

THE ACTION OF NARCOTICS

Investigations have been carried out recently in this laboratory on the mode of action of narcotics. The problem has been studied from a biochemical standpoint, the object being to discover what metabolic processes were influenced by the presence of the narcotic. The results,[4] briefly, are: (1) all narcotics have the property of inhibiting specifically, at low concentrations, the oxidation by the brain of substances important in carbohydrate metabolism—viz., glucose, lactic acid, and pyruvic acid; (2) of narcotics belonging to the same chemical type, those with the greater narcotic activity have the greater inhibitive action on brain oxidations. There is a definite parallelism between the inhibitive power on glucose oxidation of brain and the narcotic power of the drug.

It seems from the facts available that the narcotic is taken up from the blood stream at a nervous centre, where it effects a diminution of the power of the cells constituting the centre to oxidise glucose or lactic acid. The amount of energy available for the functional activity of these cells is thereby diminished and narcosis—or a depression of the functional activity of the nervous centre in question—ensues. These observations led to the supposition that narcotics may exert toxic effects in the animal organism by interfering with the carbohydrate metabolism of organs other than the brain, a view supported by experimental observations on liver oxidation in the presence of narcotics and by the fact that ketonuria is a frequent accompaniment of narcosis. It is remarkable that the development of ketosis which so frequently occurs in surgical anæsthesia has not been previously noted, to our knowledge, in prolonged narcosis.

AN EXPERIMENTAL INVESTIGATION

It was found from certain preliminary experiments that the simultaneous administration of glucose and insulin to narcotised animals brought about a decrease in toxicity of the narcotic, and this work led us to consider the possibility of administration of glucose and insulin to patients undergoing narcotic treatment.

So far, 20 patients have been investigated. The usual procedure has been to administer 2 c.cm. of somnifaine intramuscularly from two to four times in 24 hours, most patients receiving three doses a day. The urine was collected in the morning and afternoon, the morning specimen being always examined for acetone bodies. The Rothera nitroprusside test was used for the colorimetric demonstration of acetone, and in many cases acetone was estimated quantitatively.

As soon as definite ketonuria appeared the following modified procedure was adopted. Simultaneously with the next intramuscular injection of somnifaine 5 to 15 units of insulin were given hypodermically, this dose of insulin from then onwards being administered twice or thrice a day (with each subsequent dose of the narcotic). With each insulin injection the patient received (by the mouth) 50 g. of glucose in water or milk. Blood-sugar estimations were frequently made as a precautionary measure. The doses of glucose and insulin cited have been, in our experience, sufficient to avoid hypoglycæmia.

The immediate result of the insulin-glucose modification of the narcotic treatment was the entire disappearance of ketonuria within 48 hours. The patient, moreover, showed no ketonuria during the remainder of the course of the narcotic treatment, which lasted from 14 to 16 days. It is as yet too early to decide whether all other toxic symptoms disappear, but it has been noted, in particular, that cyanosis, alarming drowsiness, and vomiting are symptoms which either partially or completely disappear under the modified treatment. The accompanying Table shows typical examples of the effect of glucose-insulin treatment on the disappearance of ketosis during somnifaine narcosis.

Case.	Dosage of somnifaine throughout treatment.	Day of appearance of ketonuria after commencement of narcosis.	Acetone in urine mg. per 100 c.cm.	Day of first administration of insulin and glucose.	Acetone in urine mg. per 100 c.cm.
1	2 c.cm. t.i.d.	6th	12 (6th day); 31 (7th day).	7th	3 (8th day); nil (9th)*
2	2 c.cm. t.i.d.	7th	5 (7th day); 19 (8th day).	8th	Trace (9th day); nil (10th)*
3	2 c.cm. t.i.d.	4th	+ + + + + (4th day).	5th	Trace (6th day); nil (7th)*
4	2 c.cm. t.i.d.	1st	+ + (1st day).	2nd	Nil (3rd day)*

* and subsequent days of treatment.

In two cases glucose and insulin were given at the commencement of the course of treatment, and in neither of these cases has ketosis developed throughout the entire course. It seems probable that the most desirable procedure is to give glucose and insulin at the commencement of a course of narcotic treatment, in order to prevent the appearance of ketosis and other toxic symptoms.

Out of the 20 patients investigated, 13 have had glucose-insulin treatment, with the result that they when it is isolated in this way can the ordinary mind form a picture of a continuous "packing layer" that includes the transversalis fascia, the tela subserosa, the fibrous layer of the peritoneum, the visceral layer of the pelvic fascia, the kidney fascia, the extraperitoneal fat, and all the other indefinite terms which do so little credit to one of the exacter departments of medicine.

All the viscera can be described in relation to this layer, either sessile upon its inner surface like the liver, attached to it by a bridge of its substance like the alimentary canal, or buried in it like the kidney. Any structure that emerges from it, either during the development of the body or later, carries with it some of its tissues in prolongations of varying types, such as the fatty outer sheath of a femoral hernia, the dense fibrous sheath of the femoral vessels, or the suspension of the testis which is the subject of this paper (Fig. 5).

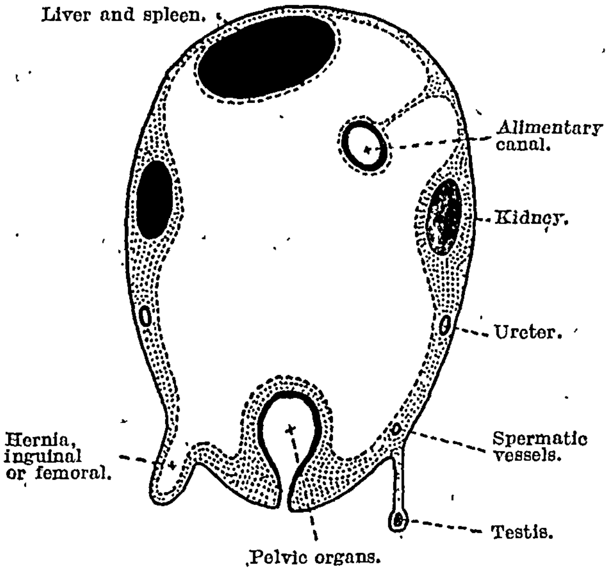

FIG. 5.—Diagram showing the arrangement and distribution of the "abdominal connective tissue," as a single layer of fat and fibres, in which the various viscera are packed between the peritoneum and the muscles, and which supplies a covering to anything that runs outwards through it.

This abdominal connective tissue varies greatly in different regions in its thickness, its shape, and in the proportions which its two elements, fibres and fat, bear to each other. As might be expected from its function as a packing layer, it is most abundant in the lower part of the abdomen into which the viscera sag and strongest round the openings (inguinal canal, anus, &c.) through which the viscera tend to escape. Wherever there is any strain the fibres of this layer concentrate and organise themselves to meet it, forming, as Lane pointed out, suspensory ligaments to take the weight of the various viscera. The two structures which have been described belong to this kind of concentration, and numerous other examples of it are well known.

It should be noted that the line of cleavage that the surgeon calls the "extraperitoneal approach" has this layer of tissue between it and the peritoneum. In consequence, if the ureter is sought by this route it is found embedded in the fibrous tissue on the inner wall of the cleft, a fact which is usually expressed by saying that "the ureter is adherent to the peritoneum."[2] It seems rather absurd to describe as extraperitoneal a line of cleavage that leads into the cave of Retzius in one direction and behind the kidney in the other; perhaps "submuscular" would be a better name.

The dissection which shows the abdominal connective tissue best is not possible in the systematic taking to pieces of the body, but it is an instructive and not particularly difficult way of doing a post-mortem examination of the abdomen. In it the muscles of the abdominal wall are divided by a cruciform incision reaching from loin to loin, and from the sternum to the pubis. The submuscular or "extraperitoneal" space is found below the muscles, and the whole abdomen is dissected in it. The œsophagus, the great vessels, and the structures emerging through the pelvic diaphragm are cut through as they are met; the testis is pulled up through the inguinal canal, and the final result is the removal of a sausage-shaped mass containing all the viscera. This mass contains the peritoneum and in many places consists of what is usually called peritoneum, but nowhere is the true membrane itself visible.

It appears to me that in this way it would be possible to offer to the student of anatomy a comprehensive yet comprehensible account of something of the utmost surgical importance—the fibrous tissue between the peritoneum and the osteomuscular wall of the entire abdominal cavity. If any professor of anatomy needs to be convinced of the utter confusion produced by the present teaching, I recommend the setting of a question on these lines at the next examination.

I owe many thanks to Mr. C. A. Keogh, F.R.C.S., for his help in the dissections and for his drawings to illustrate them.

GLUCOSE-INSULIN ADMINISTRATION IN PROLONGED NARCOSIS

By J. H. Quastel, D.Sc., Ph.D., F.I.C.
DIRECTOR OF THE RESEARCH LABORATORY, CARDIFF CITY MENTAL HOSPITAL
AND
R. Ström-Olsen, M.B. Wales, D.P.M.
SENIOR ASSISTANT MEDICAL OFFICER AT THE HOSPITAL

The development of narcotic treatment in certain types of mental disease has been greatly retarded by the knowledge that prolonged narcosis for therapeutic purposes is often accompanied by toxic symptoms. These symptoms may be such as to render further treatment with the narcotic inadvisable or dangerous, and consequently the treatment has frequently to be stopped before there is any chance of an alleviation of the abnormal mental symptoms.

In the Cardiff City Mental Hospital about 50 cases have been treated with Somnifaine[1] during the past two years. The results were extremely encouraging except in so far as toxic symptoms, including the production of ketosis, were demonstrated in a large proportion of the cases. The toxic by-effects were often so alarming that it became necessary to discontinue the treatment. It has been felt, however, that the

[1] Somnifaine is an alcohol-glycerol-aqueous solution of a mixture of diethylamine salts of 10 per cent. veronal and 10 per cent. allylisopropylbarbituric acid.

the same number of embryo filariæ in his blood, and they have maintained the same nocturnal periodicity. Apart from a hydrocele and an enlarged testicle, both probably filarial in nature, he has never developed or exhibited any further signs of filarial disease.

The number of embryo filariæ in his blood has been very considerable—about 260 to 20 c.mm. of blood at midnight—and as the patient has frequently been to the Hospital for Tropical Diseases and the Seamen's Hospital, Royal Albert Dock, for dysentery, venereal disease, and finally for pyloric stenosis, there have been ample opportunities for prolonged observations on his blood.

The observations on the nocturnal periodicity in this case were made at hourly intervals, and were carried out with meticulous care. Dry and wet films were prepared at the bedside and examined forthwith, and a standard quantity of 10 c.mm. was employed (which is half the amount of the 20 c.mm. which is commonly adopted). The main points brought out by Mr. Walters's graphs are these :—

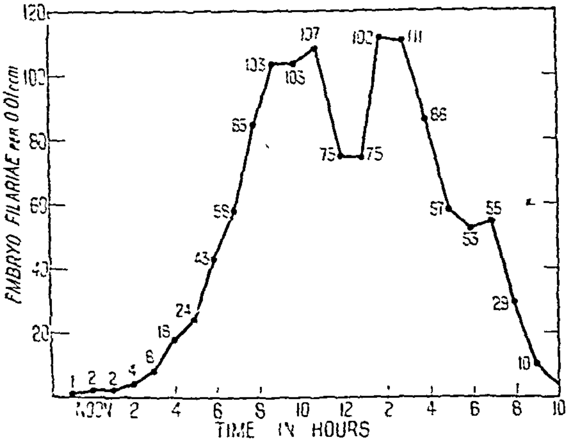

FIG. 2 shows the average number of embryo *F. bancrofti* per 0·01 c.cm. of a patient's blood during 24 consecutive hours of reversed life. The patient was given hyoscine gr. 1/100 and morphia gr. 1/48 at 10 A.M. on June 15th and put to bed in a darkened private room. 11 A.M.–3 P.M.: patient asleep. 4 P.M., awake; given a drink of water and luminal grs. 1. 5 P.M.–8 P.M., asleep. 9 P.M., dozing. 10 P.M., waking and irritable. 11 P.M., fully awake. 11.30 P.M., got up and had meal of tea, eggs, and toast. 12 P.M., out for a walk of 40 minutes in hospital grounds. 1 A.M., fully awake and chatting, feels quite well. 1.30 A.M., had meal of tea and toast; feels quite well. 2 A.M., lying quietly in bed, feeling drowsy. 3 A.M., dozing. 4 A.M., asleep. 5 A.M., awake and tired. 6 A.M., drowsy and slightly irritable. 7 A.M.–9 A.M., asleep but waking at any noise. 10 A.M., asleep.

(*a*) The periodicity curve is absolutely nocturnal but embryos are present in small numbers in the peripheral circulation during the daytime. This fact has often been noted before (Fig. 1).

(*b*) The evening rise of the embryo filariæ swarm is more gradual in character than the matutinal fall. The maximum migration of embryos occurs at 2 A.M. (Fig. 1).

(*c*) The number of embryo filariæ and the character of the curve remains remarkably constant when taken on three distinct occasions, separated by a month or more of time—viz., June 4th, August 29th, and Sept. 2nd, 1932 (Figs. 1 and 4).

(*d*) The number of embryo filariæ at the hour of midnight remains approximately the same in 1932 as it was in 1924, a period of eight years, and it has been shown by Mr. Walters that the experimental error of observation in his series is a very small one indeed (Fig. 5).

(*e*) The periodicity curve remained the same after a severe abdominal operation, but it was severely disturbed during a break of sleep (Fig. 2) and after systemic disturbance such as protein shock (Fig. 3). The fall in periodicity takes place immediately the waking state is entered upon.

This series of accurate experiments forges yet another link in the chain of evidence which supports the contention that the sleeping and waking states are primary factors in the periodicity phenomenon in this particular infection. Whether similar fluctuations can be brought about in the relative number of circulating embryo filariæ in the Pacific, non-periodic variety of *F. bancrofti* remains to be seen, and it is hoped that similar experiments on the same lines may be instituted.

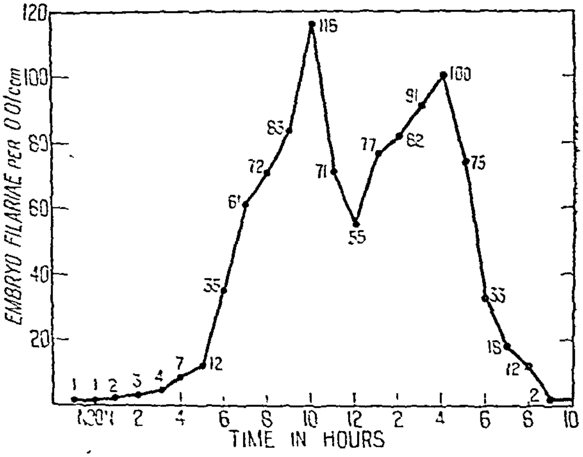

FIG. 3 shows the average number of embryo *F. bancrofti* per 0·01 c.cm. of a patient's blood during 24 consecutive hours whilst undergoing a protein shock. 5.5 P.M., the patient was given an intravenous injection of 50 million T.A.B. vaccine. 6 P.M., complains of vague pains all over body. 6.52 P.M., suffering rigor. 7.5 P.M., temp. 103·4°, sweating. 8 P.M., feels better; temp. 101°. 9 P.M., asleep; temp. 100·8°. 10 P.M., asleep; temp. 100·4°. 11 P.M., awake, temp. 100°. 12 P.M., awake; temp. 99·6°. 1 A.M., awake; given hot meal; temp. 99·4°. 2 A.M., dozing. 3 A.M.–6 A.M., asleep. 7 A.M., awake; feels all right. 8 A.M.–10 A.M., awake.

It is also hoped that Prof. O'Connor and others investigating the possibility of cyclical parturition may undertake similar observations, as the conclusions arrived at in this particular piece of work seem impossible to reconcile with their hypothesis. How, also, can a daily cyclical destruction of embryos explain the phenomenon of non-periodic filaria? In *Dipetalonema perstans* infections (non-periodic) in Uganda, Low[7] counted the embryos in a measured quantity of peripheral blood (20 c.mm.) just before patients suffering from sleeping sickness died and then, immediately after death with the blood still warm, similar measured quantities from the aorta, heart, or lungs. The numbers of embryos present in these sites were always greatly in excess of those in the peripheral blood, indicating a seat of special selection in these parts.

More work might also be done on dogs and other animals, where it will also be found that the seat of special selection of the embryos is often in the large vessels of the thorax, only the overflow, apparently, passing into the peripheral blood with no periodicity. Autopsies on dogs might prove or disprove the cyclical theory.

History and Laboratory Reports

(BY MR. WALTERS)

The patient was first seen at the Hospital for Tropical Diseases in October, 1920, when a series of intravenous antimony injections were given,[8] and again in May, 1924, when Bayer "G. 1919" was tried for treatment.[9]

He was a male Indian native aged 50, born in Calcutta, where he had lived till going to sea 18 years before. He had had fever in 1898 (? nature), syphilis in 1916, and dysentery in 1918. In 1924 he had been in the Hospital for Tropical Diseases. In 1927 he had had stomach trouble: in 1932 he was admitted to the Seamen's Hospital, Royal have finished their course of narcotic treatment without development of ketosis or other serious complications. Of the remaining 7, who showed no ketosis and who did not have glucose-insulin treatment, 3 received only two doses of somnifaine a day. While admittedly few patients have been as yet subjected to the modified treatment, the results have been so satisfactory that we have considered it advisable to publish this preliminary note. Further investigations on this mode of treatment, particularly from a clinical standpoint, are in progress.

We wish to express our appreciation of the interest taken in this work by Dr. P. K. McCowan, medical superintendent of the hospital, and to acknowledge our indebtedness to the Medical Research Council for a grant to the laboratory.

SOME RECENT OBSERVATIONS ON FILARIAL PERIODICITY

By G. Carmichael Low, M.D. Edin., F.R.C.P. Lond.
SENIOR PHYSICIAN TO THE HOSPITAL FOR TROPICAL DISEASES, LONDON

AND

P. H. Manson-Bahr, D.S.O., M.D. Camb., F.R.C.P. Lond.
PHYSICIAN TO THE HOSPITAL

With a Clinical and Laboratory Report by
A. H. Walters
SENIOR TECHNICIAN, PATHOLOGICAL LABORATORY, SEAMEN'S HOSPITAL, ROYAL ALBERT DOCKS

Interest has once more been aroused in the seemingly inexplicable phenomenon of filarial periodicity, the existence of which was discovered by Manson in Amoy and further worked out by him and Stephen Mackenzie in London in 1881–82. Since that date little or nothing has been done to illuminate further the pioneer observation of these two workers.

As is well known, the embryos of *Filaria bancrofti* maintain a nocturnal periodicity in the peripheral circulation; that is, they come into and circulate in the peripheral blood at night and disappear during the day. This curious phenomenon, as seen in this particular parasite, appears to be connected with the habits of its definitive host, and so intimately is this the case that the periodicity can in time be gradually reversed if the patient changes his daily routine—for example, sleeping during the day and sitting up at night. This is a well-established fact. In *Loa loa* infections, where the periodicity is diurnal, this reversion cannot be effected easily, and in two cases reported by Low and O'Driscoll[1] no change had taken place in six days' time. Kulz,[2] however, has shown that it may gradually take place.

The observations which are recorded below abundantly confirm the truth of Manson's original discoveries and add weight to the statement of Dr. Mortimer Granville[3]:

> "It is not sleep or waking that has this influence. It is something recurring every 24 hours, just as the habits of sleeping and waking recur, and which is capable of being inverted; just as these habits are, and by the same means. That sleep does not cause the ingress of embryos is evident from the circumstances that egress begins hours before the usual hours of waking, and periodicity is maintained even though no sleep be indulged in for two or three days, and if sleep is continuous, or nearly so, for as long a time. The facts of the case seem to indicate that the conditions favourable to the ingress of the parasites become developed ordinarily during the last few hours of the waking state and that they are slowly eliminated during the last few hours of sleep."

The novel and revolutionary theory of Clayton Lane[4] would explain the phenomenon of periodicity by periodic cyclic parturition on the part of the female filaria with a daily destruction of all the embryos, and this hypothesis has received some support from the carefully conducted observations of F. W. O'Connor[5][6] on the uterine contents of the adult female worms removed by operation at different hours of the day. What is difficult to understand in this theory, apart from the massive daily production of embryos, is the fate of the millions of embryos which would be destroyed by this daily holocaust, and the effect that the absorption of this mass of dead material would exert on the apparently healthy human body. It does not explain, either, the comparative ease with which embryos are kept alive in blood or saline solution outside the human host for a week or more. No adequate explanation is at present forthcoming of what becomes of the millions of embryos so destroyed. A fact repeatedly emphasised is that those cases of *F. bancrofti* with the highest number of embryo filariæ in the circulating blood are often those which show the fewest signs of filarial disease. A massive destruction such as that postulated would have to be sudden and swift so as to cause the disappearance of the brood every 12 hours, and the liberation of this amount of foreign protein, one would imagine, would be liable to produce considerable reaction in the human body—a species of protein shock.

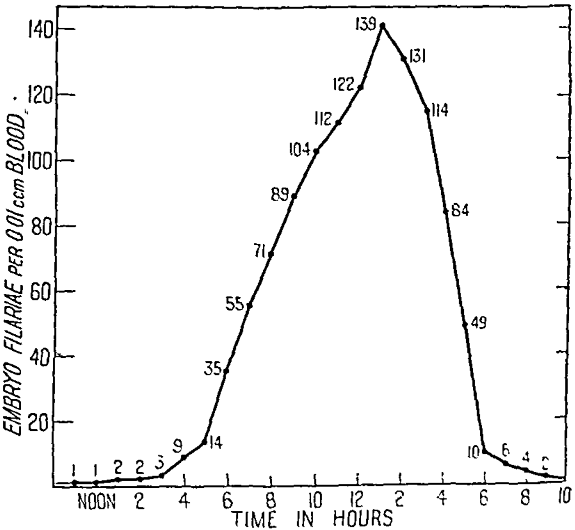

FIG. 1 shows the average number of embryo *Filaria bancrofti* per 0·01 c.cm. of a patient's blood during 24 consecutive hours of normal life. The blood was measured by means of a leucocyte-counting pipette, and these counts represent the mean average calculated from direct counts of living embryos by the cover-slip method and indirect counts from standard quantity thick blood films taken at the same times, being stained and counted afterwards.

A CASE-HISTORY

The observations recorded in the paper accompanying these preliminary remarks have been made after very considerable and minute work by Mr. A. H. Walters, the senior laboratory assistant at the Seamen's Hospital, Royal Albert Dock. The chief points in the case are these. The patient, an Indian steward of the P. and O. Line, has been more or less under observation for 11 years. During this comparatively long period he has exhibited approximately the same number of embryo filariæ in his blood, and they have maintained the same nocturnal periodicity. Apart from a hydrocele and an enlarged testicle, both probably filarial in nature, he has never developed or exhibited any further signs of filarial disease.

The number of embryo filariæ in his blood has been very considerable—about 260 to 20 c.mm. of blood at midnight—and as the patient has frequently been to the Hospital for Tropical Diseases and the Seamen's Hospital, Royal Albert Dock, for dysentery, venereal disease, and finally for pyloric stenosis, there have been ample opportunities for prolonged observations on his blood.

The observations on the nocturnal periodicity in this case were made at hourly intervals, and were carried out with meticulous care. Dry and wet films were prepared at the bedside and examined forthwith, and a standard quantity of 10 c.mm. was employed (which is half the amount of the 20 c.mm. which is commonly adopted). The main points brought out by Mr. Walters's graphs are these :—

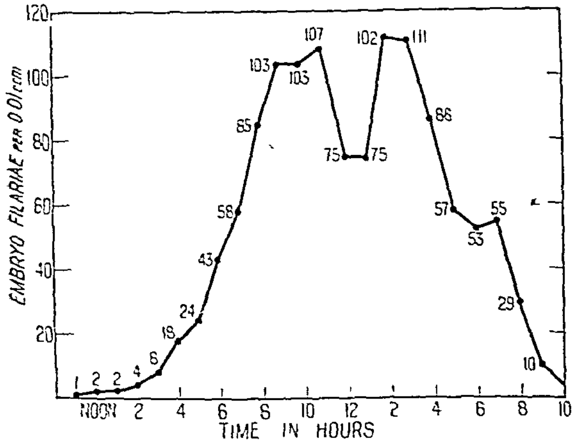

FIG. 2 shows the average number of embryo *F. bancrofti* per 0·01 c.cm. of a patient's blood during 24 consecutive hours of reversed life. The patient was given hyoscine gr. 1/100 and morphia gr. 1/48 at 10 A.M. on June 15th and put to bed in a darkened private room. 11 A.M.–3 P.M.: patient asleep. 4 P.M., awake; given a drink of water and luminal grs. 7. 5 P.M.–8 P.M., asleep. 9 P.M., dozing. 10 P.M., waking and irritable. 11 P.M., fully awake. 11.30 P.M., got up and had meal of tea, eggs, and toast. 12 P.M., out for a walk of 40 minutes in hospital grounds. 1 A.M., fully awake and chatting, feels quite well. 1.30 A.M., had meal of tea and toast; feels quite well. 2 A.M., lying quietly in bed, feeling drowsy. 3 A.M., dozing. 4 A.M., asleep. 5 A.M., awake and tired. 6 A.M., drowsy and slightly irritable. 7 A.M.–9 A.M., asleep but waking at any noise. 10 A.M., asleep.

(*a*) The periodicity curve is absolutely nocturnal but embryos are present in small numbers in the peripheral circulation during the daytime. This fact has often been noted before (Fig. 1).

(*b*) The evening rise of the embryo filariæ swarm is more gradual in character than the matutinal fall. The maximum migration of embryos occurs at 2 A.M. (Fig. 1).

(*c*) The number of embryo filariæ and the character of the curve remains remarkably constant when taken on three distinct occasions, separated by a month or more of time—viz., June 4th, August 29th, and Sept. 2nd, 1932 (Figs. 1 and 4).

(*d*) The number of embryo filariæ at the hour of midnight remains approximately the same in 1932 as it was in 1924, a period of eight years, and it has been shown by Mr. Walters that the experimental error of observation in his series is a very small one indeed (Fig. 5).

(*e*) The periodicity curve remained the same after a severe abdominal operation, but it was severely disturbed during a break of sleep (Fig. 2) and after systemic disturbance such as protein shock (Fig. 3). The fall in periodicity takes place immediately the waking state is entered upon.

This series of accurate experiments forges yet another link in the chain of evidence which supports the contention that the sleeping and waking states are primary factors in the periodicity phenomenon in this particular infection. Whether similar fluctuations can be brought about in the relative number of circulating embryo filariæ in the Pacific, non-periodic variety of *F. bancrofti* remains to be seen, and it is hoped that similar experiments on the same lines may be instituted.

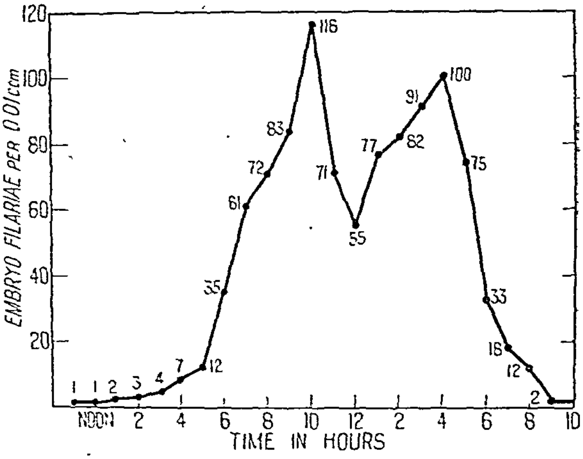

FIG. 3 shows the average number of embryo *F. bancrofti* per 0·01 c.cm. of a patient's blood during 24 consecutive hours whilst undergoing a protein shock. 5.5 P.M., the patient was given an intravenous injection of 50 million T.A.B. vaccine. 6 P.M., complains of vague pains all over body. 6.52 P.M., suffering rigor. 7.5 P.M., temp. 103·4°, sweating. 8 P.M., feels better; temp. 101°. 9 P.M., asleep; temp. 100·8°. 10 P.M., asleep; temp. 100·4°. 11 P.M., awake, temp. 100°. 12 P.M., awake; temp. 99·6°. 1 A.M., awake; given hot meal; temp. 99·4°. 2 A.M., dozing. 3 A.M.–6 A.M., asleep. 7 A.M., awake; feels all right. 8 A.M.–10 A.M., awake.

It is also hoped that Prof. O'Connor and others investigating the possibility of cyclical parturition may undertake similar observations, as the conclusions arrived at in this particular piece of work seem impossible to reconcile with their hypothesis. How, also, can a daily cyclical destruction of embryos explain the phenomenon of non-periodic filaria? In *Dipetalonema perstans* infections (non-periodic) in Uganda, Low[7] counted the embryos in a measured quantity of peripheral blood (20 c.mm.) just before patients suffering from sleeping sickness died and then, immediately after death with the blood still warm, similar measured quantities from the aorta, heart, or lungs. The numbers of embryos present in these sites were always greatly in excess of those in the peripheral blood, indicating a seat of special selection in these parts.

More work might also be done on dogs and other animals, where it will also be found that the seat of special selection of the embryos is often in the large vessels of the thorax, only the overflow, apparently, passing into the peripheral blood with no periodicity. Autopsies on dogs might prove or disprove the cyclical theory.

History and Laboratory Reports

(BY MR. WALTERS)

The patient was first seen at the Hospital for Tropical Diseases in October, 1920, when a series of intravenous antimony injections were given,[8] and again in May, 1924, when Bayer "G. 1919" was tried for treatment.[9]

He was a male Indian native aged 50, born in Calcutta, where he had lived till going to sea 18 years before. He had had fever in 1898 (? nature), syphilis in 1916, and dysentery in 1918. In 1924 he had been in the Hospital for Tropical Diseases. In 1927 he had had stomach trouble; in 1932 he was admitted to the Seamen's Hospital, Royal

Albert Docks, for a recurrence of this. He was operated on, and the stomach was found to be dilated, with fibrous thickening due to previous ulceration on the lesser curvature, sufficient to cause pyloric stenosis. Gastro-enterostomy was performed and the appendix was removed, as it was also diseased.

On June 15th, 1932, there was no definite evidence of filarial disease, apart from slight enlargement of the left testis and a slight hydrocele on the same side. The red corpuscles numbered 5,500,000; the white corpuscles 9375; and the hæmoglobin percentage was 100. A differential count showed 73 per cent. of polymorphonuclear cells, 19 per cent. of lymphocytes, 6 per cent. of eosinophils, and 2 per cent. of large mononuclears. Embryos of *Filaria bancrofti*, but no malarial parasites, were present in the night blood. The fæces showed no ova with the exception of a few *Trichuris.*

As it was evident that the patient would have to be in hospital for a considerable time, the opportunity was taken to do a series of examination of the blood for filarial embryos. Dry and wet films were used, the embryos in the latter being counted at the bedside immediately after preparation; the former were left until the following day, when they were dehæmoglobinised and stained. The counts were found to tally within 0·5 per cent. error factor.

Fig. 1 illustrates a typical nocturnal periodicity; Fig. 2, the irregularity produced by putting the patient to bed during the day and inducing sleep by means of drugs; Fig. 3, the irregularity produced by intravenous injections of T.A.B. vaccine; Fig. 4 (A), another count showing normal periodicity while leading a normal life, and (B) while leading a normal life and after five days atebrin treatment, the latter having no effect upon the periodicity; while Fig. 5 shows the number of embryo filariæ in the patient's blood on the counts done in 1924 and in 1932.

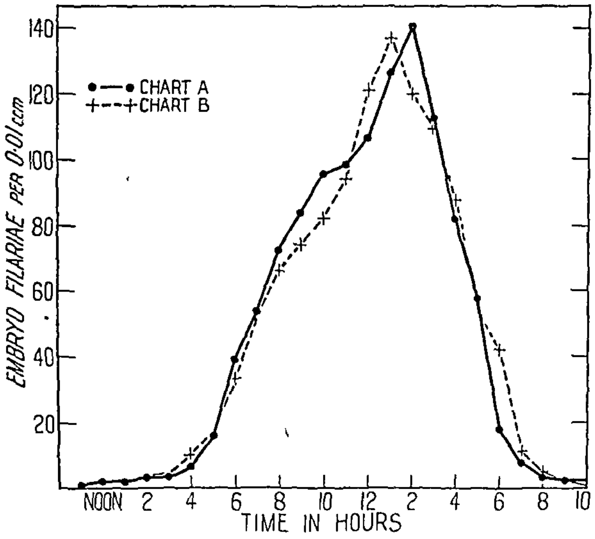

FIG. 4 (A) shows average number of embryo *F. bancrofti* per 0·01 c.cm. of the patient's blood during 24 consecutive hours of normal life and 55 days after gastro-enterostomy. (B) shows the average number in the blood during 24 consecutive hours of normal life and after five days' atebrin treatment (atebrin tablet 0·1 g. three times daily).

The total embryo filariæ counts in the report were all carried out on blood obtained by pricking the second or third finger and wiping away the first drop. Although this is the method at present in general use for blood counts and similar investigations, it is well known that pressure on the finger, size of puncture, and the surface tension set up between the capillaries, the blood drop, and the point of the pipette, all contribute to the small error factor which is undoubtedly present. When the blood was drawn up into the pipette, the ordinary wet films were prepared by mixing the blood with a 0·1 c.cm. drop of physiological saline previously placed on the slide and covering with the cover-slip. Counts were made *immediately;* no variation in embryonic movement was observed whether the specimen was taken at 1 A.M. or 1 P.M. The ordinary thick films were prepared by gently blowing the blood along the lines of an 8 mm. square placed under the slide and then filling in the square with the *remainder of the blood.* This ensured every specimen being of approximately the same dimensions and the four straight edges rendered counting accurate and rapid.

Animal experiments were carried out for us, at our suggestion, by Dr. H. M. Hanschell. The blood of two guinea-pigs, of 150 g. each, was grouped against human sera. Both were found to be non-agglutinators. One cubic centimetre of human blood (containing approximately 122,000 embryos) was then taken from the median basilic vein of the patient at midnight and injected at once into the heart of one of the guinea-pigs, under ether anæsthesia. The animal recovered from the anæsthetic in four minutes and was as alert as usual. No distress was noted in the following 24 hours.

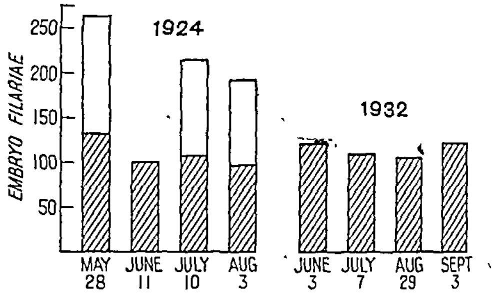

FIG. 5 shows the average number of embryo *F. bancrofti* per 0·01 c.cm. of patient's blood in two series of counts done *at an interval of eight years (1924–32). In 1924 the amount* of blood used in each count was 20 c.mm. The shaded areas indicate the number of embryo filaria in 10 c.mm. All counts were taken at 11.55 A.M. In 1932 only 10 c.mm. of blood was used for each count. All the counts were taken at 12 midnight. The actual counts per 10 c.mm. in 1924 were as follows: May 28th, 132; June 11th, 100; July 10th, 107; August 3rd, 96; average 109 per 10 c.mm. In 1932 the counts were: June 3rd, 122; July 7th, 110; August 29th, 106; Sept. 3rd, 121; average 115 per c.mm.

At 1 A.M. on June 10th, 1932, both guinea-pigs were ether-anæsthetised and 1 c.cm. of blood from the *patient (containing approximately 139,000 embryos)* was injected immediately into each guinea-pig's heart. Both animals recovered as usual, and no distress was noted. The marginal veins of their ears were pricked after 5 minutes, 10 minutes, 15 minutes, half an hour, and hourly up to 14 hours, but no embryo filariæ were detected. The urine of one of the guinea-pigs was examined, and here again nothing was found.

ENLARGEMENT OF WEST BROMWICH HOSPITAL.—Sir J. Harris Spencer, the president, last week *formally* opened new out-patient and casualty departments at West Bromwich District General Hospital. The cost, about £21,000, has been defrayed to the extent of £16,600 by a carnival and a bazaar. Donations and legacies increased the total to £18,373; the balance has yet to be raised. In addition to a covered unloading place for ambulances, there is a perambulator shelter. There are two theatres, the smaller one being for eye operations, and eye, ear, nose, and throat, X ray, and orthopædic departments. All the departments have steel furniture, and there is a canteen for light refreshments.

TYPES OF PNEUMOCOCCI IN POST-INFLUENZAL PNEUMONIA

By Ian M. Christie, M.B. Glasg., D.P.H.

RESIDENT ASSISTANT PHYSICIAN, KNIGHTSWOOD FEVER HOSPITAL, PUBLIC HEALTH DEPARTMENT, GLASGOW

The epidemic of influenza in Glasgow which prevailed during December of last year afforded an opportunity of observing the incidence of the types of pneumococci in patients with acute pneumonia admitted to hospital during this period and of contrasting the results with those obtained under normal circumstances.

The following were the general characteristics of the epidemic in the city. An increase of notifications of influenzal pneumonia became noticeable at the beginning of December, reaching a maximum of 117 during the week ending Dec. 17th; deaths certified due to the same cause reached their maximum of 86 during the following week ending Dec. 24th; thereafter a rapid fall occurred in both figures. The highest weekly general death-rate (28·7 per 1000 of the population) was observed during the week ending Dec. 24th. It may be noted that the epidemic was accompanied by a heightened incidence of acute lobar pneumonia at a time when this affection does not usually prevail to anything like the same extent. Deaths certified as due to this cause increased to a maximum of 31 during the week ending Dec. 31st, while those due to acute broncho-pneumonia reached 80 during the week ending Dec. 24th.

Between Dec. 10th, 1932, and Jan. 10th, 1933, dates within which the epidemic occurred, there were admitted to Knightswood Hospital 90 cases of acute pneumonia, of which 60 were typical cases of lobar pneumonia and 30 were broncho-pneumonia or influenzal pneumonia. Table I. gives the distribution of the lobar pneumonias in relation to the frequency and fatality percentages for each type.

Table I.—*Incidence of Types in Lobar Pneumonia*

—	Cases.	Deaths.	Frequency percentage.	Fatality percentage.
Type I. ..	14	1	23·3	7·1
Type II. ..	32	12	53·3	37·5
Type III. ..	7	3	11·7	42·8
Group IV. ..	7	—	11·7	—
Total ..	60	16	—	26·6

These results may be contrasted with those obtained in this hospital during 1932—i.e., Type I., 42·4; Type II., 37·3; Type III., 1·7; Group IV., 18·6 per cent.[1] Again, the general experience of the past three years as given by Macgregor[2] was that these types prevail in non-influenzal times as follows: 38·1, 36·0, 3·9, and 22·0 per cent. in a series of 1077 cases. It was shown by Cowan, Cruickshank, Harrington, et al.,[3] that variations in these proportions may occur. For instance, during the period September, 1931, to April, 1932, the relative incidence was 42, 29, 4, and 24 per cent., Type II. being less prevalent during that winter. It will be apparent from these figures of incidence that the lobar pneumonias of the influenza period were preponderatingly associated with Type II. (53·3 per cent.). Cases of Type I. and of Group IV. were less than usual.

Pneumonias of Type II. were not only more numerous but were unusually severe and fatal. The mortality-rate of 37·5 per cent. is much higher than is customarily experienced. In the various series of cases associated with this type, as quoted by Macgregor for Glasgow hospitals, the mortality varied from 8·6 to 27·8, and was 19·6 in respect of the whole series of 388 cases over the past three years. It thus appears that the virulence of this type was greatly enhanced during the influenza epidemic. A proportion of Type III. infections as high as 12 per cent. is possibly due to lowered resistance during the influenza period. The figures are too small to permit of separation into age-groups, but it may be noted that in the age-group 15 to 25 years there were 12 cases with 6 deaths, an age-period when Type II. pneumonias tend to have a comparatively low fatality-rate.

The behaviour of the different types of pneumococci during influenza has been little observed. Cecil, Baldwin, and Larsen[4] in their study of 2000 typed cases of lobar pneumonia state that "during epidemics of influenza there is always a marked increase in pneumococcus Type IV. pneumonia." The occurrence of Type II. pneumococcus as a prevailing organism in post-influenzal pneumonia appears to be unusual. In the present series the results of the typing of sputa from 30 cases of broncho-pneumonia showed pneumococcus Group IV. to be constantly present in the peritoneal washings of inoculated mice. On the assumption, therefore, that these organisms were responsible for the broncho-pneumonias, the part played by the different types in the 90 cases quoted (consisting of 60 cases of lobar pneumonia with 16 deaths and 30 cases of broncho-pneumonia with 7 deaths) can be expressed as in Table II.

Table II.—*Distribution of Types in 60 Cases of Lobar Pneumonia and 30 Cases of Broncho-pneumonia*

—	Cases.	Deaths.	Frequency percentage.	Fatality percentage.
Type I. ..	14	1	15·5	7·7
Type II. ..	32	12	35·5	37·5
Type III. ..	7	3	7·8	42·8
Group IV. ..	37	7	41·1	18·9
Total ..	90	23	—	25·5

A study of this group of post-influenzal pneumonias suggests that the mortality is due mainly to the invasion by Type II. and Group IV. pneumococci of persons weakened by influenza, with the consequent production respectively of lobar and broncho-pneumonia. It would also appear that when pneumococci belonging to Group IV. cause lobar pneumonia the prognosis is good, whereas in broncho-pneumonia due to organisms of the same group the death-rate may exceed 20 per cent. Another feature of this altered frequency of pneumococcal types is that the high incidence of Type II. infections occurred at a period of the year when cases of adult lobar pneumonia in Glasgow are usually of low prevalence.

Clinically the Type II. infections were severe at all ages. Of the 7 deaths under 25 years, 4 were preceded by signs of toxæmia—the blood cultures taken within 12 hours of death being sterile in two instances and showing 2 and 45 colonies respectively in 2 c.cm. of blood in the remaining two—and 3 were due to septicæmia with a colony count exceeding 1000 per c.cm. The five deaths at the higher ages were all associated with a similar severe degree of septicæmia. In contrast to the Type II. infections, Type III. pneumonia was confined to the upper age-groups. Repeated examinations of the sputum were made, and in three cases the results were verified by lung puncture. The experience gained in the diagnosis of Type III. pneumonia points to the fact that when the sputum is fresh and typically rusty the result of the first typing is almost invariably correct. The cases of influenzal pneumonia presented the clinical features common to this illness. The severity was in proportion both to the amount of lung substance involved and to the degree of capillary bronchitis present. A constant sign was the expectoration of yellowish muco-purulent sputum. Blood culture in seven severe cases proved negative.

CONCLUSIONS

(1) In a series of 90 cases of acute pneumonia admitted to hospital during the influenza epidemic in Glasgow, 60 were lobar and 30 influenzal pneumonia. (2) The distribution of types in the lobar pneumonias showed an altered frequency percentage of 23·3, 53·3, 11·7, and 11·7, as regards Types I., II., III., and Group IV., as compared with the standard for the city—*namely*, 38·1, 36·0, 3·9, *and* 22·0. (3) The incidence of lobar pneumonia during the epidemic was unusually high for the time of the year, its period of maximum prevalence being the months of February, March, and April. (4) The Type II. pneumococcus displayed a much exalted virulence, and was responsible for a case-mortality of 37·5 per cent. (5) Type III. infections occurred in elderly people already weakened by concurrent influenza.

I have to acknowledge my indebtedness to Dr. William Dow, medical superintendent of Knightswood Hospital, and to Dr. A. S. M. Macgregor, medical officer of health for Glasgow.

MEDICAL SOCIETIES

ROYAL SOCIETY OF MEDICINE

SECTION OF EPIDEMIOLOGY AND STATE MEDICINE

AT a meeting of this section on Feb. 24th, the president, Dr. WILLIAM BUTLER, being in the chair, Dr. G. C. M. M'GONIGLE, medical officer of health for Stockton-on-Tees, related some results of the

Removal of a Slum Population to Modern Dwellings

In 1927, he said, an unhealthy area in the borough was demolished and 710 of the inhabitants were housed on a self-contained municipal housing estate which had been specially built for the purpose. He decided to investigate the state of health of these people during the five years succeeding their translation from bad to good housing conditions. The borough of Stockton-on-Tees had at the 1931 census a *population of* 67,722. *Its chief industries*, shipbuilding and engineering, had suffered severely in the industrial depression, but there was also in the borough a good deal of market trade with the surrounding agricultural areas. Unemployment was and always had been rife: only once since 1922 had the percentage fallen below 20 and it was now over 40 for the total male population between the ages of 14 and 65. There were three main types of dwelling-house in the town: modern semi-detached council houses, small inconvenient "middle-aged" houses crowded together in long streets, and old insanitary dwellings, the third type mostly near the river, but also in groups throughout the town. The town council had vigorously carried out a housing policy which comprised the demolition of slums, the building of new houses, and the maintenance of the middle-aged houses. Since the war 1664 council houses had been built. In 1919 various areas of the town were scheduled as unhealthy and others were set aside for reconstruction. A particular area known as the Housewife Lane area was evacuated in the late autumn of 1927 and its 152 families were moved to the Mount Pleasant estate. A similar area known as the Riverside area remained in statu quo ante and provided a control; its population of 1298 consisted of 289 families. The Housewife Lane area consisted of old houses: *either small, containing* one or two rooms, or large, sublet in numerous tenements. One-room tenements were occupied by 83 families and the sanitary conditions and structure were bad. The Mount Pleasant estate seemed to offer everything that modern sanitary science could demand.

Nevertheless, Dr. M'Gonigle went on, after three years the health of the Mount Pleasant population seemed to have deteriorated. At any rate, the death-rate had increased. The mean crude death-rate per 1000 of population for 1923–27 was 12·15 for England and Wales, 18·75 for the Housewife Lane area, and 22·16 for the Riverside area. For the five years 1928–32 the corresponding figures were 12·2 for England and Wales, 26·71 for the Mount Pleasant estate—i.e., the transferred Housewife Lane population—and 20·45 for the Riverside area. Thus there was an increase of 8·47 per 1000 deaths for the people who had been housed on an excellent modern estate and a decrease of 2·9 per 1000 for those who had remained in the old slum conditions. These were the crude figures, but when they had been standardised in the light of the 1931 census the difference was even greater. The mean standardised death-rate for the Mount Pleasant estate was 33·55 per 1000, an increase of 46 per cent. over the mean standardised rate for the same individuals in the previous quinquennium, whereas the Riverside people and the population of Durham county showed a decrease in the second five-year period. The standardised figure for the Riverside area was 22·78 for 1928–32 and 26·10 for 1923–27.

There was a considerable increase in the birth-rate at Mount Pleasant. For England and Wales the birth-rate for 1923–27 was 18·24 per 1000 of population, and it decreased to 16·27 for 1928–32. The county of Durham, the borough of Stockton-on-Tees, and the Riverside area all showed this decrease, but Mount Pleasant had an increase from 35·08 to 44·25. This increase was *not the result of a higher* marriage-rate, an increase in illegitimacy, or a larger proportion of first births. It had not been accompanied by an increase of infant mortality, which was considerably higher at Mount Pleasant (117·8 per 1000 live births) than for the county and borough as a whole, but was substantially less than that of the same people when they were in Housewife Lane (172·6 per 1000 live births). The viability of the *infants born on* Mount Pleasant was no less than that of infants born elsewhere; the neonatal mortality

(26·3 per cent.) compared favourably with that of England and Wales and of the borough (31·5 and 34·2 per cent. respectively). The stillbirth-rate, however, amounted to 61 per 1000 live births compared with 40·5 for England and Wales. Thus the increased death-rate could not be attributed to infant mortality, and the figures showed the main increase to be between the ages of 10 and 45, although there was also an increase in the deaths of children under 10 and of adults over 55. The largest increase was in the 65–75 group, followed closely by the 25–35 and 45–55 groups. Next came the children under 5 and the old people over 75, each with a percentage increase of 9·2. There had been an actual decrease in the age-groups 55–65, 20–25, and 35–45.

The causes of death accounting for the increase were measles, cancer, heart conditions, bronchitis and pneumonia, diarrhœa, nephritis, and puerperal sepsis, but the increase in the last three was trifling. There were decreases in the number of deaths from whooping-cough, diphtheria, cerebro-spinal fever, tuberculosis, appendicitis, and congenital debility. No morbidity and sickness figures were available except the reports of the school medical officers; these showed that the incidence of defects was about the same in Mount Pleasant and Riverside, both areas showing rather more than double the figure for all the elementary school-children in the borough.

Consideration of the causes which might be responsible for the increased death-rate in the Mount Pleasant estate led Dr. M'Gonigle to exclude such environmental factors as housing, drainage, overcrowding, or insanitary conditions. He then carefully investigated the family budgets and the food supplied to the families in an attempt to find the cause of the deterioration in health. The transfer to Mount Pleasant had increased the rent paid by the inhabitants from 9*s.* to 13*s.* 4*d.* per week, but as two families were in some cases sharing a house the mean rent per family per week was now 8*s.* 10*d.* In Riverside area the figure was 4*s.* 10¾*d.* As a result of unemployment the weekly income was strictly limited. The tenants coöperated in the investigation by supplying details of the family budget; 28 budgets were obtained from the Mount Pleasant and 27 from the Riverside area. Of these, 5 of the Mount Pleasant families were employed and 8 of the Riverside families. It was found that the unemployed on Mount Pleasant could only spend 36·7 per cent. of their income on food; a total of 2*s.* 10½*d.* per "man" per week. The food purchased had been analysed and compared with a standard diet. In no case did the first-class protein attain the quantity required by the normal diet. The least deficiency (20 per cent.) was among the employed families in the Riverside area, and the greatest deficiency (about 50 per cent.) among the unemployed on Mount Pleasant. The figures for total protein corresponded. The employed of Mount Pleasant consumed 5·6 per cent. above the normal of fats, but these were for the most part margarine, lard, and bacon fat. The unemployed on Mount Pleasant and Riverside consumed only 66 and 76 per cent. of the normal fat requirements respectively. The consumption of carbohydrates in no case fell seriously below the normal, as white flour, potatoes, and sugar constituted one of the cheapest forms of bulky food and supplied the necessary calories.

There was, Dr. M'Gonigle said, reason to suppose that deficiencies in vitamins and minerals were in proportion to or somewhat greater than the other deficiencies. Calculations suggested that it was not possible to purchase normal quantities of foodstuffs for less than 4*s.* 6*d.* per "man" per week.

In summing up his conclusions, Dr. M'Gonigle remarked that comparison of the two areas revealed no adverse influence operative upon the Mount Pleasant estate other than variations in the composition of their diets. Whether these differences were responsible for the higher death-rate upon this estate might be a matter for conjecture. His investigations had failed to detect any other probable cause.

SECTIONS OF COMPARATIVE MEDICINE AND OF THERAPEUTICS AND PHARMACOLOGY

A JOINT meeting of these sections was held on Feb. 22nd, the chair being taken by Mr. W. HORNER ANDREWS and later by Dr. E. P. POULTON.

A discussion on

Plant Poisoning in Man and Animals

was opened by Mr. W. HORNER ANDREWS. He pointed out that plant poisoning of cattle in this country was much rarer than in the colonies owing to the fact that the recognised poisonous plants had been almost eradicated from our home pastures by long-continued cultivation, such poisonous plants as remained being practically confined to the hedgerows. Many reputed toxic weeds were not as toxic as they were thought to be and probably many other plants were harmful, though not recognised as being so. The most likely reason why cattle feed on poisonous plants was the lack of more appropriate food. The most difficult cases of poisoning of cattle by plants were those in which there was a considerable latent period between the ingestion of the plant and the onset of the symptoms of poisoning. In poisoning by *Senecio latifolia* the latent period was 96 days, by which time an animal might long have ceased to eat the plant and owners would be unlikely to associate it with the symptoms observed. Chronic interstitial pneumonia was, in Mr. Andrews's experience, a typical sequel to poisoning by *Crotalaria dura*, which opened a way to secondary bacterial infection. He referred also to a South African plant which contained two poisonous principles, one a cyanogenic glucoside capable of killing a beast in an hour, and one a toxic protein, which was liable to set up three days later acute gastro-enteritis in the animal if it survived poisoning by the hydrocyanic acid.

Sir WILLIAM WILLCOX said that plant poisoning of human beings in this country was practically restricted to children and to a comparatively small number of ignorant or mentally deficient adults. He drew attention to the different degree of toxicity manifested by the same poison in different animals, instancing the insensitiveness of rabbits to belladonna or to aconite and the great tolerance to strychnine shown by the horse and ox, compared with that shown by man; on the other hand, the frog was so sensitive to strychnine that the physiological test of tetanic convulsions in a frog was much more reliable than even the very delicate chemical tests for this alkaloid. As an example of delayed action of poisons in human beings he quoted the consumption of imperfectly matured tobacco which was liable to set up thrombo-arteritis obliterans, leading to gangrene and most probably amputation. He described the effects and uses of a number of poisons, including the poisoning of fish by means of picrotoxin or of Dherris root.

Dr. PAUL HAAS drew attention to the difficulties in the classification of poisonous plants. While some families, as for example, papaveraceæ, solanaceæ, ranunculaceæ and leguminosæ included plants such as the poppy, belladonna, aconite, and laburnum rich in alkaloids, other families like labiatæ or rosaceæ did not contain any alkaloid-bearing plants, though the rosaceæ contained a great number of plants containing glucosides. Remarkable differences occurred between closely related species of the same family as in the oriental poppy *Papaver somniferum*, which contained some 25 alkaloids—mostly poisonous—while the common field poppy *Papaver rhœas* contained only one alkaloid, rheadine, which was practically innocuous. The effects of climate or external conditions upon the same plant grown in different parts of the world was illustrated by the common hemp, *Cannabis sativa*, which, when grown in India, was the source of hashish, while the same plant grown in this country produced only traces of this material. Linseed, again, when grown in hot climates contained considerable quantities of the cyanogenic glucoside linamarin, while very much less of this substance was contained in plants grown in cold damp climates. Cultivation also led to loss of poisonous glucoside in the wild bitter almond or the Burma bean. Attempts to explain the significance to the plant of poisonous alkaloids were also beset with difficulties; whilst the seeds of nux vomica, belladonna, or taxus were rich in alkaloids, the seeds of the oriental poppy were free from them, although the latex obtained from the fruit capsule was very rich in these bodies.

Dr. E. P. POULTON spoke of the occasional toxicity of honey.

Mr. J. A. NICHOLSON gave a summary of his work on the feeding of rabbits and sheep on different species of buttercup from which he concluded that these were practically innocuous, though the expressed juice of *Ranunculus acris* or *R. repens* injected into the stomach in increasing doses caused gastro-enteritis followed by death, without however the exhibition of symptoms of poisoning by a highly toxic substance.

Mr. J. T. EDWARDS gave an account of the use in India of *Abrus precatorius* for the criminal poisoning of cattle for the purpose of obtaining the hides.

SECTION OF OBSTETRICS AND GYNÆCOLOGY

A MEETING of this section was held on Feb. 17th, when Dr. ELIZABETH HURDON read a paper on

Radium Treatment of Carcinoma of the Corpus Uteri

She said that radium had been used for many years as a palliative measure for the treatment of cancer of the body of the uterus but surgery had generally been looked upon as the treatment of choice for most cases. A few clinics had systematically used a combination of radium therapy and surgery. The combined figures from the literature on about 1500 cases treated by hysterectomy gave the five-years cure rate as 43 to 65 per cent., the rate of operability having been 75 per cent., and the primary mortality-rate from 3·3 to 9 per cent. Radium therapy alone had been used for 20 years. The combined results of nine leading clinics on a total of 740 cases showed a five year survival-rate of 32 per cent. on all cases and 42 per cent. for the operable cases only. The immediate risk was usually looked upon as nil, but might be as much as 3 per cent. With modern technique the five year survival-rate of operable cases was given as from 70 to 80 per cent. In the Marie Curie Hospital 68 cases had been treated since October, 1925, 700 cases of cancer of the cervix having been treated during the same period. Only 21 corpus cases were treated more than three years ago and only seven more than five. Of these, four were living and well. The one operable case had died at the end of five years from cerebral hæmorrhage and the two inoperable cases had died of metastatic cancer with no sign of growth in the uterus. Of the total cases, 46 were living.

Technique.—A microscopic examination was made in all cases. Radium was given in three applications of 22 hours each, at one and two weeks' interval. Both intra-uterine and vaginal applications were made. A central applicator containing radium tubes in tandem was introduced into the uterine cavity so as to extend the entire length to within 1 cm. of the external os. An empty rubber cuff filled the cervical canal below the applicator. In addition two small applicators were passed up into the uterine cornua. The radium was distributed so that all intra-uterine tubes contained 8 mg. of the element to each cm. of active length. A vaginal plaque was placed high up in each lateral vaginal fornix, containing 20 mg. of the element in two out of the three treatments. The radium tubes were screened with 1 mm. platinum and 1·5 mm. rubber. The standard total intra-uterine dose was 4300 to 4800 m.e.h., the vaginal dose 1760 m.e.h. Two-thirds of the standard dose was given for a small senile uterus. One primary death had resulted from giving the maximum intra-uterine dose to a small senile uterus, from necrosis of the uterine wall, and septic peritonitis. In three cases stenosis of the cervix, producing pyometra, had proved a late complication. This result would not follow with present-day technique.

Dr. Hurdon stated that fibroids interfered with effective radiation and she regarded tubo-ovarian and other pelvic infections as contra-indications. She was of opinion that the results of irradiation treatment would prove to be equal to surgical results and that combined radium therapy and external radiation was the best method.

DISCUSSION

Mr. JOHN BEATTIE compared the results of two groups of cases of operable carcinoma of the body treated respectively by combined radiation methods and by hysterectomy at St. Bartholomew's Hospital. The survival-rate was three times as high in the group treated surgically as in the radiation group, but the dosage of radium was admittedly inadequate. He discussed the various types of carcinoma with special reference to their sensitiveness to radiation, and pointed out that the majority of growths of the proliferative adenocarcinomatous type were heavily infected. The risk of inserting radium in these cases was great.

Dr. J. H. HANNAN emphasised the difficulty which sometimes arises in the histological diagnosis of fragments removed by curetting. While this uncertainty existed caution was necessary in assessing the results of radium treatment. Inevitably a certain proportion of cases classed as malignant were, in fact, innocent.

Dr. HELEN CHAMBERS discussed the histological grading of the 68 cases treated at the Marie Curie Hospital. As extensive curetting was not encouraged, the amount of tissue available was small and she was not prepared to accept this as a fair sample of the growth in the uterus. The data was insufficient to determine whether the histological grading had any bearing on prognosis.

Dr. MALCOLM DONALDSON thought that there were so few cases of carcinoma of the body which were technically inoperable and therefore suitable for radium treatment that all London gynæcologists should agree to give a trial to the same radiological technique. Discussing Dr. Hurdon's methods he doubted if the small containers which were said to be placed in the cornua of the uterus actually got into that position. An X ray photograph would decide that question. He considered that the right treatment when possible was to do a pan-hysterectomy followed by high voltage X ray therapy.

Dr. **Everard Williams** maintained that fruitful results in radium treatment of cancer of the corpus would depend on further study of the grades of malignancy in relation to their radio-sensitiveness on the basis suggested by Prof. Ewing. In our present state of knowledge he would prefer to treat the adenoma malignum type by radiation and other types of hysterectomy, preferably by the vaginal route.

Mrs. **Ivens-Knowles** was not convinced that radium treatment was suitable for all cases. She referred to a case in which it had been necessary to resect a coil of small intestine which was adherent to the fundus of the uterus. The patient was alive ten years afterwards. She favoured vaginal hysterectomy in cases of extreme obesity, advanced age, or chronic bronchitis in which abdominal operation was contra-indicated.

Miss **L. Martindale**, in reviewing a series of 56 of her own cases treated between 1920 and 1932, found that she had performed panhysterectomy on 41 of these (73 per cent.) and had treated the remaining 15 (27 per cent.) with radium. In 18 of the hysterectomy cases she had followed up treatment with intensive X ray therapy with a view to preventing recurrence. In 11 of the operated cases radium had been used in addition, mainly for recurrence in the vaginal vault or in the lower end of the vagina.

Mr. **T. G. Stevens** asked Dr. Hurdon to state on what grounds she had classified her cases into "operable" and "inoperable." He had met few cases of carcinoma which were technically or clinically inoperable.

REPLY

Dr. **Hurdon**, in reply, admitted the difficulty of determining inoperability in cancer of the corpus cases. The only cases classed as inoperable were those in which an unsuccessful laparotomy had been performed or in which massive fixed growth involving the cervix made removal by surgery clearly impracticable. In reply to Mr. Beattie, who had referred to papillary growths already infected, she stated that her practice was to insert the usual dose after preliminary douching with flavine lotion. With the exception of slight rises of temperature there were no ill-effects.

PATHOLOGICAL SPECIMENS

Dr. **M. W. Bulman** showed four specimens: A section of curettings from a woman aged 29, showing tuberculous endometritis; a specimen of sarcoma of the uterus, ; a specimen of unruptured interstitial tubal pregnancy; and a specimen of tubal pregnancy retained for two years and eight months.

MEDICAL SOCIETY OF LONDON.

Undulant Fevers in Non-tropical Countries

At the meeting of the society held on Feb. 27th, the president, Sir **John Broadbent**, occupying the chair, the subject for discussion was the increased frequency of fevers of the undulant type in non-tropical countries, and its relationship to infection by cow's milk.

Dr. **P. H. Manson-Bahr**, in opening the debate, said the term "undulant fever" was a convenient one under which to embrace several clinical pyrexias which were due to closely allied organisms. Practitioners in tropical medicine were familiar with these clinical variations in fevers due to biological strains of the same parasite; and fevers of the undulant type were all due to organisms of the same bacteriological group. Applied to this type of disease the term "Malta fever" was a misnomer, as it was to-day commoner in other countries than in Malta, and inhabitants of that island resented the implied stigma. In man the following varieties of undulant fever could be recognised:

(1) The original type contracted from goat's milk, the causative organism being *Brucella melitensis*.

(2) The localised aberrant type, such as was found in North Africa, contracted from goat's milk and due to *Brucella para-melitensis*.

(3) The abortus type, which appeared to be world-wide, but was especially prevalent in France, Denmark, Great Britain, and the United States in recent years. The causal organism here was *Brucella abortus*, and the origin of infection in man seemed to be cow's milk. In pigs especially a form was found which was due to *Brucella bronchosepticus*.

In 1905 the close association of undulant fever with the presence of goats was proved by Sir Themistokles Zammit, and soon thereafter the greater number of infected goats in Malta were destroyed, and the drinking of unsterilised goat's milk was entirely forbidden. This resulted in the almost complete disappearance of the disease.

In typical undulant fever there were wide variations in the character and undulations of the temperature chart. The temperature might rise to 105° or even 106° F. One undulation might last three months, and the fever might last for a year or longer, but seemed eventually to subside. It might be intermittent, and so lead to a diagnosis of tuberculosis. Usually the temperature was highest between 4 and 6 P.M., a point of differentiation from fevers of septic origin. Arthritic pains, with effusions, flitting from one joint to another, had led to confusion with influenza. But the pain was, in some cases, limited to fascias and bony prominences exposed to pressure. The associated night-sweats were more profuse and exhausting than those of any other disease. In the melitensis form the spleen was generally enlarged, but the absence of splenomegaly at an early stage should not negative the diagnosis. Hæmorrhages from nose or gums and hæmaturia were common, also purpuric skin hæmorrhages. Complications included neuralgias and rheumatic pains, while among the sequelæ were abscess, orchitis in the male, mastitis in the female, parotitis, and neuritis. In women the infection caused dysmenorrhœa and menorrhagia, and certainly predisposed to abortion and premature labour.

With regard to the abortus type, Dr. Manson-Bahr pleaded for a more appropriate name, for the disease was not confined to the female and did not necessarily imply liability to abortion. He suggested "undulant fever of abortus type," or "Bang's disease." The infection produced a distinct disease in domesticated animals, was communicable to man, in whom it could cause a fever almost exactly resembling that of the melitensis type. It had now become very common in high-bred cattle herds, especially when they were stable-fed. The organisms occurred in the vaginal discharge and in the uterine exudate, and they were excreted in the milk for weeks and months. In Washington 12 to 14 per cent. of commercial milk was thus infected; in Chicago 30 per cent. Often the organism had been found in bulls' genitalia, so that male animals could transmit the infection to the herd.

The diagnosis was readily made by serum agglutination, which occurred in dilutions from 1 in 100 to 1 in 10,000; the agglutinins were also present in the milk of infected cows. An intradermal test had been found useful in diagnosis. The common method of prevention in veterinary practice consisted in isolating infected animals and producing active immunisation in non-pregnant animals with living cultures, after which the abortion-rate came down to about 6 per cent. For pregnant animals immunisation was attempted by means of killed cultures. Undulant fever of the abortus type had now been reported in Italy, U.S.A., France, Denmark, Sweden, Canada, Germany, Holland, Austria, Switzerland, Palestine, and Poland.

The leucocyte count in abortus was distinctive; there was usually a slight leucopenia, with a relative increase in the lymphocytes. Abortus infections ran a much milder and shorter course in man than did those of the melitensis type. Dr. Manson-Bahr referred also to what he termed "sub-clinical cases"—i.e., those which had small rises of temperature which would not be suspected unless four-hourly readings were taken. The recovery of the organism by blood culture was the most satisfactory method of making the diagnosis, but the specimens should be taken fresh from the patients and inoculated into a sufficient quantity of medium, at body temperature; sometimes ten days were needed to allow the organism to develop.

With regard to treatment, Dr. Manson-Bahr did not feel on secure ground. He did not believe in starving patients; they should be well fed on an easily assimilable diet, with adequate fluids to promote sweating. A combination of phenacetin and aspirin alleviated the joint pains. For insomnia he ordered warm sponging, with bromides, allonal or medinal. He had not traced any marked effect from the use of vaccines. Dr. Miller had found that three or four injections of intravenous T.A.B., in doses of 50 to 150 million organisms, cut the fever short, and this was well worth trying.

THE PATHOLOGY OF THE CONDITION

Prof. G. S. **Wilson** referred particularly to the pathological side, using the term "undulant fever" in a general way, owing to the similarity of the causal organisms. The bovine abortus type would not grow under ordinary aerobic conditions; the addition of 10 per cent. of CO_2 was needed. He had collected records of 136 cases of undulant fever in which the diagnosis had been made by agglutination; in 12 it was confirmed by cultivation from the blood or urine or fæces. Ninety-two of these cases occurred in England, 18 in Scotland, and a few in Wales and Ireland. It occurred mostly between the ages of 20 and 50, and males were affected about twice as frequently as females, a curious preponderance for a milk-borne infection. Ninety-seven of the 136 cases occurred in towns. In Denmark two-thirds of the cases were related not to consumption of milk so much as to direct contact with infected cattle—i.e., on farms and dairies, but in this country the largest number of cases occurred among the clerical, medical, and engineering professions. The disease appeared to be more common in this country than it was, though the incidence could be determined only indirectly.

With regard to mode of infection, most of the subjects admitted drinking milk only when closely questioned, their first answer being a denial. Often the infection was incurred on holiday, when milk was drunk at a farmhouse. Cream was often rich in the organism. Butter was not likely to be a cause, as 90 per cent. was imported from abroad, having been pasteurised, a process which destroyed the bacillus. Hard cheeses were not the source of infection incriminated, but soft cheeses, which were usually eaten soon after manufacture, might carry infection. On the other hand, milk and cream were heavily infected. In recent epidemics, in which the CO_2 technique was used, a high proportion of raw milk was found infected with the *Br. abortus*; in Cardiff it was 34 per cent., in some other districts slightly less. Among the 136 cases all the victims had been drinking raw milk. In the large towns in this country 70 per cent. of the milk sold was pasteurised, in London 95 per cent., and comparatively few cases occurred in these towns, and those mostly among people who had recently come from the country. It used to be argued that if the disease was due to milk it should be commoner than it was; but that argument was based on the idea that the organism was the only essential cause. It was now realised that the predisposing factors were equally important, and the organism might gain access to the tissues without producing clinical symptoms; the disease might be latent, as might tuberculosis. Latent infections were very common in people who came a good deal into contact with abortus, as shown by figures recently collected. For instance, among Liverpool slaughterers instead of the usual 1·4 per cent., 12 per cent. agglutinated abortus. At the recent Veterinary Congress at Folkestone, Prof. Wilson, having persuaded 98 veterinarians to allow him to examine their blood, found that 20 per cent. contained agglutinins to abortus. In diagnosing undulant fever it was important to take both the clinical and the serological evidence together; it was not justifiable to make a diagnosis on the laboratory findings alone.

THE CLINICAL ASPECT

Dr. **Theodore Thompson** confined his remarks practically to the clinical aspect. In England the first clinical cases were described by Box and Bamforth, in 1925 and 1927 respectively. The incubation period was about the same as that of Malta fever—i.e., 5–15 days—and the symptoms resembled a mild attack of Malta fever. In a very severe fatal case of ulcerative endocarditis *Br. abortus* was grown from the blood. The most striking clinical feature was the continuance of pyrexia without obvious cause; its wave periods might last from one to four weeks. The patient might feel well throughout, the chief complaint being profuse sweating, often accompanied by an unpleasant odour of the skin. Melæna had been noted, but was not at all common. In pregnant women, undulant fever frequently led to abortion. The blood condition in the disease was very important; a mild anæmia was present, but the most striking feature was a marked diminution in the white corpuscles, which might not be more than 4000 or 5000 per c.cm. *Br. abortus* was nearly always agglutinated in a higher dilution than was *Br. melitensis*. The melitene intradermal reaction was useful in diagnosis; inoculation of the organism into the skin substance produced a large pink wheal, which continued for two or three days.

The differential diagnosis was mainly from typhoid, paratyphoid, rheumatic fever, general tuberculosis, endocarditis, Hodgkin's disease, influenza, and infective arthritis. Treatment did not appear to be of avail in a large number of cases; the disease seemed to run its course uninfluenced by drugs or vaccines. Sweating could be relieved by a pill containing gr. ¼ of belladonna.

VETERINARY EXPERIENCES

Mr. L. E. W. **Bevan** remarked on the parallelism between many human and animal diseases, and spoke of his experiences as a veterinarian in Southern Rhodesia. Having read the work of Alice Evans, it occurred to him in 1921 that some of the mysterious cases of pyrexia of unknown origin which came into the Salisbury Hospital might be the result of abortus infection. He therefore obtained serum from cows in Kenya Colony, and the Royal Veterinary College, London, and found that the serum of one particular patient agglutinated all of them. Since then some 300 cases of the kind had been admitted into Rhodesian hospitals. The diagnosis was made by serum agglutination, and sometimes by means of the abortiscope. In Rhodesia it was not always possible to obtain a laboratory diagnosis. The subjects were usually severely ill, and some had died of the disease. No remedy had been found. The subjects of the disease were often robust men. In this country bovine abortion was astonishingly prevalent. Contact with infected animals must be a very important means of infection, for veterinarians as a class did not claim that their favourite beverage was milk. In the general population of England and Wales there must, he thought, be some degree of resistance, tolerance or immunity to the organism, otherwise the incidence would be far greater.

The PRESIDENT said that some such resistance must be postulated. Recently he read in a paper communicated to a pathological congress in Paris in 1931 that in France undulant fever was caused more commonly by sheep and less frequently by goats. It had been stated that in America cases had been treated by the direct transfusion of 500 to 700 c.cm. of blood, and that thereafter the temperature fell in from one to three days.

Dr. H. L. GLYN HUGHES asked what was the duration of the shortest known and proved case.

Dr. E. CREED said that last August he had seen a man who had been ill for ten days, and was suspected to be a case of typhoid fever, but the Widal reaction was negative. Abortus agglutinations were positive in dilutions of 1 in 50. Temperature fell on the day he saw the patient, the tenth day of the illness, and there had been no feverish return.

REPLY

Dr. MANSON-BAHR said that in the Pyrenees and adjacent regions herdsmen and others associated with sheep rather than goats, and this might explain the attribution of cases to sheep. There was considerable evidence that the disease was not by any means solely contracted from the drinking of goat's milk. Some cheeses were made from sheep milk.

Prof. WILSON attributed great importance to the existence of the disease in a latent form; the presence of the causal organism in the human body was not always accompanied by detectable symptoms.

CORRIGENDUM.—In the reported remarks of Mr. C. A. Scott Ridout on p. 305 of THE LANCET for Feb. 11th, the 15th line should read: "In five years, from 1927–1931 he operated on 196 cases in private practice apart from hospital cases, and four patients died." He was speaking from 24 years' experience entirely apart from the number of cases quoted.

REVIEWS AND NOTICES OF BOOKS

Workmen's Compensation: Its Medical Aspect

By Sir JOHN COLLIE, C.M.G., D.L., M.D. London: Edward Arnold and Co. 1933. Pp. 160. 7*s.* 6*d.*

To condense the complicated law and practice of Workmen's Compensation into 160 pages, everyone of them lucid and readable, is no mean feat. It has been accomplished ably by Sir John Collie. As he points out, compensation now forms a very large part of the working expenses of industry, and there has been a steady yearly rise in the proportion of employees compensated and also in the amount paid in each case. In the mining industry in 1930 the cost to the employer per person employed in the whole industry was over £3, representing a charge of 2½*d.* on every ton of coal raised. Public sympathy naturally tends to favour the injured workman, and it is particularly desirable that the doctor's attitude should be judicial, and his report of real assistance to the employer, or to the court if the matter comes to litigation. The author reminds us that he has earned the gratitude of the profession by establishing in the courts some minor but important points of medico-legal practice—e.g., that the employer has the right to choose what medical examiner he pleases, that the workman's solicitor may not attend the examination, and that the examiner cannot be obliged to conduct his medical examination in a solicitor's office. He gives much useful information on the art of disentangling knotty problems, such as that of "partial disability" or the "novus actus interveniens"—i.e., where some new disaster has intervened giving a "fresh origin to subsequent consequences." A valuable chapter describes those industrial diseases scheduled in the Act as entitling the sufferer to compensation if contracted in the course of employment. There is much useful advice on the subject of which Sir John Collie is an acknowledged master—the detection of malingering. His very enthusiasm may prove something of a snare for the novice in the medico-legal field, who is apt to get the facts a little out of focus. Experience shows that there is need to distinguish carefully between the honest man who is not so ill as he thinks he is, a very common phenomenon, and the deliberate malingerer, who is much more rarely encountered. A patently suspicious attitude on the part of the examiner, or a tactless zeal in practising the traps so ably described by Sir John Collie, may easily harden resistance and create the very condition he sets out to diagnose. Applied with sympathy and humanity, however, the principles set forth in this book should prove an invaluable guide in a difficult by-path of medicine.

The Common Cold

Vol. VIII. of the Annals of the Pickett-Thomson Research Laboratory. By D. THOMSON, O.B.E., M.B., Ch.B., D.P.H., and R. THOMSON, M.B., Ch.B. London: Baillière, Tindall and Cox. 1932. Pp. 738. £3 3*s.*

THIS prodigious volume presents in an orderly form the contents of 2000 papers on the common cold, which appear to include everything of consequence which has ever been written on this subject. The system which has permitted this compilation is unusual, if not unique, since for years past all papers appearing in what must be a large number of journals have been classified by the authors, and the resulting collection now includes nearly 500,000 original papers and abstracts, so arranged that it would apparently be possible at once to assemble the material for a comprehensive monograph on any medical subject. This is a staggering thought. Whatever the merits of the cement (if the authors' own observations may so be described) with which this gigantic mosaic is put together, a great service has been performed in providing such a work of reference.

Although this volume is chiefly concerned with the bacteriology of the common cold, it includes considerations of the anatomy and physiology of the upper air-passages, of factors predisposing to infection, complications and sequelæ of colds, and their treatment and prevention. Each subsection concludes with the authors' own critical observations on the material presented, and their main thesis, based largely on a study of the nasal flora in health and during colds in their own persons and those of their colleagues, is that many colds are clearly attributable to ordinary bacteria. That this proposition should again be stated when there is a tendency entirely to disregard the ordinary flora in the search for a virus is a good thing; what would be better than the presentation of both hypotheses from different quarters is a study of the problem from both standpoints simultaneously by the same individuals, a thing which hitherto appears never to have been done. The authors' studies are based on cultures using Crowe's medium, and a series of excellent photographs illustrates the colonial appearances observed. There are very few references to the examination of direct films of the exudates cultivated, and no other means of judging the numbers of bacteria in the material examined are available; some form of quantitative technique would enhance the value of these studies. While comment throughout the book is mainly balanced and judicial, there are occasional quite unjustified assumptions, and the strictures passed on horses, domestic animals, and vermin on the last page, including the fantastic assertion that dogs in towns should be provided with special water-closets, would reflect seriously on the whole volume if it could not be supposed that they were written in a moment of elation at the conclusion of a colossal task. There is, of course, a full list of references; there are also very full indexes, and the pages being exceptionally large as well as numerous, the volume may be computed roughly to contain half a million words.

Le Genou

Anatomie chirurgicale et radiographique. Chirurgie opératoire. By ANTOINE BASSET, Professeur agrégé à la Faculté de Paris; Chirurgien de l'Hôpital Beaujon. Paris: Masson et Cie. 1932. Pp. 187. Fr.45.

THIS monograph on the knee-joint is one of a series on which Dr. Basset is working; each volume is to deal with the surgical and radiographical anatomy and the operative surgery of a separate joint. This, the first to appear, is clearly written, complete in detail, and beautifully illustrated. Thirteen pages are devoted to a description of the normal external, or topographical, anatomy which, as the author says, is the surgeon's guide to the internal structure of the joint. The signs and symptoms of disease do not come into the scope of the work, but every method of approach used in opening the joint and every incision is very carefully described and illustrated. A section is included on traumatic surgery, which deals with fractures of the knee, injuries of the menisci and of the cruciate ligaments, and their operative treatment. Another section deals with the various methods of simple arthrotomy in the treatment of hæmarthrosis, hydrarthrosis, and pyæmia of the knee-joint. For the last-named condition in its early stages Dr. Basset advocates arthrotomy, evacuation of the joint contents, lavage and closure without drainage; he believes drainage to be absolutely contra-indicated in early cases, but discusses in great detail the drainage methods he prefers for more advanced cases. The major operations, particularly arthrodesis and excision, are clearly described, the operation of the author's choice being first set out and followed by important modifications and alternatives.

The work will appeal to all who are interested in the practical surgery of joints.

Acidosis and Alkalosis

By STANLEY GRAHAM, M.D., F.R.F.P.S., Leonard Gow Lecturer on the Medical Diseases of Infancy and Childhood, University of Glasgow; and Visiting Physician, Royal Hospital for Sick Children, Glasgow; and NOAH MORRIS, M.D., B.Sc., D.P.H., F.R.F.P.S., Lecturer in Biochemistry to the University of Glasgow; and Biochemist to the Hospital. London: E. and S. Livingstone. 1933. Pp. 203. 7*s.* 6*d.*

PROGRESS in the study of changes in acid-base equilibrium and of their clinical importance has been so rapid, and the literature so widely scattered, that it has been difficult for the clinician to grasp and apply at the bedside the new knowledge. In this book the modern views on the regulation of acid-base equilibrium are clearly and succinctly outlined, while the various morbid conditions which are liable to disturb it are discussed in so far as they are at present understood, and attention is directed to the appropriate therapy. The approach is essentially clinical. The authors have concerned themselves primarily with disturbances of acid-base balance as they occur in childhood, since it is during this period that changes arise most readily and are of the greatest importance. The book would have been even more valuable if rather more attention had been paid to such surgical conditions as intestinal obstruction and paralytic ileus; pyloric stenosis, however, is very fully considered. The vexed questions of the biochemical treatment of gastro-enteritis of infancy and the significance of ketosis are clearly discussed, though the paragraph devoted to use of a ketogenic diet in the treatment of chronic pyuria is too brief to be of practical value. There are a few minor omissions, probably unavoidable in a volume of this size, but the book must be commended as of high practical use.

The Arches of the Years

By HALLIDAY SUTHERLAND. London: Geoffrey Bles. 1933. Pp. 293. 10*s.* 6*d.*

THIS is a loosely put together series of biographical incidents with a somewhat fantastic title, and all the chapters have similar adornment—" Arcadia " means the Highlands, " Exiled " means a visit to Spain upon the directions of a father, the " Gate of the Sun " describes Seville, and " Blood and Sand " records a bull-fight. The impression left is unfortunate because some of the occurrences related or reactions received can hardly be described as out of the common and demanding picturesque captions. But Dr. Sutherland's adventure as an amateur toreador was well worth recording; he may be congratulated upon his courage and his luck. Undoubtedly the many friends and acquaintances of the author will like to have a copy of the work, which is probably not expected to make a more general appeal than do any of the numerous personal reminiscences which are now published. It is a lively and well-written book.

THE LANCET

LONDON: SATURDAY, MARCH 4, 1933

CHILDREN IN THE CURRICULUM

At the winter session of the General Medical Council last November, when the reports of the examination committee and of the inspectors of the qualifying examinations in medicine, surgery, and midwifery were presented, an important discussion took place[1] on a recommendation regarding the place of infant hygiene and diseases of children in these examinations. The recommendation finally adopted was "that in the final examination there should be a test of the candidate's knowledge of infant hygiene and of disease in children." In the original form the terms of the recommendation were more drastic—the word "always" was included, and the test was to be "both written and clinical"—but in deference to criticism these terms were dropped out of the final resolution. The final form, although vague, is really as comprehensive as the original draft, and it opens the way for further advance in medical teaching. In this recommendation the General Medical Council may be said to have granted a new and enlarged charter to pædiatrics. This advance has been gained by the special study of the subject going on all over the world, and by the growing conviction of its importance in medical practice. In this country the General Medical Council has watched and fostered the extension of teaching of the subject since its resolutions on medical education in 1922, and the resolution of 1932 is largely due to the concentration and pertinacity of the inspectors. Both in their individual and general reports they have insisted again and again, and in strong terms, on the importance in medical practice, and therefore in medical teaching, of the two aspects of health and disease in children. Dr. J. S. Fairbairn and Dr. Wardrop Griffith, whose names appear in the printed reports, now bound up in a volume,[2] as the inspectors in midwifery and medicine who visited the medical schools of Great Britain and Ireland from 1930 to 1932, were dealing with the qualifying examinations in these subjects and not with the teaching. They commented adversely upon the rare appearance of questions about children in the written papers, and upon the almost entire absence of infants and children in the clinical material presented to candidates at examinations. And their recommendations were much stronger than that of the examination committee, for they asked for a separate written paper, and a special clinical examination, to be conducted by those engaged in the teaching of pædiatrics. But their far-reaching proposals really lie hidden in the womb (as Dr. Fairbairn might say) of the 1932 resolution; and in the fullness of time they will be brought forth.

There is a good deal of misunderstanding and confusion as to what is meant by "infant hygiene," although the term "diseases of children" seems clear enough. To make matters worse, these subjects are presented to us in the inspectors' reports as minor appendages of the great subjects of midwifery and medicine. But they are in fact not separate subjects, but parts of one subject: the clinical study and management of children in health and disease. The subject "diseases of children," as taught here and all over the world, and as presented in medical text-books, has always included both aspects of the subject; but it is taught in hospitals for sick children, and as the time allotted is short the clinical teaching is largely concerned with disease. Dr. Fairbairn's plea for more teaching in the care and feeding of young infants at maternity hospitals therefore deserves serious attention; for it is only in maternity hospitals and in postnatal clinics for infants that the necessary clinical material of healthy infants is available. The subject, although one and undivided, can only be completely and practically studied in two separate institutions. The term "infant hygiene" is misleading, partly because British medicine has never taken kindly to the word hygiene. "Pædiatrics" is better; its meaning covers the whole subject, but it too has a strange and foreign sound about it. Dr. Fairbairn wishes the teaching of midwifery and infant hygiene to be linked together: we should then have "obstetrics and pædiatrics," an unpleasant conjunction of sounds—"jangled, out of tune, and harsh." The University of Edinburgh has chosen for the subject the title "child life and health," which is good English and includes in a simple phrase the two parts of the subject, health and disease, in their broadest sense. While no doubt the name of the subject will be determined by usage, it should express the unity of this large and important subject; as the side of health (or hygiene) is bound to play a large part in its development, it would be well for the word health to appear in the title.

A discussion which began with examination went on to the more important question of teaching. There is no use in calling for a stricter examination in what is called infant hygiene, as well as in diseases of children, if the time allotted for teaching is not extended. And probably the demand for more thorough examination will have a more immediate and beneficial reaction on teaching than on the actual examination test. The average time allotted to the teaching of this subject in Great Britain and Ireland is about 60 hours, a period much shorter than in the American schools. It is possible in that time to cover a good deal of ground by means of lectures, but not to familiarise the student with the clinical examination of sick and healthy children. The British Pædiatric Association with wise prescience debated the whole subject, both of teaching and examinations, at their last annual meeting, and sent to the General Medical Council four unanimous resolutions, corresponding in their general tenor to those of the inspectors, although expressed in more cautious and peacefully persuasive terms. The Association concentrated their attack at the examination end, and their resolutions no doubt contributed to the advance secured at the November council meeting. The Association will now be well advised to direct their attention to the courses of instruction, and to take full advantage of the opportunity given by the General Medical Council to revise and extend the teaching. A door has been unlocked; it is for the teachers in pædiatrics, by tact and patience and judicious pressure, to get the door open.

AEROPLANES AND YELLOW FEVER

FASTER transport may bring us nearer to our neighbours, but it also brings us nearer to our neighbours' diseases. The development of long-distance flying and regular air routes has opened up obvious possibilities of the introduction of disease by air, and of late years the medical profession in this country has been invited by a number of writers[1] to consider the problems likely to arise. The danger is twofold. Either the time taken in transit may be so much reduced that a person may arrive in a country while incubating a disease which would normally have developed during the journey; or, where diseases are spread by animal vectors, the mosquito, fly, tick, or even rat in question might be conveyed to a fresh area safely and rapidly by aeroplane or airship. The second possibility has received some support from experiments carried out in the transportation of mosquitoes by air between Miami (Florida) and San Juan (Porto Rico).[2] Out of about thirty marked insects liberated in the cabin of a large passenger aeroplane from 3 to 13 in the different experiments were recovered alive at the end of ten-hour journeys of 1250 miles, with three stops, at which crews were changed and passengers and baggage were transferred.

In the case of Great Britain, with the possible exception of virulent small-pox, the danger of a serious epidemic from the introduction by air of cases or vectors of any of the major infectious diseases is at present almost negligible; but it is far otherwise with large areas in the tropics. Malaria, plague, cholera, and above all yellow fever, have here to be considered; and it is especially in connexion with the last-named that fears have been expressed. Calamities are prophesied if the disease is taken from West to East Africa and thence into India,[3] and Sir MALCOLM WATSON is not alone in holding the alarming views which he expressed at the last meeting of the industrial advisory committee of the Ross Institute. The grounds for apprehension are indeed far from negligible. They include: the ubiquity of the mosquito vector, *Aedes ægypti*, and the fact that several other species are potential vectors, at any rate under laboratory conditions; the presence of a huge susceptible animal reservoir in the rhesus monkey; the highly infective character of the virus and the fatal nature of the disease; and the existence of areas in which the disease is latent among the native population. Fortunately, however, there are also several factors militating against an epidemic spread by these means, and they are well summarised in a report drawn up by Colonel S. P. JAMES, which was submitted by the Yellow Fever Commission to the Office International d'Hygiène Publique last October. Yellow fever, the Commission say, is transmitted only from actual human cases in the first three days of the attack; the incubation period does not exceed six days; the agent of transmission is a domestic mosquito which remains in, or in the immediate vicinity of, the house where it has fed, and the insect, after feeding upon an infected case, must survive for 12 days or more before it can transmit the virus to another person. Lastly, it is held that "if there is adequate knowledge of where and when the disease occurs there is little or no difficulty in getting rid of it." Apart from these natural safeguards, important steps have been taken by the League of Nations Health Organisation and the various governments concerned to minimise the risk of spread. The subject has been under the consideration of the Office International d'Hygiène Publique for some years,[4] and last November a League of Nations conference of government health departments was held at Cape Town, where agreement was reached about the measures to be taken, and the early adoption of the International Sanitary Convention for Aerial Navigation by the various African governments concerned was unanimously recommended.[5] The regulations for yellow fever are strict and embody several departures from precedent. For instance:—

> "Signatory countries where yellow fever may exist will not rest content to await the appearance of typical cases but agree to take steps for searching out unrecognisable cases of the disease by biological methods and, if it is present, for defining its geographical distribution: also measures for preventing spread by aerial traffic shall be taken primarily before departure from those areas where the disease exists and only secondarily at ports of arrival; such measures include the requirement that crews and passengers shall have been free from any risk of infection during six days before embarkation and that the aircraft and cargo shall be free from the possibility of conveying mosquitoes. In addition countries which are infectible but not infected may refuse to permit the entry of aircraft from infected countries provided they report the reasons for the prohibition."

It seems clear, therefore, that the sanitary authorities of the countries concerned are fully aware of the dangers and have given them much thought. But of course the International Sanitary Convention for Aerial Navigation has yet to be ratified and brought into effective operation.

Fortunately a further safeguard may soon be in our hands. The use of vaccines and sera received a great stimulus from the discovery that monkeys and white mice were susceptible under certain conditions, and although the first results obtained from the use of vaccines containing killed or attenuated virus to produce immunity were disappointing, the simultaneous injection of biologically modified mouse-virus and immune serum seems to have given promising results in the hands of Sawyer, Kitchen, and Lloyd.[6] Obviously the power of conferring immunity from yellow fever on those passengers or airway personnel exposed to risk would allow considerable modifications in the somewhat irksome restrictions laid down by the proposed Sanitary Convention.

THE RADIOGRAPHY OF CONGENITAL PYLORIC STENOSIS

The clinical picture of pyloric stenosis in infancy may be such as to leave little room for doubt. In the typical case there is projectile vomiting, usually beginning between the second and sixth weeks of life, associated with wasting, constipation, and visible peristalsis; while the presence of a *palpable tumour—a sign to which most experienced* observers pay great attention—will almost certainly clinch the diagnosis. At the same time it seems likely that mere spasm may closely simulate a true hypertrophy, while on the other hand any one of the classical features of the condition may be absent. Thus vomiting may be infrequent and not projectile; gastric peristalsis may not be conspicuous and may be visible only after repeated examinations; and the stools are sometimes normal or even diarrhœal. It is in cases of this type that accessory means of diagnosis will be especially valuable, since it is important to have an early decision and it is clearly undesirable to operate when there is no hypertrophy.

Radiography is not yet widely used in the diagnosis of this condition, but it has warm advocates. Dr. Eric Pritchard,[7] indeed, goes so far as to say that in deciding whether operation will be needed he attaches more importance to the X ray appearance after an opaque meal than to the size of the tumour felt on palpation, projectile vomiting, visible peristalsis, or obstinate constipation. Though most clinicians would not be prepared to endorse this opinion, there is certainly increasing evidence that radiological examination may be of real value. In carrying it out the general practice is to give 80 c.cm. or more of the opaque meal by means of a spoon or tube, and importance has been attached in diagnosis to such secondary symptoms as retention of the whole or greater part of the meal in the stomach for three hours or more, excessive peristalsis, dilatation either of the pyloric antrum alone or of the whole stomach, hypertrophy of the muscle wall of the stomach, and antiperistalsis. Dr. T. Meuwissen and Dr. J. P. Slooff[8] now, however, describe a different technique which they consider more reliable than many of the others adopted; they have used it in examining the stomachs of normal infants as well as those with symptoms of hypertrophic pyloric stenosis. The infant was kept without food from midnight, and in the morning any secretion or air present in the stomach was removed by means of a duodenal tube or a Nélaton catheter No. 18. (The amount of secretion was usually found to be small, and remains of the last meal were present only in a few cases of established stenosis.) Three cubic centimetres of a thin barium meal (100 g. barium sulphate in 150 c.cm. water) was then given through a tube, and spread over the whole stomach area by moving the child. Radiograms were taken dorsiventrally in the vertical and lying positions, and a further 20–30 c.cm. of a thicker barium meal (100 g. barium sulphate to 100 c.cm. water) was passed through the tube. By compression an attempt was made to fill the pyloric canal, which was always found to be lengthened in cases of hypertrophy. Six to ten radiograms were then taken of the canal in the dorsiventral or first oblique position—the rays passing from the left posteriorly to the right anteriorly—according to the position in which it showed best. The distance of the tube from the plate was 70 cm., and of the child from the plate 10 cm. After this the barium was as far as possible washed out from the stomach.

Meuwissen and Slooff think that whereas the relatively large meals previously used will greatly alter the position and shape of the stomach, 3 c.cm. of their barium mixture will hardly alter it at all, though it gives a clear outline of the organ. Likewise the giving of large meals is likely to distort the picture because of the swallowing of air. In the examination of a considerable number of normal infants by their method, it appeared that the stomach usually lay in the left hypochondrium and extended somewhat beyond the midline; the axis generally ran in an oblique direction from the left above to the right below, but was sometimes horizontal. When the stomach was fuller, the axis altered and became curved. In all the infants examined, however, the organ showed no fixed form: indeed differences were noted when the same child was examined a second time. With the 3 c.cm. meal the stomach seemed small, and even in the cases of stenosis it was never possible to demonstrate dilatation. In these last the pyloric canal was found to be sharply differentiated from the adjacent stomach margin, and in only one (where the hypertrophy appeared to be slight and operation did not prove necessary) was the transition gradual. The canal appeared radiologically as a needle-like shadow, which could be distinguished from the duodenum when the latter began to fill, and which was four to five times longer than normal. Retention of the meal in the stomach was not found to be a reliable index of stenosis, and similarly there was little evidence of excessive peristalsis. After operation the canal was funnel-shaped, and this appearance was observable for some time after symptoms ceased. From this it is concluded that the muscle was still in spasm, although the stenosis had been cured, and in one case the symptoms are interpreted as indicating that hypertrophy was secondary to spasm. Meuwissen and Slooff distinguish two types of spasm of the pyloric sphincter—one which gives rise to hypertrophy and one which does not.

ANNOTATIONS

SHOCK AND ANÆSTHETICS

SHOCK, especially of the kind called secondary, may fairly be regarded as the chief bugbear of the surgeon who carries out extensive operations. Since the day when Lister made clear the nature and origin of septic complications, experience and continuous development of technique have brought surgeons to the point where they may justifiably claim that sepsis is preventable. Not so shock. For this condition we have no equally definite idea of causation and therefore no equally definite methods of prevention or treatment. In his Arris and Gale lecture before the Royal College of Surgeons of England on Feb. 15th, Prof. R. J. S. McDowall defined shock in animals as "the state which results from a fall of arterial blood pressure which if severe may lead to death from oxygen want." Its onset, he said, may be preceded by a compensated or even overcompensated stage in which the body succeeds in maintaining the blood pressure against the forces which would cause it to fall. This definition—better from a physiological standpoint than a clinical one—gives no indication how the fall in blood pressure may be supposed to originate. Prof. McDowall, however, pointed out that this may be from heart failure, from loss of blood, from an undue opening-up of vessels which are normally closed, or from a reduction of peripheral resistance. Shock may also be caused by violent stimulation which exhausts the vasomotor centre; in fact many regard this as the usual mode of onset of primary surgical shock. This is the kind of shock which is prevented on the operating table by deep anæsthesia. It is the relationship of anæsthetics to deferred shock which is less obvious and at the present day more important. Here the shock is apparently produced chemically by the action of histamine and similar bodies, and it seems certain from experimental evidence that ether and probably other anæsthetics sometimes make recovery from the histamine bodies impossible when it might have taken place in the absence of the anæsthetic. This incriminates anæsthetics in delayed surgical shock in the manner insisted upon by Finsterer of Vienna. Ether is believed to produce its depressing effect by dilating blood-vessels and rendering them more permeable; its action is masked at the time of operation by the stimulating nature of the drug.

It is plain that if these contentions are correct then the greater the damage which the patient suffers—in other words, the more extensive his operation, and the greater his exposure to histamine poisoning—the greater is the need for avoiding any addition of the effects of ether or the like to his histamine-loaded system. Nitrous oxide has been shown by Dale not to increase the susceptibility of an animal to histamine shock in the way that ether does. Prof. McDowall was of opinion that the future would see a greatly extended use of local anæsthetics for patients exposed to these risks. Spinal anæsthesia did not, he said, meet the case, because it interferes with nervous control of the vessels and also causes vasodilatation. He maintained also that concussion of the vasomotor centre is a more common cause of shock than is usually supposed. It may be produced experimentally by simply jarring the head. The importance of acapnia in relation to shock seems to lie chiefly in the fact that it reduces the activity of the vasomotor centre by which the body attempts to compensate for a fall of blood pressure.

POPULATION PROPHECIES

THE factors which produce changes in the quantity and quality of human populations are numerous and complex. It seems to be possible, by stressing one or other of these factors at the expense of the others, to justify any blend of optimism and pessimism about the future. The first World Population Congress was held at Geneva in 1927, when the world was in the middle of a boom, and the dominant note was optimistic. A second conference, held under the auspices of the International Union for the Scientific Investigation of Population Problems, took place in June, 1931, in London and, doubtless in response to the prevailing economic depression, the dominant note was pessimistic. The proceedings of this second conference have now been published.[1] The speakers were not hampered by the restrictions which partially stultified the former one, when discussion of the medical and sociological aspects of birth control was vetoed. This subject now received careful attention from several speakers of different nationality. Moreover, the later conference differed in yet another respect from its predecessor. By several speakers at the 1927 conference, notably by Dr. E. M. East, fears were expressed of the consequences of imminent over-population throughout the world. Dr. East drew an alarming picture of the effects upon Europe, wherein lived some 80–85 million persons depending upon imported food, of the reduction to nil of surplus food for export from food-exporting countries—Canada, Australia, and the Argentine—by reason of the increase of their own populations. But at the 1931 conference the emphasis was laid not upon the dangers of over-population in Western Europe, but upon the appalling prospects of an imminent depopulation in this area. Thus Dr. Eugen Fischer, commenting upon a table showing the decrease in the average size of completed families of certain classes in Germany between 1879–1910, remarks that "these few figures clearly indicate the condition of the people. It is that of a moribund community." Dr. Louis I. Dublin considers it to be not improbable that the population of the United States will reach a maximum of 148 millions in 1970, and that it will then halve itself in the course of the next 60 years. Prof. Fernand Baudhuin, speaking of the future of France and Belgium, says: "in any case, the peoples to which we belong will suffer the consequences of the policy they are now putting into practice; they are probably destined to disappear, or to be absorbed by newcomers." This authority draws a graphic picture of a new Western invasion by Slav races, first by Poles, and then by Russians, in the measure that the Latin countries become depopulated. And Prof. J. W. Gregory holds that the recent restrictions on immigration into under-populated and undeveloped countries, such as Australia, are likely to prove more harmful to the immigrant than to the emigrant countries—a very different prognostication from that delivered by Dr. East four years previously in Geneva. Relieving the pessimistic utterances of these and other speakers (who seem to regard human vital statistics, represented by curves on plotted charts, as inevitably destined to continue in the directions they have already taken, as do the curves made by the heavenly bodies in space) is the voice of Prof. F. H. Hankins of Smith College, Massachusetts. He effectively criticises the fatalism of Prof. Gini's "parabola of evolution," and points out that because human reproductive habits have taken a certain course in the very recent past, it does not necessarily follow that they will continue to take the same course in the future. "There seems to be no reason," he writes, "to doubt the possibility of a restoration of the birth-rate when and if the cultural opportunity develops."

[1] Problems of Population. Being the Report of the Proceedings of the Second General Assembly of the International Union for the Scientific Investigation of Population Problems. Edited by G. H. L. F. Pitt-Rivers, B.Sc. Oxf. London: George Allen and Unwin, Ltd. 1932. Pp. 378. 15s.

No thinking person can doubt the fundamental importance of population problems. Doubtless at the next conference, new notes and prophecies will be sounded. The factors affecting human births, deaths, and food-supply are all capable of sudden and dramatic change. The elaboration of a simple, reliable, and fool-proof contraceptive, the outbreak of a new and uncontrollable epidemic disease with a selective racial incidence, or the discovery of an organism capable of converting cellulose into assimilable carbohydrate, or indeed many other occurrences psychological as well as physical, might well stultify the prognostications of all existing authorities on population, and hopelessly distort their curves.

BRONCHOSCOPIC SPIROMETRY

A FURTHER stage in work on respiratory function and efficiency tests has been reached in Stockholm where H. C. Jacobæus, P. Frenckner, and S. Björkman have devised an ingenious method of connecting each lung separately to a spirometer. In a preliminary report[1] they sketch the steps which led to their use of a special type of bronchoscope (the Chevalier Jackson type) with a calibre of 7 mm. and a length of 45 cm. The proximal end was closed by a detachable hollow stopper of the same lumen as the bronchoscope and fitted proximally with an obliquely placed glass window. A few centimetres from the proximal end of the bronchoscope was an outlet for air of the same calibre as the rest of the tube. The distal, cylindrical part of the bronchoscope was enclosed by a circular, closely fitting rubber cap about 1 cm. broad. Into this cap opened a fine canal, running along the whole length of the bronchoscope, intended for inflation of the rubber cap. Before each examination a test was made of the pressure required for obtaining with the rubber cap a reliable air-tight closure of a lumen, the size of a bronchus. From a technical point of view the most difficult detail of procedure employed seems to have been placing the distal end of the bronchoscope in exactly the right place, since the distance between the bifurcation of the trachea and the origin of the bronchus of the upper right lobe is only about 2 cm. and it is obviously of great importance that the rubber cap when inflated should not obstruct this bronchus nor interfere with the trachea. An air-tight junction effected with the distal end of the bronchoscope in exactly the correct position meant that the lung under investigation could be connected to a respiratory spirometer of the Knipping pattern.

An attempt was made to determine the volumes of the two lungs simultaneously yet independently of one another. For this purpose a bronchoscope made as already described was enclosed by a second bronchoscope tube reaching from the proximal end of the former to about 10 cm. from its distal end, of such a calibre that the air volume passing between the two tubes was exactly equal to that passing through the inner tube. The distal cylindrical end of the outer tube was also enclosed by an inflatable rubber cap and from the proximal end an outlet tube was constructed to allow the same volume of air to pass per second as through the inlet of the distal end. This double bronchoscope was passed down the trachea so that the distal end of the inner tube was in the correct position in one of the main bronchi and both rubber caps were inflated, sealing one lung to the inner bronchoscope and the other lung through the obstructed trachea to the outer bronchoscope. The lung volumes, including residual air, for both lungs together was first investigated without a bronchoscope, and then the spirometry of the separate lungs was carried out after bronchoscopy. Obviously the operative interference must have a considerable effect upon the respiratory function and any consideration of oxygen consumption, for example, of the lungs separately would be open to serious criticism. In all 11 patients have so far been studied in this way and the sum total of the measurements for the left and right lung as obtained by the method here described agreed surprisingly well with the respiratory volume for the two lungs taken together. Where pathological conditions of the lungs were present X ray examination was also carried out and attempts were made to correlate the findings for "broncho-spirometry" with the radiographic appearances. A certain lack of conformity between them can probably be explained by the spirometric methods being still in the experimental stage. Further work on these lines may well prove useful.

HUMAN BLOOD GROUPS IN EVIDENCE

THE medico-legal implications of the present knowledge of the human blood groups were discussed at a meeting of the Medico-Legal Society, held under the chairmanship of Lord Riddell, on Feb. 23rd. Dr. S. C. Dyke pointed out the confusion arising from the existence of the conflicting numerical nomenclatures of Jansky and Moss, and put in a plea for the adoption of nomenclature according to agglutinogen content of the red cells, as suggested by the public health committee of the League of Nations. He drew attention to the importance of the blood groups in civil legal practice for the demonstration of non-paternity, and in criminal practice in the identification of blood stains. The original law of von Dungern and Hirszfeld that the agglutinogens A and B cannot appear in the offspring unless present in the parents still, he said, holds good. The theoretical considerations introduced by Bernstein and Furuhata limit even further the possibilities of group inheritance, but which of these views is accepted makes no difference in so far as the actual possibilities of group inheritance are concerned. The identification of the M and N agglutinogens by Landsteiner and his co-workers narrows the field in cases of disputed paternity; the discovery of the P agglutinogen might in the future take the matter even further. Dr. G. Roche Lynch pointed out that, in a case of disputed paternity recently before the Danish courts, Prof. O. Thomsen had given evidence on the basis of the M and N agglutinogens that the defendant could not be the father of the child in question; on the advice of the Danish Medical Association, however, the evidence was not allowed to weigh conclusively against other evidence, and the defendant lost. Dr. Dyke agreed that the state of knowledge of M and N agglutinogens did not justify the acceptance of such evidence as conclusive at present, though in the future it might be accepted; even now knowledge of the A and B agglutinogens was sufficient to justify the acceptance of evidence depending on these factors against circumstantial evidence. It was difficult to secure serum and red blood-cells of known groups A and B, and he hoped for the establishment of a roster of individuals of known groups whose blood might be available for medico-legal purposes. Until such a roster was available the issue in forensic work might always be clouded by doubts of the credentials of the reagents used. Dr. Dyke expressed the opinion that evidence on the blood groups given by medical witnesses called by counsel on opposing sides might merely serve to confuse the jury, and suggested that the test might be performed by order of the court by an entirely unbiased expert with no connexion with either side. Dr. F. C. Martley described his method of identifying the group of blood stains by absorption of the agglutinins from a Group O serum. Dr. Roche Lynch gave an interesting account of the identification, in the case of the "city typist" murder, of a blood-stained razor found on the top of a bus as the weapon with which the murder had been committed. The group of the blood of the murdered girl and of the blood stain on the razor was AB; the rarity of this group in the general population served as powerful evidence for the assumption that the bloods were identical. There seems to be no doubt that blood grouping has a definite place in medico-legal investigations which is likely to become even more firmly established in the future.

INFRA-RED MICROSCOPY

SIGHT and sound are not negligible because they are outside the perceptive range of the human retina or the organ of Corti. The infra-red rays thrown out by hills and trees are long enough to evade the obstacles of mist and fog and to reach the sensitised photographic plate although such rays are invisible to the unassisted eye. During the last few months infra-red photographs published in the daily press have kept us in touch with what the heights of Hampstead and Highgate would look like were our domestic chimneys not belching forth smoke, and what Burnley and Blackburn would look like were it not for the unburnt products of manufacturing fuel. These photographs reveal the landscape as it would be if we could see through the encircling gloom, and one may hope for the time when the retina can be sensitised in the same way as the photographic plate. The foreshadowed application[1] of infra-red photography to medicine is proceeding apace. Dr. S. R. Gloyne and his chief laboratory assistant, Mr. A. W. Smart, have been ingenious enough to see if it will enable them to avoid the amorphous dark pigment, so often seen in microscopic sections of lungs, and to reveal the nature of the asbestosis body. The results are shown in a series of photomicrographs in the February number of *Tubercle*, from which it is quite evident that the infra-red plate picks out certain structures and ignores others. How far the differences may be due to the alteration of focus by the infra-red filter—and of course the visual control of focusing is lacking—Dr. Gloyne leaves open for the moment. It is now well known that carbon in the atmosphere is not penetrated by infra-red rays and probably the same is true of carbon particles in lung tissue; but there are other foreign bodies in the asbestotic lung, to which the infra-red reacts differently, and the various stains used by the histologist also produce different reactions. Infra-red rays certainly penetrate thick sections better than do light rays, and their use opens up possibilities in the photomicrosc of dense structures such as pneumoconiotic lu The British Journal Photographic Almanac[2] 1933 gives some striking examples of what can done with infra-red plate and filter.

MILK GRADING IN THE UNITED STATES

Prof. G. S. Wilson[3] has lately given a deta account of the system of grading milk in the Un States of America, which he has studied on the s While many different arrangements are set the most interesting part of his report is a descrip of, and critical comparison between, the two n administrative procedures—the permit system procedure by milk ordinance.

The permit system is the older and is in forc those towns and States which have not decide operate under the milk ordinance system. Bein local system it may, and usually does, vary in details in each city or State. The different author concerned are very numerous, since there are S regulations, county regulations, the requirement the smaller towns, and, in particular, the regulat of the large cities, which may not restrict t activities to their own area but extend their inspec powers into outside areas sending milk into the c It is impossible therefore to do more than indi their trend. The general principle is that no pe shall sell milk or offer it for sale without having obtained a permit from the health officer. Be such a permit is given there is intended to be a v complete inspection to see if all requirements complied with, and to get any defects remedied be the permit is issued. In the more efficient areas is usually combined with a system of milk grad The enforcement of the grades under the pe system is dependent on inspection, and on chem and bacteriological analyses carried out in the S and in the municipal laboratories.

The milk ordinance is a system recommended the public health service of the Federal Governm for adoption by States, counties, or cities, in orde encourage a unification of milk control practice the United States. The ordinance and the code m up a bulky volume, the code giving a deta explanation of the exact meaning of each section the ordinance. The Federal Government has executive powers in the control of milk, and its fu tions are merely advisory, so the adoption of ordinance is purely voluntary. The ordinance perm as many as eight different grades—i.e., Certifi Grade A Raw, Grade B Raw, Grade C Raw, Grad Raw, Grade A Pasteurised, Grade B Pasteurised, Grade C Pasteurised. These are all defined in ter of the conditions on farm and dairy, and with defin bacteriological standards. The health officer the area that has adopted the milk ordina is required, at least every six months, and prefera once every three months, to announce the grades milk and cream delivered by all producers a distributors. These are determined by inspecti and analyses, and detailed instructions are given to the numbers of bacteria allowed. Failure comply with requirements is usually punished de-grading—i.e., reducing to a lower grade, and, extreme cases, by revocation of permission to milk. A valuable feature, both to prevent injust and to encourage the production of milk of go quality, are the clauses which enable a de-grad vendor to return quickly to his grade on proof that the unsatisfactory conditions are removed.

[1] THE LANCET, Jan. 28th, p. 209.

[2] London: Henry Greenwood and Co. Pp. 654. 2s.

[3] Quart. Bull. Health Organisation League of Nations, 19 i., 664.

The two systems have it in common that they make use of the principle of differential grading which should ensure that all milk sold within a given area is appropriately labelled. Prof. Wilson holds that "it is difficult to over-estimate the advantages of this practice. The lower class of producer or dealer is faced with the alternatives of reforming his methods, or of labelling his milk with a low-grade designation." If this goes hand in hand with adequate education, demand for the lower grades of milk almost ceases. Obviously, however, a not too high standard must be set when the scheme is introduced. The permit system, without any grading, is administratively difficult to enforce. Revoking the permit is drastic, and if the dairy persists in carrying on, a penalty for selling milk without a permit is not always enforceable in court. Prosecutions for infringement of individual violations of the regulations are troublesome and lead to a strained relationship between the health officer and the industry. These difficulties tend to laxness in administration. Under the milk ordinance system main reliance is placed upon de-grading, and the milk-seller has to put a lower grade label upon his bottle caps. If he breaks this requirement it seems that public sympathy is not in his favour, and convictions are readily obtained. The legitimate criticism that there are too many grades in the ordinance is met by the fact that the number to be adopted by the community using the ordinance is optional, and a sufficient number must be included to meet the varied local conditions. A more important objection is that the cost of inspection and laboratory work is high and considerably higher than under the permit system as usually practised. It is also obvious that good working of both schemes, but particularly the ordinance system, involves not only accurate laboratory procedure, but a high standard of technical knowledge, vigilance, and mental honesty on the part of the local health officials. Prof. Wilson considers that there is little likelihood of its uniform adoption in the near future.

COLOUR BLINDNESS IN DOCTORS

BETWEEN 3 and 4 per cent. of males are said to show gross congenital colour blindness, and if minor degrees of the defect are included the proportion must be much higher. Even severe cases, however, often pass undiscovered unless specially tested, and medical students are almost as likely to be congenitally colour blind or colour-defective as any other body of young men entering on a career. Women as a rule are exempt, but men may find the disability a serious professional handicap. This possibility has been investigated from the practical point of view by Dr. Leandro M. Tocantins and Dr. Harold W. Jones[1] of Jefferson Medical College in Philadelphia. Seventy members of the junior class of the medical school were asked individually to read the Ishihara plates (one of the modified Stilling tests), and 9 of the 70 were found to have some defect of colour sense. These nine were then required to perform six separate tasks involving the distinguishing of colours in solutions and stained microscopical slides, the results being compared with those obtained by six students of the same class with normal colour vision. The mistakes made by the colour-blind group were far in excess of those made by the normal group. Only two out of the nine in the former could distinguish Gram-negative organisms in a smear, although they could identify Gram-positive ones. The entire group failed to distinguish acid-fast bacilli if methylene-blue was used as a counter stain, though with Bismarck brown they found it easy. The colour-defective group were next questioned individually. Some had difficulty with exanthematous skin lesions. They could not recognise the rash in scarlet fever. One man could not recognise jaundice except in the sclera. Nearly all had difficulty in seeing the tubercle bacillus, a circumstance which had led to difficulties in examinations. It is evident that men with a marked defect of colour vision suffer under a serious handicap in laboratory work and in clinical medicine. As a compensation, however, for those who have colour-defective vision they seem to have a more than average ability to distinguish between various shades of light and dark, and it is said that a colour-defective engraver was specially prized by a Philadelphia publishing firm on this account. Tocantins and Jones suggest that this faculty should make young doctors with defective colour vision specially suited to take up the specialty of radiology.

CARDIOVASCULAR SYPHILIS

IN a discussion[1] recently held by the New England Heart Association Dr. T. B. Mallory pointed out that the essential pathological process in cardiovascular syphilis is an aortitis. When this lesion involves the root of the aorta the result is aortic regurgitation. Rarely, if ever, is aortic stenosis caused by syphilis, and here it is in striking contrast to rheumatism, which in attacking the aortic valve usually produces stenosis and regurgitation together. Mallory also found that of 15 cases of syphilitic aortitis with involvement of the valves all but one showed narrowing of the openings of one or both coronary arteries. Dr. P. D. White said that the incidence of syphilitic heart disease in New England is low, forming only 2·4 per cent. of cases of organic heart disease seen privately. This incidence is somewhat higher in hospital patients. In 2100 autopsies evidence of hypertension was noted more than three times as often as evidence of cardiovascular syphilis. The latter is more than five times commoner in men than in women, and the age-incidence reaches a maximum between the ages of 50 and 60, except in negroes, where it is 5–10 years earlier. That the diagnosis of syphilitic aortitis in the absence of aortic regurgitation or aneurysm may be difficult or impossible is shown by the fact that 23 of 25 uncomplicated cases presented no abnormal physical signs. Of 78 private cases 56 had aortic regurgitation and only 5 aortic aneurysm. Although 23 of the 78 patients suffered from angina pectoris, White regards syphilis as a rare cause of this condition, for among 500 patients with angina it was found in only 6 per cent. This rarity of syphilis as a cause of angina was confirmed by another speaker, Dr. S. A. Levine, who found it in only 4 per cent. of his angina cases. Despite what was formerly taught, it is also unusual for syphilis to play any part in the causation of coronary artery disease and thrombosis. Even in those rare cases in which the two diseases occur together, it is almost always found that the coronary disease is arterio-sclerotic and not syphilitic. While the Wassermann reaction is as a rule strongly positive, a negative reaction by no means rules out syphilitic aortitis, since in the autopsy series it was negative in 21·4 per cent. This finding has been the acceptance of evidence depending on these factors against circumstantial evidence. It was difficult to secure serum and red blood-cells of known groups A and B, and he hoped for the establishment of a roster of individuals of known groups whose blood might be available for medico-legal purposes. Until such a roster was available the issue in forensic work might always be clouded by doubts of the credentials of the reagents used. Dr. Dyke expressed the opinion that evidence on the blood groups given by medical witnesses called by counsel on opposing sides might merely serve to confuse the jury, and suggested that the test might be performed by order of the court by an entirely unbiased expert with no connexion with either side. That the diagnosis of syphilitic aortitis in the absence of aortic regurgitation or aneurysm may be difficult or impossible is shown by the fact that 23 of 25 uncomplicated cases presented no abnormal physical *signs*. Of 78 private cases 56 had aortic regurgitation and only 5 aortic aneurysm. Although 23 of the 78 patients suffered from angina pectoris, White regards syphilis as a rare cause of this condition, for among 500 patients with angina it was found in only 6 per cent. This rarity of syphilis as a cause of angina was confirmed by another speaker, Dr. S. A. Levine, who found it in only 4 per cent. of his angina cases. Despite what was formerly taught, it is also unusual for syphilis to play any part in the causation of coronary artery disease and thrombosis. *Even in* those rare cases in which the two diseases occur together, it is almost always found that the coronary disease is arterio-sclerotic and not syphilitic. While the Wassermann reaction is as a rule strongly positive, a negative reaction by no means rules out syphilitic aortitis, since in the autopsy series it was *negative* in 21·4 per cent. This finding has been confirmed by Levine. As regards treatment of the established condition, Dr. C. Morton Smith agreed with the view, generally accepted in England, that most reliance should be placed on potassium iodide and mercury, perhaps supplemented by bismuth intramuscularly. Arsenical preparations should be used cautiously if at all, and then only after a preliminary course of iodide. This caution applies particularly forcibly to cases with aortic regurgitation, since in them the coronary orifices are almost certainly narrowed, and any local reactionary swelling may produce complete occlusion and sudden death. This conception of the treatment of cardiovascular syphilis agrees very closely with that expressed by the majority of the contributors to a symposium lately published in France.[2]

ASCORBIC ACID AS VITAMIN C

In the story of the vitamins history tends to repeat itself. This is perhaps not surprising since these substances have at least one great property in common, the property of exercising their beneficent influence in extremely small quantities. In fitting cholesterol and carotene into their proper niches in the story, the same question arose: "Is cholesterol capable of activation by ultra-violet light to form vitamin D, or does this property belong to a contaminant?" and "Is carotene capable of acting as provitamin A or is vitamin A itself present as a contaminant?" The final verdict was not the same in the two cases: cholesterol was pronounced impure and itself inactive, being contaminated with the active ergosterol; carotene was declared pure and uncontaminated and itself active. Hexuronic acid now stands where carotene and cholesterol stood, and what will the answer be to its claim to be itself the antiscorbutic vitamin? Is the verdict to be pure or impure? Prof. A. Szent-Györgyi, the discoverer of hexuronic, which he now prefers to call ascorbic acid, is himself in no doubt, for, speaking of the antiscorbutic vitamin, he says: "To-day this substance can be bought at a relatively low price, neatly sealed in tubes in the form of beautiful white crystals."[3] The greater part of the rest of informed opinion seems to agree with Szent-Györgyi in his claim that ascorbic acid is the vitamin.[4] One of the most experienced workers in the field, Dr. S. S. Zilva, however, is not convinced, and his objections must carry weight.

Szent-Györgyi first prepared ascorbic acid from adrenal glands, but the supply of these was limited and the yield of ascorbic acid too low to provide material for an exhaustive study. Again history repeats itself; just as vitamin A defied isolation in anything approaching a state of purity until the comparatively weak cod-liver oil was replaced, as the raw material, by the enormously much more potent halibut-liver oil, so now the investigation of ascorbic acid can advance with a bound, with the discovery that a Hungarian red pepper (*Capsicum annuum*) contains ascorbic acid in very large quantities and in a state which makes purification easy. A pound of ascorbic acid has thus been prepared, on which, with international coöperation, a chemical study has been made; so the evidence thus collected seems still to support ascorbic acid's claim to vitamin status.

GENTIAN-VIOLET IN THE TREATMENT OF BURNS

The tannic acid treatment of burns is based on the theory that the symptoms associated with extensive lesions are due to the absorption of toxins from the damaged area. Dr. R. H. Aldrich[1] challenges this theory, and puts forward the view, on behalf of Dr. W. M. Firor, that the symptoms are a result partly of fluid loss, with a corresponding increase in concentration of the blood, and partly of sepsis, pure and simple. In an investigation of the bacteriology of burns they found that, for the first 12 hours, cultures taken from the burned areas were sterile, apart from occasional contaminating organisms such as *Staphylococcus aureus* and *albus* and *B. coli*; after that, in all severely burned patients, the beta-hæmolytic and gamma streptococcus could be grown in cultures taken from the wound. The concentration of the organisms increased with the obvious signs of sepsis and with the beginning of the so-called toxic symptoms in the patient, until at the end of 48 to 56 hours pure cultures of the streptococcus could be obtained; coincidently the patient showed the characteristic bad effects of burning. As gentian-violet is regarded as a specific antiseptic for this organism, Firor and his colleagues tried using a 1 per cent. solution of the dye as a dressing for burns, and claim excellent results. Without preliminary cleaning of the burned area the dye is sprayed on at two-hour intervals for the first few hours. No dressing is applied, but the raw surface is exposed to the air and protected by a cradle. A thin, tough, flexible eschar rapidly forms, and spraying is then only performed every four to six hours during the day; the treatment is continued until healing is complete. If the eschar shows signs of softening, the softened portion is removed and the underlying surface sprayed afresh. The originators of this treatment claim that analgesia is produced almost instantaneously, that loss of fluid from the burned area is prevented, and that if sepsis can be successfully avoided the characteristic signs of extensive burning—such as stupor, fever, delirium, and albuminuria—do not appear. Apart from the preliminary shock there is no great prostration, and the patient may even be able to get up. Aldrich quotes three cases of extensive burns in which this treatment produced admirable results, and a fourth in which the patient, a child of 9, who had lost over three-fifths of the skin area, died of cardiac failure after two months of encouraging progress.

FEDERATION OF THE HEALTH RESORTS OF FRANCE. The following medical tours will take place in the South of France during the Easter period. From April 10th to 18th there will be a tour of the Provence and Riviera districts, during the course of which visits will be paid to Marseilles, Aix-en-Provence, Les Baux, Arles, Cassis, La Ciotat, Hyères, St. Raphael, Cannes. From April 16th to 23rd there will be a tour along the Riviera, visiting Cannes, Antibes, Juan-les-Pins, Grasse, Venice, Nice, Mentone, Monte Carlo. The tours will be under the scientific direction of Prof. Imbert and Olmer, of the Faculty of Medicine of Marseilles, and Dr. Georges Baudouin of the Institute of Hydrology and Climatology at the Collège de France Information as to the cost of the tours may be obtained from the Secretary, Société Médicale du Littoral Méditerranéen, 24, Rue Verdi, Nice (A.M.). . . . .

SPECIAL ARTICLES

THE EFFECT OF PASTEURISATION UPON THE NUTRITIVE PROPERTIES OF MILK

BY WILLIAM G. SAVAGE, M.D. LOND., B.SC., D.P.H.
COUNTY MEDICAL OFFICER OF HEALTH, SOMERSET

(Concluded from p. 433)

Human Feeding Experiments

IN view of the very extensive literature dealing with infant and child feeding, it is noteworthy that there are scarcely any studies which are of use for a comparison of raw cow's milk and pasteurised cow's milk. The utility of cow's milk in infant feeding is universally accepted and practised. The peculiar value of milk as a growth stimulant for the young has been established by a number of special investigations, that of Corry Mann (1926)[36] being the most convincing. The problem whether this valuable food is diminished for the child by pasteurisation remains uninvestigated, probably for the very sound reason that heated milk has been so extensively used without any signs of detriment that the scientific investigator realises no call for special critical study.

In the following summary I have dealt with all the investigations I can find which have any bearing on this particular point, or which have been alleged to have a bearing.

Daniels and Stearns (1924)[37] carried out no feeding experiments with raw milk, but compared a few babies fed one group on a milk mixture pasteurised for 30 minutes at 145° F. in bottles, and the other group fed on milk mixtures brought quickly to the boil three times, taking eight minutes in all. They estimated the calcium and phosphorus retention in the two groups, and for the six infants studied they conclude "the calcium and phosphorus retention in infants fed on quickly boiled milk mixtures was considerably greater than it was when the milk mixtures were pasteurised." Their results in no way contribute to the question at issue. The food heated was not whole milk, but a mixture with cream, a carbohydrate (dextri-maltose or lactose), and water. It was a diluted milk and it may have reduced the calcium content to a dangerously low level. The calcium content of the diluted milk is not given. Their results do no more than suggest that prolonged heating may reduce the available calcium and phosphorus more than quick boiling.

Ladd, Evarts, and Franks (1926)[38] published particulars of feeding experiments with groups of children in foster homes. Dealing with infants in the first year of life the following are their main findings.

Group 1 babies (61 cases) fed on pasteurised milk without orange juice or cod-liver oil over a period of 6 to 9 months showed a percentage weight development from 82·1 at entrance to 83·8 at the end of the period, of expected weight increase. A second group of 59 cases, which had orange juice in addition, showed a percentage weight development from 82·2 at entrance to 90·1. A third group which had cod-liver oil and orange juice in addition to pasteurised milk gave percentage weight development from 80·2 to 89·7. A fourth group of 17 cases only, fed on certified milk (raw) without orange juice or cod-liver oil, showed a percentage weight development increase from 80·0 to 94·0.

In a certain number of cases periodical X ray examinations of the wrists were made at three-monthly intervals. In 17 cases of the certified milk group 13 showed no X ray rachitis at the beginning of the period of observation, but 3 of these developed mild rachitis. Of 12 cases fed upon pasteurised milk with cod-liver oil and orange juice 4 showed no X ray changes at the beginning, while the 8 which did show signs were healed or healing at the end of the period of observation. If "period of observation" includes at the beginning of feeding, obviously the two groups are not comparable while nothing can be deduced from these findings.

Since the certified milk is extremely high-grade milk from specially fed cows and the other ordinary milk of unknown quality called Grade A pasteurised milk, the comparison is valueless. The authors recognise this fallacy and point out:—

> "It is quite possible that the greater efficiency of certified milk over pasteurised milk is due to the more exact and scientific feeding of the cows in the particular supply of certified milk used and not to the quality of rawness."

Lewis (1929)[39] compared two groups of unselected children, all under 9 months and all entirely artificially fed. Group 1 consisted of 122 infants fed upon certified milk. Group 2 of 112 fed on pasteurised milk. The author found that the infants fed on certified milk made decidedly more progress than those fed on pasteurised milk, this being specially marked in the 0–3 months group. The occurrence of rickets was less noticeable in the certified group or, if present, it was milder. In every case—i.e., for both groups—the milk was *boiled* before feeding for two minutes. The author admits that the certified milk was "milk of superlative quality," while that pasteurised was ordinary milk. The chemical composition of neither milk is given. Obviously the work is useless to judge the effect of pasteurisation, but merely illustrates the nutritive superiority of certified milk.*

THE LANARKSHIRE EXPERIMENT

The milk-feeding experiment in Lanarkshire (Leighton and McKinlay, 1930)[42] was on a large scale and comprised 10,000 control children, 5000 given raw milk and 5000 given pasteurised milk. The milk used was Grade A (tuberculin tested) raw, and the same milk pasteurised. Heights and weights were the criteria used. The data germane to the present review are shown in Tables VI. and VIA.

While they show clearly the value of the milk ration in increasing height and weight, they are less valuable for comparing raw and pasteurised milk. The tables show that for boys at three age-periods there was greater weight increase with pasteurised milk, while at four age-periods it was the other way about. For the girls at two age-periods the pasteurised milk figures were higher, at four they were less, and at one practically identical. Taking into consideration differences which are significant the authors conclude:—

> "In so far as the conditions of this investigation are concerned the effects of raw and pasteurised milk on growth in weight and height are, so far as we can judge, equal."

---

* Some apology is owing for quoting these three investigations as, whatever their merits on other grounds, they are wholly worthless as yielding any evidence on the nutritive effects of pasteurisation. It is necessary however to describe them since they have been mentioned in several scientific papers [e.g., Williams and Mattick (1931)[40] and Andrews (1933)[41]] as furnishing such evidence, and extensively quoted as part of the propaganda against pasteurisation.

confirmed by Levine. As regards treatment of the established condition, Dr. C. Morton Smith agreed with the view, generally accepted in England, that most reliance should be placed on potassium iodide and mercury, perhaps supplemented by bismuth intramuscularly. Arsenical preparations should be used cautiously if at all, and then only after a preliminary course of iodide. This caution applies particularly forcibly to cases with aortic regurgitation, since in them the coronary orifices are almost certainly narrowed, and any local reactionary swelling may produce complete occlusion and sudden death. This conception of the treatment of cardiovascular syphilis agrees very closely with that expressed by the majority of the contributors to a symposium lately published in France.[2]

ASCORBIC ACID AS VITAMIN C

In the story of the vitamins history tends to repeat itself. This is perhaps not surprising since these substances have at least one great property in common, the property of exercising their beneficent influence in extremely small quantities. In fitting cholesterol and carotene into their proper niches in the story, the same question arose: "Is cholesterol capable of activation by ultra-violet light to form vitamin D, or does this property belong to a contaminant?" and "Is carotene capable of acting as provitamin A or is vitamin A itself present as a contaminant?" The final verdict was not the same in the two cases: cholesterol was pronounced impure and itself inactive, being contaminated with the active ergosterol; carotene was declared pure and uncontaminated and itself active. Hexuronic acid now stands where carotene and cholesterol stood, and what will the answer be to its claim to be itself the antiscorbutic vitamin? Is the verdict to be pure or impure? Prof. A. Szent-Györgyi, the discoverer of hexuronic, which he now prefers to call ascorbic acid, is himself in no doubt, for, speaking of the antiscorbutic vitamin, he says: "To-day this substance can be bought at a relatively low price, neatly sealed in tubes in the form of beautiful white crystals."[3] The greater part of the rest of informed opinion seems to agree with Szent-Györgyi in his claim that ascorbic acid is the vitamin.[4] One of the most experienced workers in the field, Dr. S. S. Zilva, however, is not convinced, and his objections must carry weight.

Szent-Györgyi first prepared ascorbic acid from adrenal glands, but the supply of these was limited and the yield of ascorbic acid too low to provide material for an exhaustive study. Again history repeats itself; just as vitamin A defied isolation in anything approaching a state of purity until the comparatively weak cod-liver oil was replaced, as the raw material, by the enormously much more potent halibut-liver oil, so now the investigation of ascorbic acid can advance with a bound, with the discovery that a Hungarian red pepper (*Capsicum annuum*) contains ascorbic acid in very large quantities and in a state which makes purification easy. A pound of ascorbic acid has thus been prepared, on which, with international coöperation, a chemical study has been made; so the evidence thus collected seems still to support ascorbic acid's claim to vitamin status.

GENTIAN-VIOLET IN THE TREATMENT OF BURNS

THE tannic acid treatment of burns is based o the theory that the symptoms associated wit extensive lesions are due to the absorption of toxi from the damaged area. Dr. R. H. Aldrich[1] cha lenges this theory, and puts forward the view, c behalf of Dr. W. M. Firor, that the symptoms a a result partly of fluid loss, with a correspondin increase in concentration of the blood, and partl of sepsis, pure and simple. In an investigation (the bacteriology of burns they found that, for tl first 12 hours, cultures taken from the burned are were sterile, apart from occasional contaminati organisms such as *Staphylococcus aureus* and *alb* and *B. coli;* after that, in all severely burne patients, the beta-hæmolytic and gamma strept coccus could be grown in cultures taken from tl wound. The concentration of the organisms increase with the obvious signs of sepsis and with the begi ning of the so-called toxic symptoms in the patien until at the end of 48 to 56 hours pure cultures (the streptococcus could be obtained; coincidentl the patient showed the characteristic bad effects (burning. As gentian-violet is regarded as a specif antiseptic for this organism, Firor and his colleagu tried using a 1 per cent. solution of the dye as dressing for burns, and claim excellent result Without preliminary cleaning of the burned area th dye is sprayed on at two-hour intervals for the fir few hours. No dressing is applied, but the ra surface is exposed to the air and protected by cradle. A thin, tough, flexible eschar rapidly form and spraying is then only performed every four t six hours during the day; the treatment is co tinued until healing is complete. If the esch shows signs of softening, the softened portion removed and the underlying surface sprayed afres The originators of this treatment claim that analgesi is produced almost instantaneously, that loss of flui from the burned area is prevented, and that if sepsi can be successfully avoided the characteristic sig of extensive burning—such as stupor, fever, deliriu and albuminuria—do not appear. Apart from th preliminary shock there is no great prostration, an the patient may even be able to get up. Aldric quotes three cases of extensive burns in which thi treatment produced admirable results, and a fourt in which the patient, a child of 9, who had lost ov three-fifths of the skin area, died of cardiac failu after two months of encouraging progress.

FEDERATION OF THE HEALTH RESORTS OF FRANC The following medical tours will take place in the Sout of France during the Easter period. From April 10th t 18th there will be a tour of the Provence and Rivie districts, during the course of which visits will be paid t Marseilles, Aix-en-Provence, Les Baux, Arles, Cassis, L Ciotat, Hyères, St. Raphael, Cannes. From April 16th t 23rd there will be a tour along the Riviera, visiting Canne Antibes, Juan-les-Pins, Grasse, Venice, Nice, Menton Monte Carlo. The tours will be under the scientific directio of Prof. Imbert and Olmer, of the Faculty of Medicine c Marseilles, and Dr. Georges Baudouin of the Institute c Hydrology and Climatology at the Collège de Franc Information as to the cost of the tours may be obtained fro the Secretary, Société Médicale du Littoral Méditerranée 24, Rue Verdi, Nice (A.M.). . . .

few children received no heated milk, so they were divided into the two following groups:—

A. Children who had received raw milk for more than half their lives.

B. Children who had received heated milk for more than half their lives.

There was practically no difference between the groups as regards average heights or as regards average weights. The average for Group A was 36·0 lb., and for Group B 36·3 lb. There were no differences in the financial status of the two groups. The authors conclude: "The growth-promoting capacity of heated milk plus the supplementary diet received by the average American child of 10 months to 6 years is not measurably less than the growth-promoting capacity of raw milk plus the supplementary diet received by the average American child of 10 months to 6 years."

The value of a statistical return combined in this way from many cities is not impressive. It does not deal with the most important group—children under 2 years of age. The children were weighed with only the outer garments removed. No information is available as to the other food taken, and the milk is only part, possibly a small part, of the total food intake. I do not think bulk statistics of this nature can help much in solving the problem of a slight nutritional change in one article of food when we are without any knowledge of the rest of the food intake. All that the report can be taken to show is that with a mixed diet in children aged 2–6 years these figures show no prejudicial effect from the substitution of heated for raw milk.

FEEDING WITH DRIED MILK

Dried milk is heated milk. When made by the roller drying process the temperature exposure period is only a few seconds, but the actual temperature reached is high as the temperature of the interior of the rollers is from 130° C. to 160° C. In vacuum-dried milk the temperature in the chamber is from 40–55° C., and in spray-dried milk it may be well above pasteurisation temperatures. There is probably some slight reduction of available calcium, and indeed Kramer, Ladzke, and Shaw (1928),[47] with five children aged 7–12 years, did find rather greater retention of calcium by the children with fresh milk than when supplied as dried milk.

At infant welfare centres and other places all over the country enormous quantities of dried milk have been regularly utilised for many years for infant feeding. Most of the officers of these clinics are nutritional experts and would readily notice any nutritional defects in infants so fed if they occurred. We get no such reports, and dried milk is found to be extremely satisfactory. Dried milk is not exposed to precisely the same temperature as pasteurised milk, but the chemical changes which occur are probably just as great if not much more considerable. The fact that for at least 20 years dried milk has been very widely used for infant feeding without the slightest evidence of nutritional loss or any lessened value to the infant is of considerable importance as showing that these very trivial chemical changes are not likely to be of much clinical significance.

Discussion

The basic fact in any consideration of the nutritive effects of pasteurisation on cow's milk as a food for the human child is that cow's milk is not a natural food for man at all, and its composition is based on the requirements of the calf. It is very far from being a perfect food for an infant, as is constantly recognised by physicians with their innumerable modifications to make it less unsuitable. The fact that anyone should dare to heat it, even if that heating considerably modified its composition, is not as such a crime, it may be a highly beneficial action improving its nutritive value for the child. There is nothing sacrosanct about the composition of cow's milk in relation to man.

When we study the ascertained changes caused by pasteurisation we find that they are very trivial. The diffusible calcium is reduced from 26 to 20 per cent. (as CaO), there is probably some loss of the minute amount of iodine present, and there is a reduction of the already inadequate amount of vitamin C. There is no evidence of any other significant changes. These changes are so unimportant that the opponents of pasteurisation are driven to suggest the presence of hypothetical substances in milk which might conceivably be of importance in nutrition, and which might possibly be damaged by heat treatment. These hypothetical possibilities have never materialised.

When we contrast cow's milk with human milk we find that the effect of pasteurisation is slightly to bring cow's milk nearer in composition to human milk as regards available calcium and phosphorus, and as such this heat treatment may be regarded as beneficial. For infant feeding pasteurised milk is a slight improvement.

As regards vitamin C, all experts regard cow's milk as an inadequate source of supply, so it is of no significance if this vitamin is diminished or not, since a supplementary supply is necessary whatever kind of cow's milk is supplied.

A study of the chemical changes and the composition of the two kinds of milk lends no support to the view that pasteurised milk is in any way inferior to raw cow's milk for infant feeding.

The animal experiments have been set out in detail, and it is evident that there is not the slightest evidence to invalidate the above conclusion. They may have some significance for animals with calcium needs above or equal to that of the cow but have none for human beings with relatively low calcium requirements.

When we turn to the human feeding experiments it is noteworthy that there are none which settle the nutritional effects of pasteurisation, and most of them have nothing to do with the question since the points at issue were never really investigated. We are left therefore with the immense volume of clinical experience in this country, in U.S.A., and elsewhere, showing that pasteurised milk has satisfied the needs of infant and child feeding over very many years and without any evidence of detrimental loss, provided (as for milk generally) any possible deficiency of vitamin C is made good. With this mass of clinical experience available it is for the opponents to demonstrate nutritional harm by pasteurisation, and the experimental work cited shows that this they have conspicuously failed to do.

While these facts apply with particular force to infants, the position as to older children may not be quite the same. Assuming as accurate that there is some small diminution in available calcium, and possibly of phosphorus, may it not be that this is not without effect as regards older children whose calcium-phosphorus requirements are not limited as they are for infants?

The needs for older children as regards calcium are considerable for bone formation, and Sherman (1927),[22] Bartlett (1931)[43] challenges this contention and by rearranging the age-groups slightly, and by paying special attention to the numbers in each group arrives at a different opinion. Dealing only here with his weight calculations these are shown in Table VII.

He concludes :—

> "In the light of these figures it seems impossible to conclude that raw and pasteurised milk are equal in their effect on growth in weight and height. It may be argued with truth that the actual differences in growth are small, but it must be remembered that the experiment only lasted for four months, and if a significant advantage for raw milk can be demonstrated in this short period, it will be evident that considerable differences may be expected in populations in the course of years or of generations."

TABLE VI.—*Average Increase in Weights (in Ounces) in the Three Groups*

Age.	Boys.			Girls.		
	Control.	Raw milk.	Pasteurised milk.	Control.	Raw milk.	Pasteurised milk.
5–	11·64	14·88	15·65	7·00	14·50	6·62
6–	13·75	13·51	9·96	11·21	10·61	10·05
7–	11·17	14·85	15·55	8·90	11·22	12·94
8–	11·38	14·21	15·21	9·77	13·40	13·37
9–	9·53	13·43	11·83	7·87	13·81	12·52
11–	7·10	13·53	10·39	9·51	15·08	18·96
12–	6·14	12·74	11·05	12·62	24·92	17·08

TABLE VIA.—*Average Increase in Heights (in Inches) in the Three Groups*

Age.	Boys.			Girls.		
	Control.	Raw milk.	Pasteurised milk.	Control.	Raw milk.	Pasteurised milk.
5–	0·75	0·95	0·94	0·86	0·64	0·87
6–	0·80	0·87	0·87	0·80	0·86	0·84
7–	0·76	0·87	0·82	0·75	0·84	0·81
8–	0·74	0·82	0·79	0·71	0·81	0·78
9–	0·69	0·80	0·74	0·66	0·76	0·78
10–	0·68	0·76	0·68	0·71	0·79	0·72
11–	0·69	0·74	0·70	0·77	0·86	0·81

Unfortunately the conditions of the experiment make it unjustifiable to draw any definite deduction from these very small differences. Milk was only an accessory for these children to the extent of three-quarters of a pint per day. No information is given, or probably was obtainable, as to the main part of their diet. The pasteurised and raw milk fed groups were not from the same school but the children in one school all received raw milk, in another all pasteurised. The home family conditions in the different schools may have been very different. The children were weighed in their indoor clothes, only less boots or shoes, and only to the nearest ounce, while since it extended from February to June the amounts of their clothes would fluctuate markedly. Bartlett's table shows that the raw milk gave an advantage of 1·36 oz. for each boy, 0·59 oz. for each girl, and 0·96 oz. for boys and girls together. With these variable factors an average difference of less than 1 oz. over a period of four months in rapidly growing children can hardly be considered of any significance although it is interesting.

TABLE VII.—*Average Increase in Weights (in Ounces) in the Three Groups*

Recalculated to increase the number of children in each group.

Age (years).	Boys.			Girls.			Boys and girls.		
	Control.	Raw milk.	Pasteurised milk.	Control.	Raw milk.	Pasteurised milk.	Control.	Raw milk.	Pasteurised milk.
5, 6, and 7 ..	12·38	14·25	12·77	9·92	11·00	11·32	11·15	12·67	12·04
8 and 9	10·48	13·80	13·45	8·81	13·60	12·95	9·65	13·71	13·19
10 and 11	6·73	13·20	10·68	10·77	19·13	18·17	8·75	16·18	14·39
Total of all ages	10·06	13·78	12·42	9·74	14·41	13·82	9·90	14·09	13·13

In this connexion it is worth noting that over the period of the experiment unemployment was rife and probably many of the children were underfed, and it is likely that there was considerable calcium deficiency in the home diet. This is probable from the work of Orr and Clark (1930)[44] in towns of Scotland. This point is considered further in the general discussion on this paper.

Sprawson (1932)[45] produces evidence that in certain institutions 40 children in one series showed no caries when he examined them at various periods subsequently, the average being about four years, while in a second series there were very few cases of caries. The children in the first series commenced the use of raw milk before 12 months old, and in the second between 1 and $2^7/_{12}$ years. He ascribes the relative freedom from caries to the use of the raw milk. In fact, however, the milk was not always given raw as it was given to the younger children "warmed," which may easily have been at temperatures equivalent to "flash" pasteurisation. He gives no comparable data dealing with pasteurised milk, and agrees that there is no exact knowledge whether or no effects comparable would result with pasteurised milk. He infers not, apparently from his mistaken idea that all children get a considerable milk ration during the first three or four years of life which is almost invariably sterilised by boiling or pasteurisation. This incorrect generalisation has evidently misled the author. This paper offers no evidence either way as regards the relative value of raw and pasteurised milk in preventing caries, but is a welcome contribution throwing light on the possible utility of milk as milk as a means of preventing dental caries.

Frank, Clark, Haskell, Miller, Moss, and Thomas (1932)[46] are responsible for a United States Report dealing with the nutrition of children fed respectively on raw and pasteurised milk. The statistics were compiled with the help of various State departments. The age-weight curves were plotted for 3358 children, and the age-height curves for 3319 children, all aged 2 to 6 years, and from a considerable number of cities. An insufficient number of returns were available for children under 2 years of age. Unfortunately, very

MEDICINE AND THE LAW

Heart Disease as an Accident

THERE is one more case to be added to the decisions which make the employer pay compensation as for an accident where a workman with a weak heart drops down dead at his work. No matter how diseased the heart may be, no matter how slight the strain imposed by the work, the law looks upon the combination of disease and employment as amounting to an accident. The man has tried to do something beyond his physical powers; he has miscalculated his strength; some part of his physical mechanism has given way, and this event is legally therefore an accident. A man of 46 with a diseased heart was working on a ship, loading bags weighing a hundredweight or more which were slung on board by a crane. He started at 6 in the morning, knocked off at 8 for breakfast feeling a little queer, and resumed work after breakfast. At 9.30 he gave himself a slight jerk and hurt a finger in trying to stop a line of bags from swinging. Nevertheless he went on working and presently, after a pause in the party's labours, he got up to strike a hook into a bag when he fell forward and died. Death was certified to be due to myocarditis and syncope. The case (Treloar *v.* Falmouth Docks) looked a simple one, very like previous cases where the employer has been held liable. For once, however, the county court judge went against the usual trend of decisions by holding that the injury was due to the disease and not to the employment. He said he was not satisfied that death resulted from anything the workman was doing in the course of his employment, and he was not satisfied that death was due to an injury by accident arising out of, and in the course of, his employment. The Court of Appeal, faced by this awkward finding of facts, ruled that there was no evidence on which the county court judge could find as he did; the death was contributed to by the ordinary course of the work. The judge had misdirected himself as to what constituted an accident in law. It was unnecessary to prove that there was any abnormal strain in the work which caused death. Therefore death was an accident arising out of the employment. On Jan. 30th the House of Lords agreed.

In 1929 the Scottish courts expressed a doubt about the extent of this doctrine. The Lord President of the Court of Session observed (in Millar *v.* Coltness Iron Co.) that he did not think the decision in Clover, Clayton and Co. *v.* Hughes would support so wide a proposition as that "any and every physiological breakdown in the workman's system, occurring while he is subjected to the stress of his ordinary duties," would support a claim under the Workmen's Compensation Act. Recent decisions in the House of Lords, however, show that a workman's death from heart disease during working hours will mean that the employers must pay. Heart disease is an accident against which they insure the workman. They must pay whether the man's health was previously good or bad.

"Discharged from the Dock" on a Medical Certificate

The allegations made by Scottish members in a House of Commons debate reported in our last issue (p. 448) should not be left where they stand. If no other inquiry is offered, a fresh Parliamentary opportunity can be made on a motion to reduce the salary of the Lord Advocate, who, when he returns to duty, will doubtless know how to defend actions for which he is officially responsible. In effect it is suggested that, in the Scottish Amalgamated Silks trial, rich persons implicated in a crime escaped from justice on an untrue medical certificate, one of them being "discharged from the dock" by this method. Is life as easy as this in Scotland? Are there not three stages? Not only must a venal doctor be bribed to sign a false certificate; in addition a venal prosecutor must be bribed to abandon the proceedings at sight of it, and a venal court must be bribed to permit the abandonment. If all these conditions were fulfilled, the administration of justice would indeed be in a desperate way. An English commentator must walk warily in the field of Scottish procedure. In the English courts, in cases of drug addiction, reckless driving, or shop lifting, or in any circumstances where mental instability is pleaded, medical evidence for the defence is certainly tested by the cross-examination of counsel for the prosecution and it is often rejected by the bench. In England, too, there survives, for what it is worth, some safeguard against the stifling of a prosecution inasmuch as anybody has in theory a right to prosecute, and a "voluntary bill" has in certain cases been submitted direct to the grand jury. In Scotland prosecutions are in the hands of public officers known as procurators fiscal. The Lord Advocate has a general responsibility for such duties as are discharged in England by the Director of Public Prosecutions; but ordinarily the decision to prosecute or not to prosecute is taken by advocate deputes in Scotland. It is easy to think of valid reasons why, when several persons are initially accused of a crime, some of them may not ultimately be placed on trial. Evidence against some may be inadequate—an important consideration where the charge is one of conspiracy. Or some may be released in order to assist the prosecution. Ill-health too may be an element, since, if several men are charged together, it would not be fair to postpone trial indefinitely till one of them recovered from illness. It is unfortunate that the allegations made in the House of Commons leave the public in doubt as to what really did happen. Until particulars are available and proper inquiry has been made, the suggestion of impropriety in the signing of medical certificates need not be taken too seriously. Every medical practitioner knows that not only he himself but the whole of the medical profession will be judged by the standard of truth in the certificates he signs.

Customs Offence by Doctor

Learned writers have classified offences as *mala in se* and *mala quia prohibita*. There is greater moral obliquity in doing something wrong in itself than in doing something which is merely wrong because it is forbidden. In the latter category revenue offences may be placed, and here the reprehension will be a matter of degree. The morning newspapers of Feb. 18th reported proceedings against a London doctor who had been summoned at Dover the previous day for attempting to evade customs duties. A representative of the Customs said the accused was bringing back surgical instruments from Germany. Asked in the usual way if he had anything to declare, he produced two gramophone records and two woollen articles. Asked if he had anything else dutiable, he answered in the negative. When 12 pipettes and two surgical needles were found in a suit-case, he said he had done wrong and should have declared them. He said he had nothing else dutiable, but on the back of the car which he had brought over on the boat was an autotonograph, an instrument quoting Herter, points out that there must be an average storage of about 37 g. of calcium annually for the years 3 to 16—i.e., an annual daily storage of about 0·1 g. Although calcium is abundant in many foods, there is in fact often an inadequacy in the diet of many poor children. It is probably the abundance of calcium and phosphorus in milk which makes it such a good growth stimulant for the child.

Mentioning but one paper, Sherman (1923)[48] *reports studies of 21 children aged 3–14 years, covering* a period of 417 experimental days. In the first series the children on ordinary mixed diet received 750 g. (about ¾ quart) of milk daily. On this diet they stored calcium in quantities approximately proportional to their body-weight. In the second series when the amount was increased to 1000 g. (1 quart) per child per day the rate at which the children stored calcium was materially improved.

Of course intake and retention are two different things, while the ratio of calcium to phosphorus is of importance, as Stearns (1931)[49] has shown, but generally a high calcium phosphorus intake is helpful.

The slight diminution in available calcium possibly may be a drawback to an older child on a diet inadequate in calcium, and over a long period might have some influence on growth magnitude. The effect is so small that it is not an argument of any weight against pasteurisation. Over a long period it might account for a slightly less weight increase, and the *difference of just under 1 oz. in four months*, as shown in the criticism of Bartlett, may be explainable on this supposition.

Summary

1. The known changes in cow's milk produced by pasteurisation are very slight. The proportion of insoluble calcium is increased by about 6 per cent., the iodine is reduced by about 20 per cent., and there is a reduction of vitamin C.

2. These changes in the calcium, and possibly in the phosphorus, content of cow's milk effected by pasteurisation make it approximate a little more closely in composition to human milk, and as such are an improvement when cow's milk is substituted for human milk. The diminution of vitamin C is unimportant, as this vitamin is usually inadequate and has to be supplemented for both raw and pasteurised milk.

3. Animal feeding experiments provide some evidence that pasteurised milk is less growth-promoting than raw milk for animals whose calcium needs are equal to or greater than that of the calf. They furnish no evidence that pasteurised milk is less nutritive for animals such as the human infant, whose needs for calcium are below that of the calf. Any deductions, from experiments on the one group to the other, are unscientific.

4. There are no human experiments which demonstrate that pasteurised milk is less nutritive to the young child than is raw milk.

5. *There is a vast mass of clinical experience which* shows that heated milk has been consumed for years by infants and young children without any detectable deterioration in their nutritive condition. In view of the negative evidence as to any nutritional damage by pasteurisation, this volume of clinical experience is entitled to the highest consideration.

6. For much older children, if their diet is insufficient in calcium, it is possible that the small reduction in available calcium which seems to occur with pasteurisation might exert a slight retardation of growth. At the most this would be slight and probably unimportant, while at present it is only a possibility. It is too small to have any significant bearing on the value of pasteurisation.

CONTRIBUTORY SCHEMES AS A "MENACE" TO HOSPITALS.—The following passage appears in the annual report of the Birkenhead and Wirral Children's Hospital: "A serious menace to voluntary hospitals is the alarmingly increasing numbers of people claiming free treatment, either as being in receipt of help from public funds or on account of being members of contributory schemes. The grants made by those organisations to meet the growing expense to the hospitals are not commensurate with the services expected and provided." The year's working of the institution shows a deficit of £3332.

CORRESPONDENCE

DICHOTOMY

To the Editor of THE LANCET

SIR,—The alternatives before me are to connive at dichotomy or to lose a large part of my practice. This may seem a personal matter, a private dispute between my conscience and my pocket; it is because I believe it to have a far wider significance than this that I venture to bring my experience to your notice.

Dichotomy may be classified into three main groups. The first, which includes all those cases in which the general practitioner and the consultant amicably conspire to split the fees between them, does not concern me. I have never been a party to such practices, and, for reasons that will be obvious, know nothing about their prevalence in our profession. Unfortunately, those who grow fat on them maintain a reticence on the subject that makes it a little [illegible] for the rest of us to benefit from their experience. But of the other two groups [illegible] great deal. In the one I include all those [illegible] which the practitioner, too proud to beat about the bush, too honourable to hide his intentions, [illegible] the consultant beforehand of his decision [illegible] a slice out of the fee which the innocent [illegible] imagines to be for the consultant alone. In the other are those cases in which the consultant's [illegible] intimation that there has been dichotomy comes [illegible] the event, when he is presented by the practitioner with a smaller, sometimes considerably smaller, amount than he arranged to exchange his services for.

Here are two recent experiences, one of each kind. A general practitioner called me in to perform an abdominal operation. "I have arranged with the patient," he said, "that your fee [my fee, if you please!] shall be 75 guineas, of which I am taking 30 myself." No nonsense about this practitioner; nothing could have been fairer than his statement of the terms; nothing more generous than his decision to give the lion's share to me; and, for my part, all I had to do was to submit to blackmail or lose what might prove to be a valuable connexion. As I handed him the cheque he blandly said, "These are the only plums we general practitioners get."

The second case is also recent. On this occasion the practitioner was above the sordidness of discussing fees beforehand, but after I had operated on the patient sent me a fee of 20 guineas. Not much, I said to myself, but these are hard times for patients as well as doctors. A few weeks later the patient came to see me again about an apparent recurrence of symptoms, and in the course of conversation I said, quite casually, "By the way, what did I charge you for that operation?" "Sixty guineas," was the reply. "Quite," I said, and then, "let me remember, did that, or didn't it, include your own doctor's fee for looking after you before and after the operation?" "Oh, no," said the patient, "I paid a separate account for that." Forty guineas commission on a 60-guinea job, and a separate account on top of that!

I would not trouble you with a recital of these cases were it not for two things. First of all, they are typical, so typical, indeed, that I could tell you of others, similar in all essentials, in connexion with [illegible] half the practitioners who call me in. And in [illegible] second place, these cases are significant because [illegible] ethical code of our profession does next to nothing to prevent their multiplication. If I, a young surgeon, followed my conscience and told such practitioners that I would have no truck with dichotomy, they would tell me to go to the devil. I speak from bitter and costly experience. I, who loathe dichotomy, find myself practising it, simply because my only alternative at present is to divert a large part of my practice to surgeons who are not troubled with these old-fashioned scruples.

May I suggest as a remedy the formation of a professional organisation of consultants which, just as the trade-unions tend to help up the standard of life of their members by making it impossible for any of them to accept lower pay than the rest, could deal with the evil of dichotomy by imposing upon all its members the obligation of never conniving at it, no matter what the form may be in which it presents itself.—I am, Sir, yours faithfully,

London, W., Feb. 21st. UNWILLING ACCOMPLICE.

*** Of the occurrence of these practices we have evidence, but not of the prevalence suggested by our correspondent.—ED. L.

MOBILISATION OF SUGAR INTO THE BLOOD DURING REST

To the Editor of THE LANCET

SIR,—A boy of 7½ years was recently put under my care for diabetes mellitus of several years' standing, since it was found that his glycosuria and acetonuria were getting out of control. He had had a fixed daily quantity of insulin—I think 18 units—with a fairly constant diet.

I began by putting him on a rigorously exact diet of 1000 cal., his weight being a little over 3 st. 1 lb. He gained 3 lb. in a fortnight, but his blood-sugar showed what appeared to me to be remarkable nocturnal fluctuations. At the beginning of treatment he was having morning and evening doses which I hoped would be able to be determined by the evening and morning urine respectively, but he was very shortly reported to be having attacks of sweating and pallor about four to five hours after the evening dose of insulin, in spite of the fact that the morning urine was loaded with sugar. Estimation of the blood-sugar showed a figure of 0·055 per cent. four hours after the evening insulin dose, whereas ten hours later—that is, following the period of normal sleep and absence of food during the night—the figure rose to 0·35 per cent., the urine being then, of course, loaded with sugar.

In order to counter this state of affairs, it was determined to give the doses of insulin at eight-hour intervals instead of twice a day, raising or dropping the morning, afternoon, and midnight doses by one unit according to the presence or absence of glycosuria four hours after the time of corresponding previous injection. This plan has so far succeeded, but it is interesting to note that of the three doses thus regulated, the midnight one is the highest, although it precedes a period of complete rest and of eight hours' starvation; that is to say, much less sugar is found in the specimens of urine taken four hours after the morning and afternoon injections than in the 4 A.M. specimen. (I may say that every care has been taken to see that the patient could not get any nourishment during the night hours.)

It seems impossible to resist the conclusion that, in this case, during the night sugar is mobilised from the tissues into the blood more quickly than during the day, when the boy is up and about and taking a diet easily enabling him to maintain weight and good health. I should be very interested to know the experience of others in this respect: is the mobilisation ed in research work in connexion with blood essures. He said he did not declare it because he 1 not want to unpack it, and he did not see why should pay on his own goods. At first he said he d taken it to and from Germany; afterwards he id he bought it in Germany three weeks before d had not yet used it. The Customs representative vited the magistrates to take a serious view of an fence committed not by a poor or ignorant person t by one who was well able to pay the duty. The cused, who did not appear, pleaded guilty. A e of £150 with £6 10*s*. costs was inflicted.

BERLIN

(FROM OUR OWN CORRESPONDENT)

SPECIALISTS AND THE MEDICAL TARIFF

An important judgment has been given by the preme Court at Leipzig in respect of the official riff which regulates the fees of medical men in ses where no previous arrangement has been made. is tariff is equally binding on doctor and patient, t hitherto there has been some doubt whether it plies to specialists. Now, however, the court has cided that the whole medical profession must arge according to the official tariff in cases where agreement has been reached, and that there is precedent which exempts university professors d well-known specialists. It was held that it ould be difficult for a local court to decide in a rticular case whether a certain medical man was authority in his special branch of medicine whose ale of charges would therefore be unaffected by e tariff. Patients are recommended to come to an greement with their medical attendant about the e before treatment is begun.

REFORM IN MEDICAL STUDY

It has always been regarded as a disadvantage the German medical student that though the eoretical lectures he attends are excellent his portunities of coming in contact with patients fore a late stage of his career are slight. Medical aching is exclusively in the hands of the universities, d in the university vacations it is interrupted. uring the last summer vacation, however, the irchow Hospital in Berlin arranged for students to ork in the hospital. They lived in the hospital and d regular service in the departments which they d chosen. They began work early in the morning d carried on till noon, when the cases seen were scussed by the staff and the students. The students ere invited to ask questions which were at once swered. The arrangement has proved a great ccess, and it is proposed that during the Easter acation students will again be allowed to work in e hospital. This innovation is of fundamental portance, since it would open to the students the mense field of clinical material to be found outside e university clinics in other hospitals, especially the great cities, which is at present lost to them. he medical staffs of these hospitals, men of the ighest competence, would then also be available s teachers. The first step towards a reform has been ade, and it is to be hoped that others will follow.

EVIPAN NARCOSIS

The compound evipan used to produce a quick nd deep sleep[1] is recommended also as an anæsthetic operations. Dr. Weese reports that with an intravenous injection of sodium evipan anæst of short duration rapidly develops. The chief su of the Martin Luther Hospital in Berlin, Dr. Baet reports that in about 400 operations he has inj 8–10 c.cm., the result being that the patient at fell asleep. The surgeon was able to begin the op tion immediately after the injection, and the narc lasted 15–20 minutes, after which ether can employed if need be. Dr. Holtermann, of the gyna logical clinic of Cologne University, also rep favourably on the results he has obtained.

A GREAT JOURNAL

Eighty years have elapsed since the first numb of the *Münchener medizinische Wochenschrift* appeare and it is therefore the oldest of the great Germa medical weekly journals. It was founded under t name of *Ärztliches Intelligenzblatt* as the organ o Bavarian medical profession, and had in th year of its publication only 1000 subscrib 1883 the *Intelligenzblatt* became a medic journal under its present name. In 19 than 1150 original articles were printe there are now 15,000 subscribers, in part of the civilised world.

ATTEMPT OF SUICIDE WITH ASPIR

Cases of suicide by means of aspirin ar case of this kind is described by Dr. Man Hanover municipal hospital. A man was there who had taken 60 tablets of aspirin o each. He had a temperature of 36·1° C. and cya The pulse-rate was 82, but no abnormal ca signs were discovered. In the course of his ill œdema developed, although his general state improved, and later an enlargement of the he was noted. The œdema disappeared under t influence of digitalis. The starved condition the man when he attempted to commit suicide, th direct action of the salicylates, and the strain on th heart when the man got up all combined to cause the injuries to the heart at such a late stage. To combat the noxious action of excessive doses of salicylates the administration of bicarbonate of soda is recommended.

SHOULD PATIENTS WITH ERYSIPELAS BE ISOLATED ?

A man suffering from disease of the ear which he attributed to the war was conveyed to hospital for observation on behalf of the Court for War Claims. He had at the same time tuberculosis of the knee-joint with an open fistula. In hospital he was in the same room with a patient with erysipelas, and when he was discharged an erysipelas infection developed in the fistula at the knee. He accordingly brought an action against the hospital to recover the costs and damages caused by the erysipelas, alleging that the medical staff had acted negligently in taking him in a room with a patient suffering from erysipelas. The local court dismissed the action, pointing out that according to the opinion of expert witnesses it was doubtful whether an isolation of erysipelas patients was necessary. They gave evidence that eminent surgeons had never isolated such patients whilst others of the same renown had done so. On appeal the High Court of Leipzig reversed the decision, saying that even if medical scientists disagreed about the necessity of isolation it was the duty of hospital physicians to adopt the most painstaking measures of precaution.

INTENTIONAL LEAD POISONING

A turner complaining of lead poisoning was admitted to hospital, and there it was discovered

ARLY DIAGNOSIS OF MALIGNANT DISEASE

To the Editor of THE LANCET

SIR,—Dr. Lindsey Batten in his admirable letter ut clearly what he considers the pros and cons eriodic overhaul. He agrees that the chances scovering disease in its early stages would be ased by examining patients without waiting for ptoms. Further, that it would bring about a adual extension and diffusion of knowledge and erstanding of the normal,” and he suggests that “a r amount of good advice on personal hygiene would spread abroad.” After this promising opening, he ecides against the general overhaul on the grounds hat a number of unfortunate and unprofitable discoveries would be made. Surely, when a proper understanding of the normal has been recognised by the profession, such conditions will be ignored. Then he objects to my suggestion for a limited examination of the sites where accessible cancers arise on the grounds that it guarantees nothing at all. But such an examination *does* guarantee that there is no macroscopic disease in those organs.

It seems, however, that it is on psychological grounds that Dr. Batten bases the weight of his argument against examination of the fit. He does not seem to realise how very prevalent is the fear of cancer. How can it be otherwise when 56,000 families are added to the list each year of those who have lost a near relative? I am convinced that he is wrong in his belief that such examinations become “cumulatively alarming,” or “even completely demoralising,” and in my experience the fact that nothing was found on the last examination gives greater hope to the patient that nothing will be found on the next occasion.

His final objection is entirely from the doctor’s point of view—namely, that he will some day find a patient with an inoperable growth in spite of the fact that a periodic overhaul has been carried out six months previously. This idea that a growth in the accessible sites develops at such a rate is due to the fact that the medical man sees the patient for the first time when the growth is already advanced, and *hears from the patient* that there was no symptom or sign a short time previously. In considering Dr. Batten’s letter generally, one feels that it emphasises the fact that students are not sufficiently taught how wide are the limits of normality, and for this reason the majority of practitioners are reluctant to examine a patient lest they should come across the normal and not recognise it.

In regard to your correspondent, Mr. Arnold Walker, I agree that none of us is infallible in the question of diagnosis, but I am surprised that he does not consider it justifiable to tell a patient with a laceration, or even a slight erosion, that there is no evidence of malignant disease. These are exactly the cases that should be examined every six months, and then, if there is any change in the picture, a section should be taken. Mr. Walker says that patients should be taught “to visit their doctors when they notice a change in the behaviour of an organ,” but I should like to ask him what change there is in the behaviour of a breast when carcinoma is present in the early stages.

The “good doctor,” if he knows anything about psychology, will realise that he cannot reassure his patient without stating that the examination reveals no sign of cancer. The general public are not so stupid as Mr. Walker appears to think. They only expect that those kinds of cancer which can be diagnosed should be excluded. It is the accessible cancers that the public think about most, because the distressing symptoms of ulceration, &c., are most obvious, and my contention is that such periodic examinations will satisfy a very large proportion of the public, and allow them to go about their work thinking only of health, and not of disease.—I am, Sir, yours faithfully,

Harley-street, W., Feb. 28th. MALCOLM DONALDSON.

CHLOROFORM CAPSULES IN CHILDBIRTH

FOR some time Queen Charlotte’s Hospital and Middlesex Hospital have been experimenting with the use of crushable capsules of chloroform as a means of lessening pain in childbirth.[1] Good results have been recorded, and the National Birthday Trust Fund recently offered to supply capsules to any institutions and practitioners that would give them a trial and send a report of the effect on the pain felt by the patient, and on the normal course of labour. A total of 2000 reports have been returned by 42 hospitals and 56 private practitioners, and these were analysed by Mr. L. Carnac Rivett in a paper read at a meeting of the Fund in London last Monday. In all these cases, he said, not one maternal death has occurred, and in the very few cases of stillbirth it was definitely stated that death could in no way be attributed to the chloroform capsules. “Our experience at Queen Charlotte’s Hospital and Middlesex Hospital has been the same; we have administered the chloroform capsules to nearly 4000 patients, and no maternal or infant deaths have been caused by the capsules. . . . At both these institutions the midwives are already using these chloroform capsules with success, and at Queen Charlotte’s Hospital we are now instructing practising midwives how to use them.”

In over 90 per cent. of the records, Mr. Rivett said, the patient obtained relief from pain. In over 50 per cent. of the cases it was noted that the patient felt great relief. In about 5 per cent. the patient became excited and refused chloroform at all; but such excitement might occur during the administration of any anæsthetic, and therefore these few failures were to be expected. In over 60 per cent. of cases it was recorded that the course of labour was not altered at all; in about 15 per cent. the use of capsules were said to assist the progress of labour by abolishing the actual pain and allowing the natural powers to act unhindered by restraining efforts of the patient. Occasionally labour was prolonged but the delay was never serious, and the number of cases in which instruments were used was below the average. Perhaps, however, this was partly because the capsules were for use in normal cases.

After quoting some of the opinions expressed by practitioners who had used the capsules, Mr. Rivett concluded by saying: “This is a completely safe and foolproof method of relieving the intense pains of childbirth, and one which is easily learnt at a very short course of instruction. It is a method eminently suitable for use by nurses and midwives in institutions where there is a resident medical officer.” But there must, he added, be two nurses. It was not convenient for one midwife alone to administer the capsules and conduct the labour.

PETERBOROUGH HOSPITAL.—Last year the Peterborough and District Memorial Hospitals received 1786 in-patients, the largest number hitherto treated. Their average stay was 22·65 days, as against 23·49 in 1931, and their average cost was £5 17*s.* 7*d.*, a reduction of 11*s.* 6*d.* on the previous year. Out-patients cost 11*s.* each, a reduction of 1*s.* 0½*d.*

of sugar into the blood a normal nocturnal phenomenon corresponding to the nocturnal fall of temperature and pulse-rate? One would have thought the contrary; it seems more likely to be correlated with the diminished oxidation and output of CO_2' which accompanies the resting hours.

I am, Sir, yours faithfully,
MARTIN O. RAVEN.
Broadstairs, Kent, Feb. 25th, 1933.

LYMPHOGRANULOMA INGUINALE

To the Editor of THE LANCET

SIR,—May I be permitted to thank Dr. Hanschell for drawing attention to a point which he suggests I had not made quite clear? Until some better nomenclature has been introduced it is still useful to apply the term lymphogranuloma inguinale to cases in which infection has been acquired in temperate countries, sometimes referred to as poradenitis nostras, while reserving the name climatic bubo or poradenitis tropica to those infected in the tropics. When I said that I believed cases of lymphogranuloma inguinale were possibly going unrecognised in this country, I quoted the figures of the Royal Albert Dock V.D. clinic, among others, merely as showing that my opinion was not shared by every one. I did not suggest that cases were being missed at that clinic. It is the one V.D. clinic perhaps where unrivalled opportunity exists for the diagnosis of lymphogranuloma inguinale (poradenitis nostras), as to the same clinic come a continuous stream of seafarers suffering from climatic bubo (poradenitis tropica). I am, Sir, yours faithfully,

HUGH S. STANNUS.
Wimpole-street, W., Feb. 25th, 1933.

CONTROL OF INFECTIONS IN CHILDREN'S WARDS

To the Editor of THE LANCET

SIR,—Dr. Spence's letter appearing in your issue of Feb. 25th serves a most useful purpose in calling attention to the subject of infection in the wards of children's hospitals. Its special importance lies in the emphasis laid on the spread of non-specific infections, especially those of the respiratory and alimentary tracts, among infants in children's hospitals. Dr. Spence's brief rules are admirable in most respects, though I cannot agree with the suggestion that infants should be segregated into groups of approximately the same age. I always try to distribute the infants' cots among those of the older children. In this way I think a certain amount of cross infection may be avoided.

The spread of respiratory infection can, to a large extent, be controlled by structural arrangements which limit the dissemination of infective material through the atmosphere. Gastro-intestinal infection, on the other hand, is probably carried directly or indirectly by the hands of the attendant. Faulty nursing technique is therefore its chief cause. *In all* but our most modern children's hospitals the facilities for exercising proper cleanliness are insufficient, and to my mind it is here that the chief fault lies. However well trained and however careful nurses may be, it is impossible for them to avoid errors in technique if they have neither room nor apparatus for employing their craft. The tools, not the workman, are to blame.

In my experience I have found that one is courting disaster if too many infants are congregated in a ward. The bad results are not due to insufficiency of but to the fact that only a limited number of in can be properly attended to with the facilities a able. In the treatment of sick infants perfect technique is no doubt the primary necessit the construction of new hospitals, more a should be paid to the provision of ample acco tion and suitable apparatus for carrying practice if the dangers attending the reside *infants in hospital are to be avoided.*

I am, Sir, yours faithfully,
GEOFFREY B. FLEMI
Royal Hospital for Sick Children, Glasgow, Feb. 27th, 1

THE CLIMATE OF MADEIRA

To the Editor of THE LANCET

SIR,—The tepid oceanic currents bathing these subtropical regions seem associated with an immunity from chill which in the 72 years of my medical experience has been undisturbed by any serious departure from an established stability of temperature. For though we have suffered from unusual drizzle and cloudy skies the thermometer in this most trying season has hardly varied one degree from 57° F. at our official 9 A.M. reading. This is a winterless shelter in convalescence from "flu," pneumonia, and renal malady; and catarrhal chill, with consequent relapse, is hardly known in the revitalising sunshine of Madeira.

I write to point out that in spite of prevailing weather conditions our stability of climate here has suffered no serious transgression from its known quality; no winter resort has established conditions more potent in convalescence.

I am, Sir, yours faithfully,
Madeira, Feb. 10th, 1933. MICHAEL GRABHAM.

DYSENTERY AS A CAUSE OF SUDDEN DEATH

To the Editor of THE LANCET

SIR,—I was interested to read Dr. Eileen Harvey's paper in your issue of Jan. 28th, but the statement that fulminating infection with sudden death due to *B. dysenteriæ* Sonne had not been previously reported is incorrect. As long ago as 1921, K. Mita[1] described a series of 73 cases which included six deaths, of which three occurred within 36–60 hours from the onset. In 1925 W. G. Savage and P. Bruce White[2] reported three outbreaks of food-poisoning in one of which (No. 91) there was a case with death 18 hours from the onset. In 1928 I[3] reported the case of a boy, aged 10, who died 16½ hours after the onset; in this case I isolated the organism from the contents of the large intestine and from the enlarged lymph glands in the ileocæcal angle. In the same year F. H. A. Clayton and J. W. Hunter[4] reported a case which terminated fatally in about 13 hours. In all the above cases complete identification of the organism by isolation was made; in Dr. Harvey's case no such proof is forthcoming.

While it is perfectly true that infections with Sonne's bacillus are usually mild and clear up quickly, it is obvious that the possibility of severe and fatal types of infection with this organism has been recognised for some time.

I am, Sir, yours faithfully,
Liverpool, Feb. 23rd, 1933. W. HOWEL EVANS.

I still had my horses and it did not serve as much relief to them. By 1912 the horses were finally displaced, and for the next ten years I did my work with a petrol car of French make which did not give me any trouble. If in a good deal which follows I compare, for such work as mine, mechanical transport with horse-driven vehicles, sometimes to the disadvantage of the former, this is but one example of many that might be quoted of the way in which distinct benefits are bestowed upon the community by developments which are not necessarily well fitted to universal needs.

I have now reached the period in this personal story when the National Health Insurance Act came on the scene. This Act has had its advantages, but in such a practice as mine its disadvantages from the pecuniary point of view are obvious. The fact that before the passage of the Act the sums paid per annum for attending the servants in the large country houses were a useful asset must be mentioned, but of course the Act had no direct influence in emptying the houses. As a matter of fact, the time had gone by before I began to practise when the master of the house not only paid his servants' bills, but often those of his guests as well. Under the first conditions of the Act the total capitation fees which I received from the servants in these houses did not amount to the sum that used to be expected from one of the great houses, so that until the mileage fee was arranged the Act was a dead loss to the country doctor.

A great part of my life, and of those who practise on the same lines, is occupied by going to and fro—this is often forgotten. Village life no longer forms a centre of medical practice, for village industries are largely dead; the old kind of inhabitant living on from generation to generation in the same house and carrying on the family trade has gone. I may have to travel 40 miles in a day seeing only four or five patients; on other days I may have to see double that number, and in this district 10 or 12 professional visits makes a very long day's work. It is then that I sometimes think that the horse had his great merits, and I often wish I had a horse. I travel to inaccessible places to which no motor can get, and this means walking over marsh and moorland. I sometimes have three or four gates to open and shut on a by-road, and this means much trouble getting in and out of a car, which was absent when riding. I have often, on a dark stormy winter's night, had to improvise a stretcher and get help, sometimes from over a mile away, to carry an acute surgical case across a heathery moor in mud or slush to a waiting car, and then to go 25 miles to the hospital.

Motor traffic has further brought great responsibilities. I have frequently had people brought to my house after a motor smash, generally on a Sunday afternoon or evening, week-end drivers being numerous. Fractured skulls and compound fractures of thigh and leg may then have to remain (with their immediate needs seen to it is true) for hours before they can be removed. And more than once the victim of these accidents had been shot over a neighbouring bridge into the river, and was brought to my house not only badly injured but half-drowned. These are samples, and not very exceptional ones, of what a country doctor may have to do, and such occurrences do not come the way of any other type of doctor; they bring grave responsibility when there is no hospital handy. And of course in ordinary routine I have to treat fractures in the homes of the people where the cases in urban practice would inevitably be sent to the hospital.

THE EVIDENCE OF A COLLEAGUE

I have shown these notes to a colleague and friend who practises a few miles from me, but in the hills and dales. His district is probably one of the most difficult in all England. He confirms what I have said and could add to it with some striking reminiscences of his own. His district is sparsely populated and, until he was able to secure payment for the travelling expenses, it was impossible to earn enough money to live, for his time was so fully occupied in getting there and back. He finds the benefit of the car, and reminds me of certain obvious disadvantages in the use of the horse. When he was dependent upon horses it was almost routine for him to have to drive five or six miles with a saddle carried in the back of the trap; at the necessary place the horse was taken out of the trap, saddled, and another five or six miles of riding would follow, and in some cases he had still not arrived at his destination, but was compelled to walk the last lap, leaving his horse tied to a fence. The car has mitigated this sort of thing for him, and the ordeal it must have been in winter and darkness can be imagined; but even now he may have to ford rivers in his car three times in one round, and finish the journey on foot with some risk in stormy weather of being unable to get back to the car, when he is compelled to walk an indefinite way home. He told me that once he got lost in a snowstorm on a journey like this, and in the darkness walked into a morass. He was then obliged to sit down on the first piece of solid ground that he could find and wait there till the light came, when he found himself two miles from his car, which was practically snowed up. These are experiences trying enough for the young man, and my friend is no longer young.

AND YET A CAREER OF CHOICE

Concluding with my personal experience, the real change in my professional life, next to the invention of the motor-car, was made by the installation of the telephone in my village. The telephone has now extended to surrounding villages, and many people in the countryside have it in their houses. This has revolutionised communications between doctor and patient, but it has also multiplied the number of calls, a certain proportion of which may be entirely unnecessary. When the messenger to the doctor had to walk, or drive, or, later, when he used the bicycle where it was possible, the doctor was only summoned when the case appeared to warrant it, now this need not necessarily be so. But undoubtedly midwifery practice has become more satisfactory. I still recall the time when the tramp of any horse in the village might wake me, a light sleeper, and if the horse stopped at my door, I knew that it would mean the rousing-up of a groom, the putting to of a horse, and, if I was detained at a confinement, I should have to send my man away with the gig to be put up where a place could be found. The telephone and the car have eased that situation.

The hardest thing in the life of the single-handed doctor is that he has always to be on the spot. He cannot ever get free for more than a few hours, without going to the expense of engaging a locum-tenent, and the income will too often not permit of this. Just a week-end off duty will be longed for but seldom obtained. No other type of practitioner is so tied up and unable to get help from a colleague. However, if we make our bed, so we must lie on it, and the life has its charms; and had I my time to begin again I would still be a country doctor. But there is only a certain type of man cut out for the job.

Reduction in the Stay of In-patients.—Last year Dewsbury and District General Infirmary received 1810 in-patients, an increase of 486 on the preceding year. Their average stay was 14·7 days, as against 19 days in 1931. At 6471 the out-patients increased by nearly 1000, and their attendances numbered 54,603.

Victoria Infirmary, Glasgow.—This hospital, which expended £69,486 on maintenance account last year, had a deficit of £16,339. New in-patients numbered 8740; they stayed 19·2 days on the average, and cost £7 7*s.* 5*d.* each, as against £8 4*s.* 10*d.* in 1931. The cost per head was £141 10*s.* 8*d.*, as compared with £150 8*s.* 5*d.* There is a waiting-list of about 300. Cases of motor accidents treated in the wards fell from 217 to 183, and 40 fewer were attended in the dispensary.

THE DOCTOR'S DAY

"Come, tell me how you live," I cried,
"And what it is you do!"

XVII.—IN THE DEPTHS OF THE COUNTRY

There must be many readers of The Lancet who know little of the life and work of the purely country doctor, and who can hardly appreciate the "doctor's day" of the man who lives in a village working single-handed. And to be single-handed is a very important factor in his life, for he works with no professional neighbour near at hand, far from a hospital, and perhaps unable to secure the assistance of an ambulance.

I must leave to some extent to the imagination the make-up of any single day in such a practice, while I describe rather what any day may bring forth. In doing this it is impossible not to seem to be merely reminiscing; yet, while country medical practice has been revolutionised in the same manner as the whole of society by the advent of the motor-car, there remain in isolated country practices instances when bygone habits might to-day be more convenient than those of which an advancing twentieth century has compelled the adoption; and there are places where quite old-fashioned customs must persist.

But speaking generally, before the arrival of the motor-car the country practice had a very different pattern, so different that I am ready to believe that many real country practices have ceased to exist; the outlying communities have learned to dispense with the doctor on the immediate spot because of the facilities offered by car and telephone for obtaining medical assistance from the nearest larger centre. Still there remain some of us who have once practised in the heart of the country under the old conditions and amenities, and who, continuing to practise under the new conditions, appreciate their advantages, but none the less are compelled sometimes to make unfavourable comparisons. The vast differences in the scientific position of the medical profession as far as the knowledge of disease was concerned were not, I am compelled to think, reflected in quite the disadvantageous way in practice that younger men may think, despite the simpler machinery of professional life. My predecessors were good doctors, and I found myself able to practise my profession in accordance with what I had learned. This is not to say that I consider that society has not benefited by our scientific progress; but I want to suggest, as one who practised in a purely rural district when the telephone was in its infancy and the motor-car was unborn, that the mechanical developments of the age have not brought about a millennium.

MAINLY REMINISCENT

I live in a village of some 600 inhabitants. There are half a dozen other villages at a distance of some four to six miles away, and within the area thus comprised there are six large country houses, the old centres of rural life. The country side is sparsely inhabited, the occupations are entirely agricultural, and, incidentally, most of the country houses are deserted (their original owners feeling the stress of high taxation), or transformed into week-end resorts. There are two small country towns which lie respectively nine and ten miles north and south of my house. These now have each a cottage hospital, but the nearest general hospital of any size is 25 miles away.

I came here 40 years ago after some experience of practice in a mining district and in two large towns. The fact that that life I led did not appeal to me proves, I think, that I belong to the kind of man who would sooner starve in the country than make a fortune in the town and there must remain some like me; they will find it difficult to exercise their preference. I live in a Jacobean house which has been the home of a line of country doctors, all of one family—father to son—for four generations, and the continuity, I like to think, is not broken, for my wife was a daughter of the last of this series, and if my doctor son succeeds me here the long line will be continued. My predecessors were all horsemen, they were hunting men, and some of them farmed while carrying on their practices. They went their long rounds either on horse-back or open gig in all weathers, and at all times wore a silk hat—this was their badge of a professional life. They began the day's work between seven and eight in the morning and did not get home till evening on a big day's round. This meant keeping three or four horses all the year round. In my first 25 years the only means of transporting patients to hospital was by horse vehicle, and all kinds of contraption were pressed into the service. For lying down cases a flat cart open to the weather was usually employed, and a long journey in, or rather on, such a thing was a grave ordeal. Yet I have seen serious cases of all sorts, acute abdominal patients and patients who had sustained compound fractures, transported apparently with no serious damage to the hospital, though it was often difficult to impress upon them the necessity of going there, because of the terrible reluctance on the part of many of them to enter a hospital in any circumstances. This led to the performance of many operations in the homes of the patients, but treatment on the spot did not necessarily mean a saving of time for the patient, for it might easily take the doctor as long to get to the patient as it would have taken the patient to get to the hospital.

During my term of practice surgery has enormously progressed, but looking back, I am amazed at the good results we got then considering the difficulties. When called upon to operate to-day in a case of appendicitis I have to remember that I saw many cases of what was called "inflammation of the bowels" 40 years ago, and that, though some of them were very ill, a surprisingly high proportion slowly got better without surgical interference. I am not belittling scientific progress, but am noting that its effects are not generally perceptible in an isolated country practice. I can go back to the days when a woman might lie in the clothes she was confined in for a week, because "it was the custom," and I remember the fights which I had with the old country midwives when I wanted their patients to receive proper attention. They simply would not obey, and said that washing and changes of linen would be dangerous. When I once did the necessary offices myself in face of opposition, I was told that if anything happened the woman's death would be at my door. I saw my first death in childbed 30 years after that, and although the child was born naturally and the placenta expelled before my arrival and the patient had a nurse, she died of puerperal septicæmia on the tenth day. The person who would consider this as an argument against scientific progress would be a lunatic; I mention the case to show how such enigmatic happenings prejudice the bucolic mind against necessary improvements. In practice here I have had only once to have recourse to craniotomy; that was 35 years ago, and I have found it necessary to perform one Cæsarean section, two years ago, in something over 1200 cases of midwifery. Cæsarean section is, of course, now done in circumstances when in earlier years the procedure would not have been contemplated. I have had to tackle cases of placenta prævia and various malpresentations single-handed, under anæsthesia produced in the most unfavourable conditions, and have been fortunate in having no fatalities, although often the women were very ill. One had to act alone, there was no other way, and no near help.

THE MODERN CHANGES

In 1909 I ventured upon a steam-car; I do not want to dwell on my experience with that car;

and proceeded to St. George's Hospital, where, having obtained the M.B. degree at Cambridge, he served as assistant surgical registrar and house surgeon. In 1885 he took the diploma of F.R.C.S. Eng., and decided to specialise as an otologist, the impulse in that direction coming from the late Sir William Dalby, then aural surgeon at St. George's, and well known as a pioneer in this country of the modern system for educating the deaf subject. In 1892 Bull became aural surgeon at St. George's in succession to Dalby and was elected consulting aural surgeon to the hospital at the expiration of his time-limit on the active staff.

Bull was a very quiet man, and did not make, or try to make, the public impression which his attainments warranted. He was a good hospital officer, and, within limits which he laid down for himself, a careful and successful operator, but he devised no original methods either in the operating theatre or in his communications to medical literature. A competent teacher, a courteous companion, and a generous host, he was content to be those things, and he leaves behind him the reputation he would most have desired with a large circle of friends.

Bull leaves a widow and one daughter to whom we tender our sympathy.

One of his colleagues on the hospital staff writes: "Bull leaves a pleasant memory in the minds of all those who worked with him as pupils or as colleagues. Without making a strikingly notable figure at his hospital and school he yet achieved that solid appreciation which comes to a man who does his work well and conscientiously, who treats his patients with kindness, his colleagues with courtesy, and his juniors and friends with charming and abundant hospitality. The branch of surgery with which Bull was concerned had not in his years of active service at St. George's reached the pitch of elaboration to which it has now attained, but the aural surgery of his day he carried out efficiently and with marked success. Tonsils were then not necessarily removed in their entirety, and operations on the mastoid were less meticulously performed than is now usual, but these two procedures, which formed the backbone of his operation lists, were systematically executed by Bull with consistently satisfactory results. He was a good judge of a case, and it might be claimed that, as an aural surgeon, his greatest strength lay in diagnosis. In his earlier years Bull had wide experience with anæsthetics and this, as generally happens, made him a tolerant and understanding colleague for any anæsthetist working with him. He was a cool operator, who neither got worried himself nor worried those about him. Outside his professional occupations Bull devoted a good deal of time to works of art and had a nice taste in pictures. This same taste was shown in Bull's appreciation and choice of wine and of food and consequently to dine with him in the family circle was a delightful demonstration of how pleasant an hour may be passed with a few people of good taste and manners, and a knowledge of the world. In his young days Bull was suspected of tuberculous infection and gave up months to its cure in Switzerland. His ruddy complexion and fine figure were for years a striking proof that whatever his early ailment was it had been completely outlived. Much more recently, only about four years ago, he was obliged to undergo an operation for duodenal ulcer, but from this too he made a complete recovery.

PANEL AND CONTRACT PRACTICE

Mileage

INSURANCE practitioners who live in country areas necessarily have to travel further in the course of their panel work than those who live in a closely populated industrial area. A sum of £250,000 set aside to pay for the extra cost of travelling and the extra time is called the Mileage Fund.

The scheme is to make every doctor put in a claim to his insurance committee for mileage under a system of units, one unit corresponding to every mile over two miles from the residence to that of his doctor of each insured person. Thus, for an insured person living five miles away from his doctor the latter would be paid the ordinary standard rate of pay 9s. (less 10 per cent. at the present time), plus three units of mileage. Free choice of doctor enables a patient to choose one who is not necessarily the nearest; in some areas the mileage paid used to be calculated from the patient's home to that of his nearest panel doctor, but this arrangement was altered by the distribution committee a few years ago.

Each insurance committee receives claims from doctors in its area for mileage units and forwards these to the Ministry. The Ministry divide the £250,000 available for this purpose by the total claims for mileage, and the result of this division gives the value of the unit. The returns are periodically revised; the last figures were obtained in 1930 and used for the first time in 1931. The unit, as will be seen from the method of calculation, depends chiefly on distance and probably takes in sufficient account of time occupied.

Quite apart from places of difficult access like the Highlands or Lake districts, for which special provision is made, some panel patients live in lonely cottages several fields from the nearest road or in a lane, perhaps up a steep hill, guarded by gates which seem innumerable. At a recent meeting of the distribution committee the Ministry furnished interesting returns by 430 practitioners who were roughly divided into three groups: A, with many places of difficult access; B, with the average type of country practice; C, with no difficult places to visit, but a few patients living outside the two-mile limit of a mainly urban practice.

There were records of 104 practices of class A. Between them they travelled 1,219,722 miles; paid 173,095 visits to insured patients, and 274,138 visits to private patients. The number of insured persons on the lists were 86,244 and the units of mileage allotted 175,028. To reduce these figures to easier proportions we may assume that the mileage is divided proportionally amongst the insured and private patients according to the number of visits to each. Although the assumption is not necessarily correct the errors will be approximately the same for both sets of figures. On this basis the insured mileage figure works out at 463,594 miles which divided amongst 86,244 insured persons gives 5·4 miles travelled per insured person, and 2·7 miles travelled for each standard unit. The figures for B group work out at 3·4 miles per insured person and 3·9 miles for each standard unit, and for C group 1·6 miles per insured person and 9·7 miles per standard unit. At first sight the discrepancy between the miles travelled for a standard unit in different classes of practice seems very great. The fact that the

OBITUARY

SIR THOMAS JOSEPH GALLWEY, K.C.M.G.

LATE COLONEL COMMANDANT, R.A.M.C.

We regret to announce the death of Sir Thomas Gallwey who, in 1916, was Director of Medical Services of the Home Forces, and who for more than half a century played a distinguished part as a leader in the Army Medical Service. His final illness was protracted, and his death occurred at Pelham-place, London on Feb. 25th.

SIR THOMAS GALLWEY

[*Photograph by Russell*

Thomas Joseph Gallwey was the fourth son of the late Henry Gallwey, an Irish magistrate, of Tramore, Co. Waterford, and was born in 1852, being in his 81st year at the time of his death. He received his preliminary education at Stonyhurst and his medical training at the Royal University of Ireland, where he graduated as M.B., M.Ch. at the age of 21, and entered the Army Medical Service immediately. From the beginning he proved himself both a capable doctor and a good officer. He first saw service in the Afghan war, but in 1885, being little over 30 years of age, he was specially promoted surgeon major for services in Egypt. He made good use of great opportunities. For in 1885 the failure of the dual control by England and France of Egyptian affairs led to successful Arab revolts, the sending of British and French Fleets to Alexandria, the refusal of the Sultan of Turkey to assist in putting down the disorder, and finally to the intervention of the British Government, France and Italy having declined cöoperation. Gallwey was in the middle of all these events. By the Egyptian expedition of 1882 the revolt was suppressed at the battle of Tel-el-Kebir, and Gallwey received the medal with clasp and the Khedive's Star. He took part in the Sudan expedition when the Sudan was established as an integral part of the Khedive's dominions. Restoration of order in the province became a British responsibility, and when the defeat of the army of Hicks Pasha led to the rise of the Mahdi and the fall of Khartoum, where General Gordon was immured, the Nile expedition under Wolseley followed. It was a time of continuous struggle. The operations against Mahdyism during the 11 years from the end of the Nile expedition ended in the withdrawal from the Sudan, while the Dongola campaign constituted the story of the suppression of the Dervishes. The Sudan operations for the next four years were conducted by Kitchener as Sirdar of the Egyptian Army, and the Dongola campaign recovered the province for Egypt. In this expedition Gallwey distinguished himself, being mentioned twice in despatches and receiving British and Egyptian distinctions and the C.B. He dealt with particular success with an outbreak of cholera among our troops at the beginning of the campaign. In the following year, 1897, he was appointed P.M.O. in the Egyptian Army and was present at the battles of Atbara and Khartoum, and was again mentioned in despatches.

In 1898 there followed more military and administrative work of an important sort on the outbreak of the South African war. He was first appointed P.M.O. of an infantry division at Cape Town, and later P.M.O. in Natal, and, as had previously been his experience in Egypt, he was again in South Africa present at some of the most critical actions in the war, notably at Spion Kop and Colenso and the relief of Ladysmith. He was mentioned in despatches twice, received various military decorations, and in 1900 was appointed K.C.M.G. He remained in South Africa until his appointment as P.M.O. in India, a post which he held for four years with distinction. His administrative work proceeded efficiently and smoothly under his particularly acceptable personality, although the official side of medicine in India was already beginning to manifest its later troubles. At the expiration of the Indian appointment he returned to England as P.M.O. of the Aldershot Command and at the expiration of this appointment in 1911 he retired.

But not for long. Immediately on the outbreak of the European war in 1914 he returned to the Aldershot Command as Deputy Director of Medical Services. He was successful in discharge of the heavy responsibilities which fell upon him, his long and extraordinarily important official experience enabling him to manage men and affairs with promptitude and decision. At the close of the war he was made Colonel Commandant R.A.M.C.

This record of Sir Thomas Gallwey's life as soldier and administrator would be incomplete without reference to a side of his activities which played a vital part in his career. Gallwey was a really great sportsman. He was one of the founders of the Turf Club in Cairo, while he was the owner of two famous horses, "Hidden Mystery" and "Leinster," the former of which was favourite for the Grand National some 30 years ago. He won the Calcutta Cup at rackets in India, which corresponds to the home amateur championship at that game—the cup it is understood he gave to Lord Kitchener who was always a great personal friend. He was a fine polo player, and received a presentation cup for a victory over John Roberts at billiards when that great professional was touring India, the amateur no doubt receiving points. He organised for the military meeting at Sandown for over 20 years, and for a long period was a steward at Sandown and Kempton. Horse-racing was a passion with him.

Sir Thomas Gallwey married in 1901 Maud Margaret Howard, daughter of the late Capt. J. W. J. Giffard of the Hon. Corps of Gentlemen-at-Arms and widow of Capt. C. W. Gordon, R.A.

WILLIAM CHARLES BULL, F.R.C.S.

CONSULTING AURAL SURGEON, ST. GEORGE'S HOSPITAL

We regret to announce the death of Mr. W. C. Bull, the well-known aurist, which occurred at his home in Clarges-street, Piccadilly, on Feb. 24th.

William Charles Bull was the son of Mr. Goodman Bull of Liverpool, and was born at Bromborough in 1858. He was educated at home and at Gonville and Caius Colleges, where he had a successful career as a student, and also won some prominence as a cricketer. He graduated in the Natural Science Tripos

PARLIAMENTARY INTELLIGENCE

NOTES ON CURRENT TOPICS

Exchequer Grants to Local Authorities

In the House of Commons on Feb. 21st the following resolution was considered in Committee, Sir D. HERBERT, Chairman of Committees, in the chair:

> That in respect of each year in the second fixed grant period: (*a*) the amounts to be included in the General Exchequer Contribution for England under Para. (c) of Subsection (3) of Section 86 of the Local Government Act, 1929, and in the General Exchequer Contribution for Scotland under Para. (c) of Subsection (3) of Section 53 of the Local Government (Scotland) Act, 1929, shall be respectively the sum of £5,350,000 and the sum of £850,000; and (*b*) the amounts to be paid under Para. (b) of Subsection (1) of Section 87 of the Local Government Act, 1929, and under Para. (B) of Subsection (1) of Section 54 of the Local Government (Scotland) Act, 1929, respectively, out of the Road Fund towards the contributions aforesaid shall be the same as were payable in respect of each year in the first fixed grant period.

Mr. SHAKESPEARE (Parliamentary Secretary to the Ministry of Health), in moving the resolution, said that its object was to enable a Bill to be introduced to fix the Local Government (General Exchequer Contributions) under the Local Government Act for the second grant period of four years. The new money to be provided under Section 86 of the Local Government Act, 1929, was fixed at £5,350,000 for England and Wales, and under Section 53 of the Local Government (Scotland) Act at £850,000 in respect of Scotland. The second point was to determine the variable element in the annual contribution from the Road Fund towards the General Exchequer Contribution, and in the resolution that amount for the second grant period was to be the same as it was for the first grant period—namely, £3,000,000. The Local Government Act, 1929, introduced very far-reaching and, indeed, revolutionary changes in the whole structure of local government. It recast the financial relationship between the exchequer and the local authorities. It deprived local authorities of a large amount of revenue through its derating provisions to the extent of £22,250,000. It changed the basis of grants; it stopped the percentage grants in respect of certain services, the assigned revenues and the grants under the Agricultural Rates Acts; it discontinued a total amount of grants of £16,250,000, and it provided new money fixed at £5,000,000. The loss of rates, loss of grants, and new money made up the General Exchequer Contribution which was a consolidated block grant paid annually. That grant was fixed for the first grant period of three years, which would terminate on March 31st, 1933. The second grant period would last for four years, and thereafter each grant period would be for five years. The second grant period would commence on April 1st next. As against those who contended that the Exchequer Contributions proposed for the second grant period were too high in view of the present financial position of the country, and those, on the other hand, who contended that they were too low, he claimed that the Government were entitled to argue that in adhering to the minimum proportion laid down in the Local Government Act justice was done. The Local Government Act was a network of compromise and concession. One of the main safeguards that the local authorities sought was to the effect that there should always be this equilibrium between the General Exchequer Contribution at the start of a grant period, and the rate-borne and grant-borne expenditure of the penultimate year of the previous period. After the lapse of 17 years the whole of the General Exchequer Contribution was to be paid out according to a famous formula, which was roughly determined by weighting population for given factors where the need most lay. For the first grant period only £15,000,000 of the £43,500,000 comprising the General Exchequer Contribution was allocated according to the formula; for the second grant period an identical amount of £15,000,000 would be so allocated; but thereafter more and more would be allocated according to the need and less and less according to the loss of rates and grants, until at the end of the 17-year period the whole of the vast consolidated block grant would be given according to need.

The reforms embodied in the Local Act had not yet been carried out. There was a sort of reconditioning going on the whole time within the counties to prevent overlapping of services and to promote efficiency, and if almost at the start of the 17-year period, when the Government were undertaking to help local authorities to reorganise their areas and services, they were to break faith with them, and at the end of three years reduced the General Exchequer Contribution below the minimum proportion laid down in the Act, it was easy to see that the achievement of the ultimate object might be jeopardised. At all events, one could at least say that the whole structure of the Local Government Act might well be strained. About 8 per cent. of the £15,000,000 in the first period went in respect of the unemployment factor. In the second period 20 per cent. of that sum would go to those areas where unemployment was more severe than it was before. Therefore, if they reduced the amount of new money it was obvious that a relatively more severe reduction would take place in those areas whose financial circumstances were strained in consequence of unemployment, while more prosperous areas with little or no unemployment, and where there had been no change of population would receive very little reduction in their allocation of the new money. For those two reasons the Government had decided to adhere to the minimum proportion. The Minister of Health had promised some months ago that he would inquire into the operation of the formula to see whether the various factors were operating wisely. That inquiry was still proceeding and anything done under the present resolution, and the Bill which was based upon it, was without prejudice to any recommendation made or adopted as a result of that inquiry.

Mr. GREENWOOD said that the services in respect of which percentage grants were discontinued under the Local Government Act were maternity and child welfare, with minor exceptions; the treatment of venereal disease, the treatment of tuberculosis, and the treatment of mental defectives. These were fundamental social problems. They all knew that there was hardly a town in the country where maternity and child welfare services were as highly developed as in the national interests they ought to be. That certainly applied to the treatment of tuberculous people. As long as there was unnecessary luxury these vital services which went to men-making and women-making in this country ought not to be crippled as they were being crippled to-day. The indictment of the Opposition against the Government in respect of this resolution was because of its meanness. They had penalised, for 16 months, the local authorities; they had held a bludgeon over those authorities for 18 months and there was another bludgeon still over their heads in the shape of the Ray Report. The Government were bludgeoning the local authorities at a time when, whatever might be said about certain national services, local government services ought to be pressed forward because of their enormous permanent value to the nation during the coming hard years.

Mr. HERBERT WILLIAMS said he thought that local government was grossly extravagant at the present time. The country was so over-taxed that unless the burden was reduced they would not be able to restore large numbers of people to employment. In first two miles travelled are included in the total distances travelled, but do not count in claims, may have a special effect on doctors in group C who travel constantly within an area of two miles, though able to claim mileage only when they go beyond this range. In this way their total mileage per unit mounts up. These figures are to be considered further by the distribution committee with the object of discovering whether the distribution as carried out at present is equitable in the various classes of practice.

The comparable figures for 1928 show quite clearly the increase in work being done nowadays. Although the number of doctors keeping records was not so high (291 in 1928 against 430 in 1932), the figures are as follows :—

	Group.	1928.	1932.
Miles travelled per insured person.	A ..	4·3	5·4
	B ..	2·6	3·4
	C ..	1·4	1·6

	Group.	1928.	1932.
Miles travelled per standard unit.	A ..	2·2	2·7
	B ..	3·4	3·9
	C ..	8·3	9·7

Possibly one reason for increased mileage is the increased number of references to the regional medical officer. In the country this often involves a visit from doctor to patient, whereas in town a patient may call to see the doctor.

These figures show the wisdom of keeping records accurately. Part of the capitation fee is paid definitely for the purpose of having records kept, and those doctors who fail to carry out this obligation are doing disservice to their fellow practitioners, for regional medical officers who examine their records are led to believe that they are doing less work than they are really doing, and consequently the payment they receive per attendance appears higher than it actually is. Thus a difficult position is created for negotiators who advance the argument that the remuneration offered is too low, having regard to the amount of work and standard of skill required to carry out obligations under the Act in these times.

R.S.V.P.

One of the points brought out in the Onslow report was the need for some standard form which a medical man could use when sending a patient to a hospital out-patient department for advice and/or treatment. It had been openly stated that insurance practitioners were in the habit of unloading troublesome cases on hospital consultants, with the result that hospitals were doing work which insurance practitioners ought to do themselves. There was not much, if any, evidence of this placed before the committee, and the representatives of the London Panel Committee and of the London Public Medical Service made it clear that such a shifting of responsibility was not at all what they wanted; their complaint was that a case sent to hospital for an opinion only was apt to be treated and kept on the out-patient list until cured. The reason for this, they thought, was that it was the line of least resistance for the consultant; it saved him writing letters, and he felt certain the patient was obtaining the treatment ordered. Also it swelled the out-patient attendances, which was a good advertisement for the hospital and thus helped to get subscriptions. Such methods, they felt, showed a lack of that spirit of coöperation which should exist between hospitals and general practitioners in the neighbourhood. To make the position clear, these delegates advised the preparation of a leaflet, to be used by practitioners sending cases to hospital, containing a statement that the doctor wanted the case back. This leaflet was to be drafted by the hospitals committee of the British Medical Association and then submitted for approval to the various interests concerned: King Edward's Hospital Fund committee, hospital committees, consultants, and panel committees. The B.M.A. model form was eventually considered by the general purposes sub-committee for London and, although its cost was thought to be somewhat high and the arrangement not very satisfactory, yet they advised the panel committee to accept it. It was, however, rejected, largely as a result of the omission from the leaflet of any indication that the practitioner did not want a patient to be treated at hospital if he could properly be treated at home. The panel committee then decided to draft a form in which this position was safeguarded by the additional words:

> "As I wish to continue the treatment of this patient, I shall be glad if you will refer him/her back to me unless you consider either in-patient treatment or special out-patient treatment is necessary."

When this draft was submitted an amendment was moved and carried to delete the words "as I wish to continue the treatment of this patient," as it would not be right to say that about a case (say) of carcinoma of the pylorus, and as the rest of the sentence made it plain that the doctor did want the case back if suitable for return.

The panel committee form will be printed for economy on one side of the paper only, not on alternate sides as in the B.M.A. form. It seems a pity that the two bodies could not agree on a single form. There is, of course, no obligation on any doctor to use either of these forms. There is also nothing in this courtesy arrangement to prevent a hospital consultant from seeing a patient if he thinks fit without an introductory note from the attending practitioner. In both forms there is a note on the reply page which runs: The information on this form is strictly confidential and for your own use only.

THE SERVICES

ROYAL NAVAL MEDICAL SERVICE

Surg. Lt. V. G. Horan to be Surg. Lt.-Comdr.

The following appointments are notified: Surg. Lt.-Comdr. D. H. Kernohan to *Vivid*, for Plymouth Hospital. Surg. Lt. H. L. Belcher to *Pembroke*, for Chatham Barracks.

ROYAL NAVAL VOLUNTEER RESERVE

Surg. Sub-Lt. G. S. Thoms to be Surg. Lt.

Surg. Lt. J. E. Davenport to *Victory*, for Haslar Hospital.

ROYAL ARMY MEDICAL CORPS

The undermentioned Lts. (on prob.) are confirmed in their rank: T. M. R. Ahern, R. Johnston, A. P. Trimble, J. B. Macfarlane, T. J. Moloney, J. L. Martin, H. K. G. Nash, A. D. Bourne, G. W. Crimmin, and G. W. Kendrick.

The undermentioned to be Lts. (on prob.): F. King and H. Clain.

ROYAL ARMY RESERVE OF OFFICERS

Col. G. A. Troup, ret. T.A., vacates the appt. of Hon. Col., R.A.M.C., Units, 54th (E. Anglian) Div., on completion of tenure and is succeeded by Col. W. D. Watson, ret. T.A.

TERRITORIAL ARMY

Col. A. J. Brown retires on completion of tenure of appt. as A.D.M.S., 52nd (Lowland) Div., and retains his rank, with permission to wear the prescribed uniform.

Lt.-Col. and Bt. Col. A. P. Watson, from Gen. List, R.A.M.C., T.A., to be Col., and is apptd. A.D.M.S., 52nd (Lowland) Div.

Maj. J. E. Rea, R.A.M.C., to be Divl. Adjt., 43rd (Wessex) Div., *vice* Maj. G. G. Drummond, R.A.M.C., vacated.

John Burns to be Lt.

INDIAN MEDICAL SERVICE

W. S. Morgan to be Lt. (on prob.).

against them they were ruled out of unemployment benefit from the time of suspension until the decision of the medical referee; and if he would consider taking steps to meet this situation.—Sir Henry Betterton replied: Such persons are not prevented from signing the register by any rule of the Department, but in order to claim benefit they would have to sign a declaration that they are capable of and available for work at a time when they are contending for the purposes of workmen's compensation that they are not capable of work. It has been decided by the Umpire that a person who is contending that he is not capable of work cannot be available for work and is therefore not qualified for benefit.

Mr. Tinker: Does not the Minister see the difficulty in which an applicant is placed. First of all he thinks he is not fit for work and then the medical referee declares him to be fit for work; that causes the difficulty. Will the right hon. gentleman when he brings in legislation consider this point.

Sir H. Betterton: Yes, I will consider it, but the hon. Member forgets that he is contending that a man is not capable of work because he is under a disability. If he makes that contention on the one hand it is almost impossible I should think to make the submission that he is fit for work.

Mr. Tinker: The medical referee says that he is.

The Death of Madame Vlora

Mr. Cocks asked the Home Secretary what action had been taken by Scotland Yard in response to the two applications from Avry Bey Delvina asking for information regarding the death of his sister Madame Vlora; and why that information had not been furnished.—Sir John Gilmour replied: As this death had been the subject of a coroner's inquest, Mr. Delvina was advised by the Commissioner of Police on the 18th instant that any application for official information concerning the circumstances of Madame Vlora's death should be addressed to the coroner, whose name and address were furnished to him.

Mentally and Physically Defective Children

Viscountess Astor asked the Parliamentary Secretary to the Board of Education the total number of children who entered school at 5 years of age last year; and what proportion of them were suffering from mental or physical defects.—Mr. Herwald Ramsbotham replied: I have no information which would enable me to give the precise figures asked for. Of all children who entered public elementary schools for the first time in 1931 (the last year for which information is available) 19·4 per cent. were found to require some form of medical treatment. The corresponding figures showing the proportion suffering from mental defects are not available. Such defects are frequently not diagnosed until a later stage.

Viscountess Astor: Is it not true that the chief medical officer in his report says that 27 per cent. of the juveniles in elementary schools are physically defective, and also that there are diseases that could be easily prevented, and that the best way to treat them is by open-air nursery schools? Does the Government think that this is a good time to establish open-air nursery schools?

No answer was given.

Discharges from Mental Hospitals

Mr. David Grefell asked the Minister of Health if he would issue a regulation with a view to acquainting the public with their rights under the Lunacy Act, 1890, that Section 79 should be posted up in all waiting-rooms where friends came to visit the inmates of mental institutions in order that the patient's friends, as distinct from his relatives, might know that it was in their power to apply to the visiting committee for the patient's discharge to their care.—Sir E. Hilton Young replied: There are objections to a regulation of the kind suggested. I am advised that the situation is adequately met by the existing rule which requires the managers of every institution, on the admission of every rate-aided person, to send a notice, embodying the substance of Section 79 of the Lunacy Act, to all persons whose names appear as relatives or friends of the patient on the statement of particulars accompanying the reception order.

Milk Adulteration

Brigadier-General Clifton Brown asked the Minister of Health whether his attention had been called to the comments in the Report of the Milk Reorganisation Committee on the unfairness of the Food and Drugs Adulteration Act, 1928, to the milk producer; and whether he would now consider legislation to amend that Act by distinguishing between the wilful adulterator and persons who acted in complete good faith.—Sir E. Hilton Young replied: I am aware of the comments referred to. This matter will be considered in conjunction with my right hon. friend, the Minister of Agriculture, in the light of the recommendations of the Commission as a whole.

Influenza

Major Despencer-Robertson asked the Minister of Health whether, in view of the number of deaths from annual influenza epidemics, which in the first few weeks of this year amounted to over 10,000, and of the dislocation of public services and of industry arising from the widespread character of the epidemics, he would consider making influenza a notifiable disease.—Sir E. Hilton Young replied: I fully appreciate the gravity of the effects of influenza, and the question of making it a notifiable disease has been frequently considered. I am advised, however, that this course would not be likely to reduce either the morbidity and mortality from influenza or the dislocation of public services and of industry to which my hon. and gallant friend refers. The many clinical forms which influenza takes, and the many uncertainties of its diagnosis would in any event make it difficult to draw satisfactory conclusions from notification figures. My hon. and gallant friend is no doubt aware that acute influenzal pneumonia is already a notifiable disease.

MONDAY, FEB. 27TH

All-India Medical Council

Mr. Parkinson asked the Secretary of State for India whether the Government of India would consider the advisability of delaying the introduction of the All-India Medical Council Bill until such time as the federal legislature had been constituted.—Sir S. Hoare replied: The Bill has already been introduced.

Medical Examinations and Pensions Claims

Mr. Harcourt Johnstone asked the Minister of Pensions whether it was the practice to make fresh medical examinations, on behalf of his department, of men whose claims to disability pensions had been finally disallowed in cases where fresh evidence had been brought forward by independent medical men.—Major Tryon replied: Where fresh evidence of fact is produced which indicates that the decision was given on an incomplete knowledge of the material facts, such action is taken as may be required, including further medical examination, if this is found to be necessary to determine the specific point at issue—namely, the origin of the condition complained of.

Local Authorities Expenditure

Mr. Herbert Williams asked the Minister of Health on what basis it had been estimated that the total local expenditure from all sources would show a reduction of as much as £20,000,000, as compared with the figure for the year 1929–30.—Mr. Shakespeare (Parliamentary Secretary to the Ministry of Health) replied: The estimate to which my hon. friend refers was that total local expenditure showed a reduction of £20,000,000 over the figure for the year 1929–30. This figure was, as my right hon. friend was advised, the approximate reduction in local expenditure on the figure of 1929–30 which the Ray Committee estimated would be secured as a result of the economy measures taken in the autumn of 1931.

TUESDAY, FEB. 28TH

The Panel Committee in Glasgow

Mr. McGovern asked the Secretary of State for Scotland the reason for allowing doctors who had no panel practice to serve on the national health insurance panel committee of the burgh of Glasgow; and were they required to pay subscriptions similar to the panel doctors.—Mr. Skelton (Under Secretary for Scotland), replied: The arrangements for the appointment of panel committees in Scotland are laid down in regulations of which I am sending the hon. Member a copy. These regulations provide that only medical practitioners who are under agreement to treat insured persons shall be entitled to take part in the election of members of panel committees, that all the members shall be duly qualified medical practitioners, and that not less than two-thirds of the members shall be practitioners under agreement to treat insured persons. I have no reason to think that the provision whereby these committees may include a certain proportion of non-panel practitioners is other than a desirable one. The arrangement under which the administration expenses of the panel committee for the burgh of Glasgow are defrayed by means of a system of voluntary subscriptions by practitioners is a private one with which I have no concern.

Mr. McGovern asked the Secretary of State for Scotland the reason for the increase of the national health insurance panel committee of the burgh of Glasgow from 30 to 51, in view of the provisions of the National Health Insurance Panel Committee Regulation.—Sir Godfrey Collins replied: I am sending the hon. Member a copy of amending Regulations made by the Department of Health for Scotland on April 21st last which, as he will observe, provide that the government borne on rates and grants was roughly £105,000,000, and in the year March 31st last it was £319,000,000. The cost had been growing in recent years. In 1922–23 it was just under £261,000,000. In 1928–29 it had grown to £294,000,000, and last year it reached £319,000,000. If they applied the change in the value of money as well as the increase in the cost of local government, local authorities were spending to-day on real values 75 per cent. more than ten years ago. This growth of local expenditure was intolerable, and unless it was checked it would lead to disaster.

Viscountess ASTOR strongly urged on the Minister of Health the necessity of watching the health of children, especially up to 5 years of age.

After further debate,

The resolution was agreed to.

On Thursday, Feb. 23rd, the resolution was agreed to on Report. The Bill was then brought in and read a first time.

Broadcasting

Mr. EMMOTT moved the following motion:

> That this House, being satisfied that the British Broadcasting Corporation maintains in general a high standard of service, is of opinion that it would be contrary to the public interest to subject the Corporation to any control by Government or by Parliament other than the control already provided for in the charter and the licence of the Corporation; that controversial matter is rightly not excluded from broadcast programmes, but that the governors should ensure the effective expression of all important opinion relating thereto; and that only by the exercise of the greatest care in the selection of speakers and subjects can the function of the Corporation be fulfilled and the high quality of the British broadcasting service be maintained.

Sir S. CRIPPS moved as an amendment:

> To leave out from "That," to end, and add "in view of the growing importance of broadcasting in the life of the community, particularly its actual and potential influence in the realm of political controversy, it is expedient that a Select Committee be appointed to review the work of recent years and make recommendations.

After further debate,

Sir KINGSLEY WOOD (Postmaster-General) said that the British Broadcasting Corporation was held in high respect throughout the world. It had and could have no other motive or object than that of public service. It had taken its responsibilities seriously, and was it not the least that Parliament could do to encourage and support it in its purpose and work.

Sir E. GRAHAM-LITTLE said that the whole trend of the debate had been towards the political aspect of broadcasting. He wished to introduce the educational aspect. An examination of the current Year Book of the British Broadcasting Corporation showed, under the heading "Events of the Year," that for ten months during which some 300 or 400 events were mentioned, only four of those could in any sense be described as promoting education in a wide and liberal sense. He would plead for a wider use of educational opportunities. The disregard of educational opportunities was particularly absurd in London, because in the administrative County of London there were 50 or more colleges of university rank contributing fresh knowledge and competing with each other in putting forward that knowledge. He did not think that the B.B.C. need have any fear that what were called "high brow" discourses would not be acceptable. University members, he thought, might point with pride to the growth of the number of students in the universities of the country, which demonstrated the fact that there was a large and increasing audience for serious material.

The amendment was negatived by 203 votes to 27. Mr. EMMOTT's motion was then agreed to.

Home and Empire Settlement

In the House of Commons on Friday, Feb. 24th, Mrs. WARD moved the second reading of the Home and Empire Settlement Bill, a measure to amend the Empire Settlement Act, 1922. She said that the object of the Bill was to give greater power and facilities to the Secretary of State for the Dominions to coöperate in schemes of land settlement in the United Kingdom and the Dominion overseas. The Bill set up a board of five persons whose sole job it would be to promote the development of the natural resources of the Dominions and the United Kingdom.

Mr. THOMAS (Secretary of State for Dominion Affairs) said that while this was not a time when they could hope that any large number of people could be sent overseas, he believed that ultimately prosperity would be restored to the Dominions and then the opportunity for migration would come. In the interval he agreed that they ought to get ready. The Government therefore supported the second reading of this Bill, and hoped that as a result of discussions in Committee practical suggestions would emerge of which the Government would be ready to take advantage.

After further debate,

Sir FRANCIS FREMANTLE said that the population question was changing the alignment of the world. While the increase in the populations of the West was drawing to its close the populations of Asia were increasing. That fact was never taken seriously enough by our thinkers, who light-heartedly referred to the advantages of the declining birth-rate. The vital statistics had filled him with serious anxiety in the last 30 years. If they could keep the position stable it would be a different question, but they could not. They had seen the birth-rate decline from 35 to about 15 per 1000, and it was getting very near to the death-rate. The death-rate had declined from 24 to 12 per 1000, but it could not go much lower. In fact, as the population was becoming on an average more aged, so it was bound to go up. Before long the death-rate would be bound to go up to 20 per 1000, which meant an average life of every individual born of 50 years. This meant a shrinking of the population. They must see what Mr. Baldwin said in one of his notable speeches—the grim vision, the spectre that was lurking behind those facts. Australia with her shrinking birth-rate, and before long her increasing death-rate, would not be able to maintain with her population of 8,000,000 the whole of the continent in face of the enormous advance of the populations of Asia. A white Australia depended on the reinvigoration of the population from the populations of other parts of the Empire. The Empire could not carry on as it was unless the problem of Empire migration was settled. That was really the great case for this Bill.

The Bill was read a second time.

Pharmacy and Poisons Bill

In the House of Lords on Feb. 28th the Earl of LUCAN presented a Bill to amend the law relating to pharmacy and poisons.

The Bill was read a first time.

HOUSE OF COMMONS

WEDNESDAY, FEB. 22ND

Tuberculosis in Scotland

Mr. MCGOVERN asked the Secretary of State for Scotland the number of cases of tuberculosis in Scotland in the last 12 months.—Mr. SKELTON (Under Secretary of State for Scotland) replied: The final figures are not yet available but provisional returns show that the number of new cases of pulmonary tuberculosis notified in Scotland during the year 1932 was 5512 and that the corresponding number of non-pulmonary cases was 3888.

THURSDAY, FEB. 23RD

Medical Referee and Workmen's Compensation

Mr. TINKER asked the Minister of Labour if he was aware that persons whose compensation was suspended under the Workmen's Compensation Act pending the decision of the medical referee were not allowed to sign on at the labour exchange, and if the decision of the medical referee was

Thursday.—10 A.M., Neurological Clinic. 11.30 A.M., Fracture Demonstration. 2 P.M., Eye and Genito-urinary Clinics. 4 P.M., Lecture: Dr. Burnford: Febrile States.

Tuesday, March 7th.—5 P.M., Dr. H. T. Barron: Common Eruptions in Childhood. (Chesterfield lecture.)

Thursday.—5 P.M., Dr. W. N. Goldsmith: Benign Growths of the Skin. (Chesterfield lecture.)

ATIONAL HOSPITAL, Queen-square, W.C.

Monday, March 6th.—2 P.M., Dr. Riddoch: Out-patient Clinic. 3.30 P.M., Dr. Hinds Howell: Vascular Diseases of the Nervous System.

Tuesday.—2 P.M., Dr. Walshe: Out-patient Clinic. 3.30 P.M., Dr. Martin: Demyelinating Diseases of the Nervous System.

Wednesday.—2 P.M., Dr. Martin: Out-patient Clinic. 3.30 P.M., Dr. James Collier: Clinical Demonstration.

Thursday.—2 P.M., Dr. Kinnier Wilson: Out-patient Clinic. 3.30 P.M., Dr. Walshe: Cerebral Tumours.

Friday.—2 P.M., Dr. Adie: Out-patient Clinic. 3.30 P.M., Dr. James Collier: Virus Diseases of the Nervous System.

T. MARK'S HOSPITAL, City-road, E.C.

Thursday, March 9th.—4 P.M., Mr. J. P. Lockhart-Mummery: Fistula in Ano.

ENTRAL LONDON THROAT, NOSE, AND EAR HOSPITAL, Gray's Inn-road, W.C.

Friday, March 10th.—4 P.M., Mr. J. D. McLaggan.

ST. PETER'S HOSPITAL FOR STONE, Henrietta-street, W.C.

Wednesday, March 8th.—3 P.M., Dr. John Roth: Radiological Investigation of Urinary Disease.

SOUTH-WEST LONDON POST-GRADUATE ASSOCIATION, St. James's Hospital, Ouseley-road, Balham, S.W.

Wednesday, March 8th.—4 P.M., Mr. W. E. Tucker: Manipulative Surgery.

MEDICAL OFFICERS OF SCHOOLS ASSOCIATION, 11, Chandos-street, W.

Friday, March 10th.—5 P.M., Dr. J. A. H. Brincker: Presidential address.

NATIONAL COUNCIL FOR MENTAL HYGIENE.

Wednesday, March 8th.—5.30 P.M. (11, Chandos-street, Cavendish-square, W.), Dr. E. A. Bennet: Confidence.

ROYAL NORTHERN GROUP OF HOSPITALS.

Wednesday, March 8th.—3.15 P.M. (at the Royal Chest Hospital, City-road), Dr. F. E. Saxby Willis: Cancer of the Lung.

KING'S COLLEGE HOSPITAL MEDICAL SCHOOL, Denmark-hill, S.E.

Thursday, March 9th.—9 P.M., Mr. V. E. Negus: Diagnosis and Treatment of Pharyngitis.

MANCHESTER ROYAL INFIRMARY.

Tuesday, March 7th.—4.15 P.M., Dr. W. Brockbank: Pleural Effusion.

Friday.—4.15 P.M., Mr. H. H. Rayner: Demonstration of Surgical Cases.

ST. MARY'S HOSPITALS, Manchester.

Friday, March 10th.—4.15 P.M. (at the Whitworth-street West Hospital), Post-graduate Lecture. Dr. Bramwell: The Cardiac Complications of Pregnancy.

ANCOATS HOSPITAL, Manchester.

Thursday, March 9th.—4.15 P.M., Dr. N. Kletz: Colitis and Affections of the Colon.

GLASGOW POST-GRADUATE LECTURES.

Wednesday, March 8th.—4.15 P.M. (at the Western Infirmary), Dr. J. G. Macgregor-Robertson: Venereal Diseases (Male).

Appointments

Foster, J., M.B. Camb., F.R.C.S. Eng., has been appointed Ophthalmic Surgeon, Leeds General Infirmary.

Page, C. Max, M.S. Lond., F.R.C.S. Eng., Consulting Surgeon to the Royal Hospital and Home for Incurables, Putney.

Certifying Surgeons under the Factory and Workshop Acts: Burnie, R. McC., M.B., Ch.B. Edin. (Mochrum, Wigtown); Cogan, L. D. B., L.R.C.S. Edin., L.S.A., L.M.S.S.A. (Northampton); and Sherwood, C. H., M.B., Ch.B. Birm. (Willenhall, Stafford).

Vacancies

For further information refer to the advertisement columns

Aberdeen University.—Lecturer in Medicine. £400.

Aylesbury, Buckinghamshire County Council.—Asst. County M.O.H. and M.O.H. £800.

Barnstaple, North Devon [illegible] rate of £150.

Bolingbroke Hospital, W [illegible] Hon. Surgeon to Ear, Nose and Th [illegible] Pathologist.

Bootle General Hospital.—Cas. O. At rate of £150.

Bradford Municipal General Hospital, St. Luke's.—H.P.'s and H.S.'s. Each at rate of £150.

Brighton Sanatorium and Infectious Disease Hospital.—Jun. Res. M.O. At rate of £150.

Chelmsford and Essex Hospital.—Two Res. M.O.'s Each £150.

Chester, East Lancashire Tuberculosis Colony, Barrowmore Hall, Great Barrow.—H.P. At rate of £100.

Durham County Hospital.—H.S. £150.

East Ham Memorial Hospital, Shrewsbury-road, E.—H.P. At rate of £150. Also H.S. and Cas. O. At rate of £120.

Golden-square Throat, Nose and Ear Hospital, W.—Hon. Anæsthetist.

Greenwich, Dreadnought Hospital.—H.P. and H.S. Each at rate of £110.

Grimsby and District Hospital.—H.S. £200.

Guernsey States Mental Institutions.—Mental Officer. £800–£1000.

Hampstead General and N.W. London Hospital, Haverstock-hill, N.W.—Cas. Surg. O. for Out-patient Dept., Bayham-street. At rate of £100.

Hospital for Tropical Diseases, Endsleigh-gardens, W.C.—H.P. At rate of £120.

Leicester Royal Infirmary.—Two Cas. H.S.'s. Each £125.

Liverpool, Alder Hey Children's Hospital.—Res. Asst. M.O. £200.

Liverpool, Mill-road Infirmary.—Med. Supt. £1000.

Liverpool Stanley Hospital.—Two H.S.'s. Each at rate of £100.

L.C.C.—Temporary District M.O.'s. £140–£200. Pathologist at Group Laboratory, Mile End Hospital. £1100. Also Asst. Pathologist to Group Laboratories. Each £650.

London Lock Hospital, 283, Harrow-road, W.—Res. M.O. At rate of £175. Also Surg. Reg. £100.

Manchester, Ancoats Hospital.—Res. Surg. O. £200. Also Orthopædic H.S. At rate of £100.

Manchester Ear Hospital, Grosvenor-square.—Res. H.S. £120.

Manchester Royal Children's Hospital, Gartside-street.—Two Asst. M.O.'s for Out-patients' Dept. Each at rate of £150.

Manchester Royal Eye Hospital.—Jun. H.S. £120.

Manchester, St. Mary's Hospitals.—Res. Surg. O. for High-street Hospital. £175. Also Two H.S.'s for Whitworth-street West Hospital. Each at rate of £50.

Manchester, Victoria Memorial Jewish Hospital.—Res. Surg. O. £200. Also Jun. H.S. and Res. M.O. Each at rate of £125.

Miller General Hospital, Greenwich-road, S.E.—Res. Surg. O. and Reg. £250. Also H.P. £100.

National Temperance Hospital, Hampstead-road, N.W.—Hon. Asst. Physician.

Newcastle-upon-Tyne, City Hospital for Infectious Diseases.—Res. Med. Asst. £350.

Newcastle-upon-Tyne, Hospital for Sick Children.—H.P. Also Sen. and Jun. H.S. Each at rate of £100.

Northampton General Hospital.—H.P. and H.S. Also H.S. to Ear, Nose and Throat Dept. Each at rate of £150.

Northwood, Mount Vernon Hospital.—Res. M.O. £250. Also Asst. for Radio Therapeutic Dept.

Nottingham General Hospital.—H.P. At rate of £150.

Princess Beatrice Hospital, Richmond-road, Earl's Court, S.W.—Res. M.O. At rate of £100.

Princess Louise Kensington Hospital for Children, St. Quintin-avenue, N. Kensington, W.—H.S. At rate of £75.

Queen Charlotte's Maternity Hospital, Marylebone-road, N.W. Asst. to Pædiatrician and M.O. to Infant Consultation Centre. 1½ gns. per Clinic.

Queen's Hospital for Children, Hackney-road, E.—H.P. and Cas. O. Each at rate of £100.

Radium Institute, Ridinghouse-street, W.—Res. Surg. Reg. At rate of £250.

Royal National Orthopædic Hospital, 234, Great Portland-street, W.—H.S. At rate of £150.

Royal Northern Hospital, Holloway, N.—H.S. At rate of £70.

St. Leonards-on-Sea, Buchanan Hospital.—Sen. and Jun. H.S. At rate of £175 and £125 respectively.

St. Marylebone General Dispensary, 30, Marylebone-lane, N.W. Gynæcologist.

St. Paul's Hospital for Diseases of the Genito-Urinary Organs and Skin, Endell-street, Holborn, W.C.—H.S. At rate of £150.

St. Peter's Hospital for Stone, &c., Henrietta-street, W.C.—H.S. At rate of £75.

Salford Royal Hospital.—H.P. and H.S. Also Cas. H.S. Each at rate of £125.

South Africa, Central Hospital, Bloemfontein.—Radiologist. £900.

Stockport Infirmary.—Secretary-Superintendent. £500.

Swansea General and Eye Hospital.—H.P. At rate of £150.

Swindon and North Wilts Victoria Hospital.—Res. M.O. At rate of £125.

University College Hosp., Gower-street, W.C.—Asst. Obst. Surg.

Walsall Manor Hospital.—Asst. M.O. £350.

West Bromwich, Hallam Hospital.—Res. H.P. At rate of £200.

West London Hospital, Hammersmith-road, W.—H.P. Two H.S.'s to Spec. Depts. Also Res. Anæsthetist. Each at rate of £100.

Weston-super-Mare General Hospital.—Res. H.S. £150.

Wolverhampton Royal Hospital.—H.P. Also H.S. for Ear, Throat and Nose Dept. At rate of £125 and £100 respectively.

York County Hospital.—Res. Anæsthetist and Asst. H.S. £150.

The Chief Inspector of Factories announces a vacant appointment for a Certifying Factory Surgeon at Woolpit, Suffolk.

INDEX TO "THE LANCET." VOL. II., 1932

The Index and Title-page to Vol. II., 1932, which was completed with the issue of Dec. 31st. is now ready. A copy will be sent gratis to subscribers on receipt of a post-card addressed to the Manager of The Lancet, 7, Adam-street, Adelphi, London, W.C.2. Subscribers who have not already indicated their desire to receive Indexes regularly as published should do so now.

panel committee for the burgh of Glasgow should consist of 56 persons instead of the former number of 30. The increase was authorised to provide, among other things, for the fuller representation of medical practitioners in the city, whose numbers have very considerably increased since the original regulations were made.

Pit-head Baths

Mr. PARKINSON asked the Secretary for Mines the number of mines in England and Wales that had pit-head baths; and what further action was being taken to increase the facilities for washing and cleaning at the pit-heads.—Mr. E. BROWN replied: 98 mines in England and Wales (besides 28 in Scotland) have pit-head baths in use, and bath installations are in course of erection under the Mining Industry Act, 1926, at 35 other mines in England and Wales and 10 in Scotland. These numbers exclude baths for mine officials only. According to present plans, from 30 to 35 additional mines will be provided with baths annually under the Mining Industry Act, 1926.

Use of Skimmed Milk in Chocolate Manufacture

Sir PATRICK FORD asked the President of the Board of Trade whether he was aware that the importation of skimmed milk into this country on advantageous terms as compared with full cream condensed milk or milk powders was discouraging the manufacture of milk chocolate of a high nutritive value in favour of milk chocolate of a low nutritive value; and if he would consider a marking order to distinguish the two kinds of milk chocolate or some other method of encouraging the manufacture and sale in this country of the more nutritive variety.—Mr. RUNCIMAN replied: There is no power under the Merchandise Marks Act to make an order of the kind suggested. Questions of quality in relation to foodstuffs are more within the province of the Minister of Health.

Men Rejected for the Defence Services

Mr. LUNN asked the Financial Secretary to the War Office how many men who offered themselves for the Army during 1931 and 1932 were rejected on medical or other grounds.—Mr. DUFF COOPER replied: The figures for the recruiting year 1930–31 were 82,682 men served with notice papers and 46,818 rejected. The corresponding figures for 1931–32 were 70,418 and 41,667. The hon. Member will find these and other figures relating to recruiting in the General Annual Report on the British Army which will be in the possession of members in a few days.

Mr. T. WILLIAMS asked if the hon. gentleman attributed this large volume of rejections to a higher standard of military requirements, or was their rejection due to the continuous deterioration in the physique of the manhood of the country.

Mr. DUFF COOPER: No, I do not think that any such conclusion could be drawn from these figures. The standard does go up and down in different districts in proportion to the number of recruits that have been obtained.

Mr. LUNN asked the First Lord of the Admiralty how many men who offered themselves for the Navy during 1931 and 1932 were rejected on medical and other grounds.—Lord STANLEY (Parliamentary Secretary to the Admiralty) replied: As the Admiralty require only about one-fourteenth of the total number who offer themselves for the Royal Navy and Royal Marines, only the very best men are taken. In the financial year 1930–31, 43,453 men offered themselves. Of these 38,028 were rejected by recruiters for miscellaneous causes (including obvious physical defects) and 2451 on examination by medical officers. The comparable figures for 1931–32 are 47,054, 41,063, and 2781.

Mr. LUNN asked the Under Secretary of State for Air how many men who offered themselves for the Air Force during 1931 and 1932 were rejected on medical or other grounds.—Sir VICTOR WARRENDER (Vice-Chamberlain of the Household) replied: The figures for men recruits for the calendar year 1931 were as follows: application forms completed, 11,321; applications taken up, 5914, of which 3768 were rejected. The corresponding figures for 1932 were 8265, 2042, and 1255. It should be added that the requirements in 1932 were much below those of 1931.

Mr. LUNN asked if the answers to all these questions did not show that they were getting towards a C3 population. (Cries of "No.")

No answer was given to this question.

QUEEN'S INSTITUTE OF DISTRICT NURSING.—At the annual meeting of the council last week it was reported that since December last 22 associations had been affiliated, and that notwithstanding adverse industrial conditions 12 new ones were formed last year in Durham and Lancashire. Steps are being taken for the organisation of a county nursing association for Middlesex.

Medical Diary

SOCIETIES

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

TUESDAY, March 7th.—8.30 P.M., PATHOLOGY. Laboratory Meeting at the National Institute for Medical Research, Hampstead, N.W. Short Communications; Mr. W. J. Elford and Dr. C. H. Andrewes: Observation on the Neutralisation of Phages by Antisera. Miss W. I. Strangeways: *Streptobacillus moniliformis* Infection of Mice. Dr. C. H. Andrewes: Antigenic Specificity of Fowl-tumour Viruses. Demonstrations: Dr. W. E. Barnard: The Virus of Canary Pox. Dr. F. M. Burnet: Inclusion Bodies in Canary Pox. Dr. A. Clark: Effects of a Sapotoxin Isolated from *Xanthosoma atrovirens* on the Kidney of the Rat Sir Henry Dale (for Dr. E. Schuster): Apparatus' Continuous Slow Infusion. Mr. P. Hartley: Demonstration of Biological Standards. Prof. E. Hindle and Dr. P. Bruce White: *Precipitin Reactions* with Specific Substances from Spirochætes. Dr. W. E. White, Dr. M. K. McPhail, Dr. M. Hill, and Dr. A. S. Parkes: Methods of Performing Hypophysectomy in Animals. 8.30 P.M., ORTHOPÆDICS AND SURGERY. Discussion: Acute Suppurative Arthritis of the Knee-joint. Openers: Mr. V. H. Ellis and Mr. R. W. Butler Orthopædics, and Mr. P. H. Mitchiner Surgery.

WEDNESDAY.—5 P.M., SURGERY: SUBSECTION OF PROCTOLOGY. Clinico-pathological Meeting. Specimens Mr. Cecil A. Joll: 1. Carcinoma of Colon from a Girl aged 17. 2. Inflamed Diverticulum of the Cæcum Simulating Acute Appendicitis.

FRIDAY.—5.30 P.M., CLINICAL. (Cases at 4.30 P.M.) Dr. Hugh S. Stannus: Addison's Disease. 5 P.M., OPHTHALMOLOGY. Clinical Meeting at St. Bartholomew's Hospital, E.C. Demonstration: Mr. J. W. Tudor Thomas: A Projection Protractor for Use with a Bjerrum Screen. Cases and Specimens: Mr. Humphrey Neame: 1. Familial Macular Disease in Twins aged 11 Years. 2. Cysts of the Retina with Cholesterin Crystals in or behind the Retina. Mr. H. B. Stallard: Specimens of Metastatic Carcinoma in the Choroid.

MEDICAL SOCIETY OF LONDON, 11, Chandos-street, Cavendish-square, W.

MONDAY, March 6th.—9 P.M., Mr. V. Zachary Cope: *Pathology of Acute Abdominal Disease.* (Last Lettsomian lecture.)

HARVEIAN SOCIETY OF LONDON.

THURSDAY, March 9th.—8.30 P.M. (at Paddington Town Hall), Prof. William Wright: a Pre-Harveian Lecture on the Anatomy and Physiology of the Central Nervous System. (Harveian lecture.)

WEST KENT MEDICO-CHIRURGICAL SOCIETY.

FRIDAY, March 10th.—8.45 P.M. (Miller General Hospital, Greenwich), Dr. W. S. C. Copeman: Spa Treatment and Medical Hydrology.

SOUTH-WEST LONDON MEDICAL SOCIETY, Bolingbroke Hospital, Bolingbroke-grove, Wandsworth Common, S.W.

WEDNESDAY, March 8th.—9 P.M., Clinical Meeting.

MEDICAL SOCIETY OF INDIVIDUAL PSYCHOLOGY, 11, Chandos-street, W.

THURSDAY, March 9th.—8.30 P.M., Mr. W. McAdam Eccles: Psychological Surroundings of the Surgical Patient.

ROYAL SOCIETY OF ARTS, John-street, Adelphi, W.C.

WEDNESDAY, March 8th.—8 P.M., Mr. J. L. Musgrave: Recent Developments in the Warming and Ventilation of Buildings.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

ROYAL COLLEGE OF PHYSICIANS, Pall Mall East, S.W.

TUESDAY, March 7th, [illegible] SDAY.—5 P.M., Dr. Charles New[illegible] of the Gall-bladder and its Functional Abnormalities. (Goulstonian lectures.)

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, W.

MONDAY, March 6th, to SATURDAY, March 11th.—MEDICAL SOCIETY OF LONDON, 11, Chandos-street, Cavendish-square. Practical Problems in Medicine and Surgery. Lecture by Mr. C. *Price Thomas on Empyema* at 4 P.M. on Tues. (Free to Members and Associates of the Fellowship of Medicine.)—NATIONAL TEMPERANCE HOSPITAL, Hampstead-road, N.W. Evening M.R.C.P. Course. Mon. and Fri., at 8 P.M.—ROYAL WATERLOO HOSPIT[illegible] S.E. 1. Post-graduate Course [illegible] næcology. All day.—ROY[illegible] HOSPITAL, 234, Great Portland-street, W. *Post-graduate Course in* Orthopædics. *All day.—BRITISH RED CROSS* CLINIC FOR RHEUMATISM, Peto-place, N.W. Evening Course in Rheumatism. Tues. and Thurs. at 8.30 P.M. (Courses, &c., open only to Members and Associates of the *Fellowship.)*

WEST LONDON HOSPITAL POST-GRADUATE COLLEGE, Hammersmith-road, W.

MONDAY, March 6th.—10 A.M., Medical Wards, Skin Clinic. 11 A.M., Surgical Wards. 2 P.M., Surgical Wards, Gynæcological and Eye Clinics. 4.15 P.M., Lecture: Dr. R. Ironside: Anæsthetics.

TUESDAY.—10 A.M., Medical Wards. 11 A.M., Surgical Demonstration. 2 P.M., Throat Clinic. 4.15 P.M., Lecture: Mr. Hamblen Thomas: Deafness.

WEDNESDAY.—10 A.M., Medical Wards, Children's Clinic. 2 P.M., Eye Clinic. 4.45 P.M., Venereal Diseases.

NOTES, COMMENTS, AND ABSTRACTS

JOHN HUNTER: THE LANGUAGE OF FACTS

Sir CRISP ENGLISH, in delivering the Hunterian oration of the Hunterian Society, at the Mansion House last Monday, took as his title the Language of Facts, which he said was the great lesson of John Hunter's life. His letters to his friend Jenner illustrated his wide and insatiable interest in all living things. Every page of his life showed that he stood for science, truth, and reality. He had been the enemy of wild imagination and crude theory. His great work had been the discovery and collection of facts relating to medicine and surgery. He had initiated and handed on the language of facts.

Great advances had been made since Hunter's day, but a great field of research still awaited discovery. Research called for three groups of men, as Lord Balfour had pointed out: the research worker, the man who applied discovered facts where they were needed, and the man who used them for the benefit of mankind. Research workers must be men with open minds, acute imagination, and the habit of trying. John Hunter's were seldom born and never made. Medical research should be limited to the chase of facts which would help in the fight against disease. All workers should be kept in contact, and overlapping must be prevented. Research and clinical work must go hand in hand. Much greater facilities for post-graduate work would be demanded in the near future, for general practitioners found it extremely difficult to keep in touch with new advances.

Practitioners must weigh and face facts day by day, said Sir Crisp English, both for themselves and for their patients. The first step in a difficult case was to collect all available facts; the second was to draw deductions; and the third to express an opinion. This order should never be varied. Bluffing was no good in medicine. It was of vital importance all through to check the principles on which diagnosis was based and not to be led away by imagination, impressions, and the stories told by relations and friends. Facts must not be mixed with deductions. The people of this country showed an increasing tendency to ignore medical facts in favour of the phantasies of modern cults. Any new cure for cancer attracted a large crowd of adherents. These cults knew not the language of facts; they seldom kept records and seemed to know no failures. Argument was usually a waste of time, but if inevitable it should turn on the question of facts, first as to diagnosis and secondly as to cure.

The great work initiated by Hunter would never cease. "New" methods would soon be old, but the facts would survive and lead to yet more discoveries. There had been a wonderful accumulation in recent years of new facts leading to the cure of disease. It was largely John Hunter's language of facts that made the medical profession ring true.

In the subsequent discussion Sir WILLIAM WILLCOX remarked that in Hunter's time the opinion of a medical man of personality and power had been accepted without question, but now it had to be backed by laboratory investigations. One of the great charms of medicine to-day was that the clinical diagnosis could be criticised by the language of facts. In some countries hundreds of facts were collected before the physician attempted to make his diagnosis and he was apt to get lost among them, but the English physician owed his admitted supremacy in diagnosis to his habit of using his clinical sense first.

Mr. A. E. MORTIMER WOOLF said it was not always wise to use the language of facts. But the legend of Hunter's unpopularity with his colleagues was not altogether accurate; new evidence would shortly be available to show that Hunter had been much honoured and admired by his contemporaries. The extraordinary accuracy of his work in relation to the atmosphere of chicanery and quackery of the time was an astonishing thing.

Dr. J. CAMPBELL MCCLURE pointed out that many people were content to live on facts as they had been taught them and pose as the great apostles of the accepted doctrine. The great man regarded each fact as a stimulus to reach on to more, and as another small stone to set in the temple of knowledge—not as an achievement to himself.

METAL FITTINGS IN HOSPITALS

AMONG the many new materials made available for industrial purposes during the present century, metals, which within the memory of most middle-aged people were only chemical curiosities, and alloys in which they form essential constituents, occupy a prominent place. Aluminium, nickel, chromium, tantalum, tungsten, the strong light alloy duralumin, the non-rusting chromium steels, the highly magnetisable cobalt steels are outstanding examples. The demand for a high standard of cleanliness, with a minimal expenditure of labour in hospitals, has led to the utilisation of many of these new products. One of the newer alloys has a rather curious origin. Monel metal is an alloy containing about 60 per cent. of nickel, 33 per cent. of copper and iron, with small quantities of other metals to make up the remaining 7 per cent. As it is obtained by the unusual process of smelting a natural ore, its composition is variable, but only within small limits. Like most alloys containing much nickel it is white ("white gold" is a gold-nickel alloy), not easily tarnishable, and will stand the action of most of the liquids likely to be spilt upon it in a hospital ward. For instrument handles, furniture, utensils for ward and operating theatre, besides kitchen fittings, food trolleys, and sterilising apparatus it appears to be very suitable, possessing the advantage over aluminium, for some of these objects, of superior hardness and a nicer surface, whilst it is much more amenable to the ordinary methods of the metal worker than stainless steels. It appears from a still somewhat limited experience of its use to be a very satisfactory material. Chromium plating has achieved great popularity both in hospitals and homes for taps, towel rails, and such fixtures. It is necessary to impress on all who use it that gentle rubbing with a cloth is all the cleaning needed, as the coating of chromium is very thin and will retain its polish without the use of abrasive materials which will soon remove it. To be satisfactory, chromium should not be plated directly on steel, but fairly heavy layers of copper and nickel, or nickel alone, should first be plated and the nickel be highly polished before the final thin layer of chromium is applied. If this is not done the coating may be discontinuous and, under the influence of atmospheric corrosion affecting the under metal, the chromium will flake off. A case of this kind came under our notice some time ago, but the conditions for success are now well known. It is claimed that the chromaloid process is particularly suitable for the protection of car parts which not only have to stand all weathers, but are subject to much abrasion from grit in the air.

SECOND-HAND MEDICAL BOOKS

Menno Hertzberger, of the Internationaal Antiquariaat, Amsterdam, has issued a useful catalogue (No. 66) of "Books on the History of Medicine." This catalogue includes a few finely-printed books, but is chiefly valuable for the number of indispensable reference books listed in it, such as Choulant's "Bibliographie der anatomischen Abbildung" or Osler's "Incunabula medica." There are also some important library catalogues and special bibliographies, besides a variety of reprints and facsimiles, as well as recent medico-historical works. The prices seem very reasonable. An attractive series of illustrated "Dance of Death" books includes a Paris-printed "Book of Hours" of 1502, priced at 375 guilders, several unusual seventeenth and eighteenth century editions, and a number of modern reproductions.

MEDICAL NEWS

University of Cambridge

On Feb. 24th the following degrees were conferred :—

B.Chir.—G. A. W. Whitfield (by proxy) and S. F. L. Dahne.

University of London

At a meeting of the Senate on Feb. 22nd, Mr. J. B. S Haldane, F.R.S., was appointed to a university chair of genetics tenable at University College.

Since 1922 Prof. Haldane has been reader in biochemistry in the University of Cambridge, and since 1927 he has been head of the genetical department of the John Innes Horticultural Institution. In 1930 he was elected Fullerian professor of physiology at the Royal Institution.

Prof. Cyril Burt, D.Sc., was appointed to deliver the Heath Clark lectures for 1933, and Prof. W. Blair Bell, F.R.C.S., was appointed representative of the university on the court of the University of Liverpool.

It is announced that the King intends to lay the foundation-stone of the new university buildings on June 26th.

The following have been appointed staff examiners in the subjects of examination for medical degrees for 1933 :—

Anatomy : Prof. Edward Fawcett and Prof. Thomas Yeates. Bacteriology : Prof. C. H. Browning. Forensic Medicine and Hygiene : Dr. G. Roche Lynch, Prof. M. E. Delafield, and Dr. J. H. Ryffel. Medicine : Prof. F. S. Langmead, Dr. M. A. Cassidy, Dr. Anthony Feiling, Prof. W. E. Hume, and (associate examiners) Dr. Adolphe Abrahams, Dr. T. Izod Bennett, Dr. C. M. Hinds Howell, and Dr. E. Bellingham Smith. Mental Diseases and Psychology : Dr. Henry Yellowlees and Dr. Edward Mapother. Neurology : Dr. C. P. Symonds and Dr. F. M. R. Walshe. Obstetrics and Gynæcology : Dame Louise McIlroy, Mr. J. D. Barris, Mr. D. W. Roy, Prof. J. M. Munro Kerr, Prof. F. J. Browne, and (associate examiners) Mr. Stanley Dodd, Mr. William Gilliatt, Prof. John McGibbon, Mr. Frank Cook, and Mr. Leslie Williams. Oto-Rhino-Laryngology : Mr. W. M. Mollison and Mr. W. G. Howarth. Pathology : Prof. James McIntosh and another, and (associate examiners) Prof. J. S. Dunn and Dr. W. D. Newcomb. Pharmacology : Prof. W. J. Dilling and Dr. Eleanor Scarborough. Physiology : Prof. B. J. Collingwood and Dr. L. E. Shore. State Medicine and M.D. Hygiene : Prof. W. W. Jameson and Dr. Charles Porter. Surgery : Mr. N. C. Lake, Prof. E. D. Telford, Prof. C. C. Choyce, Mr. V. Zachary Cope, Mr. G. T. Mullally, and (associate examiners) Mr. R. Davies-Colley, Mr. J. Paterson Ross, Mr. P. H. Mitchiner, and Mr. H. C. Edwards. Tropical Medicine : Colonel W. P. MacArthur.

Royal Institution

Prof. Elliot Smith's course of afternoon lectures on the Evolution of the Mind, announced for March 16th, 23rd, 30th, and April 6th, and his Friday evening discourse on March 24th, have been postponed because of illness.

Post-graduate Work in Berlin

Medical visitors to Berlin are invited to apply to the Medizinische Informationsbüro at the Kaiserin-Friedrich Haus, Robert Koch-Platz 7, Berlin, N.W.7, which is ready to supply information about hospitals, clinics, public health, and continuation courses. The office is, it is stated, of a semi-public nature, and all information is furnished impartially and gratuitously.

Royal Medical Benevolent Fund

At the meeting held in January the committee voted 84 grants amounting to £2089. At the February meeting £693 was voted to 34 applicants.

The following are particulars of a few cases helped :—

M.B., aged 39. Married, two sons, aged 12 and 9. The applicant is suffering from disseminated sclerosis, and is totally incapacitated from following any occupation ; he is unable to move one step without help. It was found that his total income was £123, with which he has to maintain himself, his wife, and two sons. Fund voted £40 in four instalments, and assistance is being obtained from other societies.

M.B., aged 69. Married, wife aged 62. Applicant is suffering from macular choroiditis in an advanced stage in both eyes, and four years ago had to sell his practice. Since then he has been living on his capital, which is now almost exhausted. Income for past 12 months was £101. Fund voted £40.

Widow, aged 41, of M.B. Husband contracted septic pneumonia, and died at the age of 36, leaving the widow with two children, girl aged 9 and boy aged 5. The boy has recently developed epilepsy. Total income £1 a week. Fund voted £26 in four instalments, and is obtaining help from other societies.

Widow, aged 46, of M.R.C.S. Husband died in December, 1932, at the age of 56. He was a retired Lieut.-Colonel in the R.A.M.C. The widow is left with an army pension of £90 and a children's allowance of £16 for each of the two youngest—making a total of £132. Fund voted £26 in four instalments.

Cheques should be made payable to the hon. treasurer of the fund, 11, Chandos-street, Cavendish-square, London, W.1.

Chicken-pox has been made notifiable in the City of London for 12 months commencing on March 18th.

British Institute of Philosophy

The Dean of St. Paul's will deliver an address on Religion, Science, and Philosophy at 8.15 P.M. on Tuesday, March 14th, at University College, Gower-street, London, W.C. Tickets may be had from the institute's director of studies, University Hall, 14, Gordon-square, W.C.1.

Course on Disorders of Digestion

A fortnight's course on the medical and hydrological treatment of digestive and nutritional disorders will begin on May 1st at the Hôpital Necker, Paris, under the direction of Prof. Maurice Villaret. There will be a study tour to Vichy from May 13th onwards. Particulars may be had from the laboratoire d'hydrologie of the Faculté de Médicine de Paris (École pratique).

Royal Sanitary Institute

On Friday, March 17th, at 4.30 P.M., a sessional meeting will be held, in conjunction with the Yorkshire branch of the Society of Medical Officers of Health, in the Winter Gardens, Royal Baths, Harrogate. Dr. J. A. Charles, medical officer of health for Newcastle-on-Tyne, will open a discussion on the Problem of Bacillary Dysentery, and Lieut.-Colonel J. A. Dixon, chief veterinary officer for Leeds, a discussion on Food Inspection from the administrative Aspect.

Tata Research Scholarships in Hæmatology

In supplement to the announcement made in our issue of Feb. 18th (p. 376) it is explained that the number of scholarships offered for research on diseases of the blood has now been increased to four, and that they are open to candidates from all nations, including India. Nominations in respect of Great Britain and the Dominions will be made to the trustees in Bombay by an advisory committee in London. Applications may be addressed to Dr. H. S. Patel, Capel House, 62, New Broad-street, London, E.C.2; Prof. A. Vacha, Calvinstrasse 27, Berlin, N.W.40; or directly to the trustees, c/o Messrs. Tata Sons, Ltd., Bombay House, Bruce-street, Fort, Bombay.

Glasgow Hospitals

In 1932 the ordinary expenditure of Glasgow Royal Infirmary exceeded the ordinary income by £26,000; the similar deficit of the Glasgow Western Infirmary was £14,900. The Royal Infirmary's in-patients were 16,313 and they stayed 17·3 days on the average. There were nearly 116,000 out-patients, whose attendances increased so considerably that the existing accommodation "will have to be replaced without delay by more commodious and modern premises." At the Western Infirmary and the David Elder Infirmary, which is administered as a unit of the main institution, there were last year 12,893 in-patients, and over 48,000 out-patients, also a large increase. The average residence was 17·83 days and the daily cost 7*s.* 5*d.*, a fractional reduction. The average cost per patient was £6 13*s.* The accommodation in the pathological department has been gradually becoming more and more taxed, and is now so deficient in various respects that extension will have to be considered at an early date.

Fellowship of Medicine and Post-Graduate Medical Association

A debate will take place on Thursday, March 9th, at 9 P.M. at the Medical Society of London (11, Chandos-street, Cavendish-square, W.) on the motion that Immediate Operation is indicated in every case of "Acute" Appendicitis. Lord Moynihan, president of the Fellowship, will occupy the chair, and the principal speakers will be Mr. R. M. Vick and Mr. W. H. Ogilvie for the motion, and Mr. V. Zachary Cope and Mr. R. J. McNeill Love against the motion. Members and associates of the Fellowship and their friends are invited to be present. On Tuesday, March 21st, at 8.30 P.M., Mr. R. Lindsay Rea will give a demonstration on the Fundus Oculi at the in-patient department of the West End Hospital for Nervous Diseases, Gloucester-gate, London, N.W. Forthcoming courses include a course on psychological medicine at the Maudsley Hospital, Denmark-hill, London, S.E., from March 14th to April 7th ; a course in neurology at the West End Hospital for Nervous Diseases, 73, Welbeck-street, London, W., from March 13th to April 8th ; and a course in proctology at the Gordon Hospital, Vauxhall Bridge-road, London, S.W., from March 20th to March 25th. Further particulars of the courses may be had from the secretary of the Fellowship, 1, Wimpole-street, London, W. 1.

ADDRESSES AND ORIGINAL ARTICLES

THE TREATMENT OF ENLARGED TONSILS IN CHILDREN*

BY T. B. LAYTON, D.S.O., M.S. LOND., F.R.C.S. ENG.
SURGEON IN CHARGE OF THE THROAT AND EAR DEPARTMENT, GUY'S HOSPITAL, LONDON

WE may divide enlargement of tonsils into those cases where the increase is a part of an increase of all the lymph tissue of the body and those cases where it is a local manifestation. It is clear that in the former group it is our business to treat the general cause of the general enlargement. I think the commonest condition under which this is found is that described by the late Dr. Eustace Smith[1] as mucous disease of children, but which is now included as a part of the wider problem known as the exudative diathesis.

For the isolated increase of lymphoid tissue in the tonsils the treatment has for many years been operative. Before we discuss the indications for operative treatment let us consider whether there is, as yet, any alternative treatment that will take its place. There is the burning away of the tonsil used by Morell Mackenzie and reintroduced by Irwin Moore. There is the slow destruction by diathermy advocated, in selected cases, by Dan McKenzie, and there is the emptying of the tonsils by the suction method of Waring. All these methods necessitate repeated séances under local anæsthesia or without anæsthesia with the mouth open, and for this reason are unsuitable during childhood. There is the rapid diathermy at a single sitting which is either a modification of technique or, if different in principle, is yet unproven to have fewer disadvantages than operation by other methods. There is the use of X rays and of ultra-violet light which as yet have not been shown to be efficient. When a method has been devised of destroying or removing the tonsil which is as efficient as operation, without there being any increase of risk or unpleasantness, then I am willing to give up operating on children's tonsils. But I maintain that no such substitute for operation has as yet been found.

Reasons for Operation

In effect then we are met here to consider the question of the removal of enlarged tonsils in children. The answer, in my opinion, is that to-day this is only necessary on the rarest occasion. The enlarged tonsils for which the operation of tonsillotomy was devised are now seldom seen, and I remember but one such case in the last five years. This statement may sound sweeping; it is, and it is meant to be. For I wish to sweep away a misunderstanding with regard to the tonsil problem that lies, I believe, at much of the excess of operation that so many deplore.

It comes to this, we have changed our indications for the removal of tonsils without changing our title; and I believe we have not changed our title because the modern concept for removal is not definable in any strict terms, it is not describable by any pretty adjective, and it is incapable of diagnosis in the accepted sense. In other words, it is neither a clinical nor a pathological entity; some even deny, as we shall learn later, that it is an anatomical entity.

Personally I suspect that the condition of "enlarged" tonsils was not as common in the early nineteen hundreds as it was in the 'eighties of the last century; but I am confident that we then saw more cases than we do to-day. If we read the description in Morell Mackenzie's book[2] which was published in 1880 we realise that he is describing a clinical picture that is seldom seen to-day. I need only quote his description of the tonsils to realise this. "The augmentation of volume of the tonsils varies in different cases. They are often the size of a chestnut, but sometimes attain the dimensions of a bantam's egg, and in rare instances they are nearly the size of a hen's egg." The great indication for operation was obstruction to breathing in the faucial region.

This disappearance of the "enlarged tonsils" is not, I believe, the only change that has occurred in the upper respiratory tract during the present century; but the other parts of this subject are not germane to the present discussion.

History of Tonsillotomy

Let us consider the matter from the history of the tonsil operation. Though guillotines were devised in 1827, I do not think the operation was common before the 'nineties. It was then a tonsillotomy performed for the enlarged tonsil with a view to removing the redundant lymph tissue. In the great majority of such cases the operation was efficient, but in a few cases cicatrices around the openings of the crypts led to trouble and in the early years of this century surgeons were having great difficulty in removing such stumps. They therefore decided to remove the tonsil completely in the first instance. Since then there have been two landmarks in the history of tonsillar operative surgery.

The first was when G. E. Waugh,[3] of the Hospital for Sick Children, Great Ormond-street, in 1909 published his technique for removal of the tonsils by dissection. This was a very great advance and has standardised the operation for this country. All surgeons to-day are indebted to Waugh when they set out to dissect a tonsil.

Unfortunately it was attended by two disadvantages. It made the operation easy. Anyone with a good enough pair of hands, who would give up time to practising it, could learn to do it.

The second disadvantage was that too much lymph tissue was removed. The original operation of tonsillotomy was merely for the removal of hypertrophied lymphoid tissue. This idea led to the removal of the lingual prolongation of the tonsils down and even on to the tongue, and an insistence upon the necessity for removing this has always been a tenet of this school. It led to two results: a failure to recognise the implications of the new conception that was then arising with regard to the reason for the removal of tonsils, and a refusal to consider the second landmark of tonsillar operative surgery. This came in 1910, when S. S. Whillis and F. C. Pybus,[4] of Newcastle, published their method of enucleation of the tonsils with the guillotine.

[3] THE LANCET, 1909, i., 1314.

[4] Ibid., 1910, ii., 875. At about the same time Sluder of St. Louis, Mo., published a very similar technique. According to our insular custom of ignoring any new thing from home while hailing that from abroad, the method is often called Sluder's although that of Whillis and Pybus is usually employed.

PHYSICAL THERAPY

A FASCINATING little work on the growth of the four sections of physical therapy, divided into massage and exercises, water, electricity, heat and light, has been issued as one of a series of primers on the history of medicine.[1] Dr. Coulter has delved into ancient as well as into modern writings. Sun worship and sun therapy is traced from the Chaldean and Egyptian times through the Greek and Roman to the Rollier Clinic at Leysin. The indications for massage and mobilisation are set out carefully by Hippocrates, and these measures were used extensively by Galen. In the seventeenth century Quellmaltz in Germany and Andry in France started work on orthopædic lines and included massage and movements in their teaching. All the older physicians seem to have attempted to apply vigorous exercises to the treatment of a variety of sedentary and plethoric ailments. Their patients must have been of hardier calibre than some of the nerve-strained patients who consult us nowadays. Occupational work and exercise seem to have been used in certain asylums in the late eighteenth century both in England and France.

The chapters on water and electricity yield many interesting sidelights on mediaeval and eighteenth century procedure. Dr. Coulter suggests that electricity, rescued from quacks, is capable of much development as a therapeutic agent, and he expresses astonishment at the contrast between the use to which it has been put in commerce and the slow development of its medical application.

THE "ELPEY" BANDAGE

WE have received specimens of a new type of surgical bandage now placed upon the market by the Liverpool Packings Company, Nottingham Buildings, 19, Brunswick-street, Liverpool. These bandages have new features which can be warmly commended. They are of the crepe type, and made of rubber, so that the bandage by its elasticity can conform to the shape of the limb, and being self-adjusting painful constriction is avoided if swelling occurs after bandaging. The porous nature of the material provides for ventilation, while a slightly corrugated surface, described by the manufacturers as "knurled," is an insurance against slipping. For this reason the dressing is maintained in position without any pressure on a painful or inflamed area. The bandages can be boiled or sterilised in the usual manner without damage. It is stated that the bandages have been tested by practitioners and at institutions with good results. The conditions for which they are obviously useful will be sprains, varicose veins, and, perhaps especially, the annoying recurrent œdema met with in limbs and around joints which have been encased for a long period in plaster. The bandages are supplied in three weights, light, heavy, and medium, and they can be made of any width.

THE CICELY NORTHCOTE TRUST

THIS fund was given to St. Thomas's Hospital in 1909 to complete the system of social work which had been begun in the casualty and out-patient departments of the hospital four years earlier. In addition to routine social work amongst patients in the wards, and the follow-up work resulting therefrom, the Trust was designed to act as a pioneer in experimental ventures of its kind. The twenty-third annual report of the Trust has recently been published, and like its predecessors is a record of fine social service. Of the follow-up work in cancer patients during the year it is stated that 1185 have been kept under observation, 196 assisted, 901 visited (in some cases many times), 101 provided with extra comforts and extra nourishment, and 28 sent to homes for the dying. The Northcote Trust Hostel has admitted 40 girls during the year. The social service department of a hospital becomes more highly specialised and technical each year. Plans for the after-care of patients have to be made with greater speed; more technical work is needed on behalf of patients in connexion with the insurance societies, the Road Traffic Act, and other measures, whilst certain special departments involve special efforts. For example, the work of the diabetic clinic would be unproductive if arrangements could not be made to enable the patient to pay for the diet recommended and for the insulin needed. Year by year the Cicely Northcote Trust meets the increasingly heavy burden placed upon it. This year it starts with a debit balance in spite of rigorous economy and active efforts to raise more money. Its record of work is so fine that a curtailment would be deplorable.

MALARIOTHERAPY IN GENERAL PARALYSIS

Two Japanese workers, I. Omaru and H. Eguchi,[1] report the results of the treatment of 260 cases of general paralysis of the insane with tertian malaria. They claim 40 per cent. of complete remissions, 15 per cent. of incomplete remissions, 18 per cent. unchanged, and 8 per cent. modification in the clinical picture; the remainder of the patients died. The prospect of remission, they find, is good in the neurasthenic and expansive forms, but bad in the demented and depressive forms. The prognosis is favourable in the forms resembling manic-depressive psychosis, but unfavourable in those resembling schizophrenia, except the katatonic type. They found that patients of the pyknic physical type responded better than others. Research into 111 cases showed no special relationship between the blood picture and the clinical result. The Wassermann reaction in 30 cases was tested over a year, but there appeared to be no connexion between the blood picture and the disappearance of a positive result.

Births, Marriages, and Deaths

BIRTHS

CAIRNS.—On Feb. 21st, at St. John's Wood Park, N.W., the wife of Hugh Cairns, F.R.C.S., of a daughter.

GIBBERD.—On Feb. 21st, at Welbeck-street, W., the wife of G. F. Gibberd, F.R.C.S., of a son.

MARRIAGES

CHARLTON—SMITH.—On Feb. 22nd, at Hampstead, P. H. Charlton, M.B., to Margaret, only daughter of Mr. and Mrs. H. N. Smith.

CORR—BROWN.—On Feb. 22nd, at St. James's Church, Spanish-place, W., Dr. J. Patrick Corr, to Phyllis E. L. Brown, both of Brighton.

FERGUSON—WILSON.—On Feb. 21st, at the Parish Church, Chapel-en-le-Frith, by the Vicar, Rev. W. H. Green, Dr. Fergus R. Ferguson to Dr. Kathleen Wilson.

SMITH—STEWART.—On Feb. 18th, at St. Stephen's Church, Dulwich, K. P. Smith, L.D.S., R.C.S., of Alleyne, Petts Wood, to Beth, youngest daughter of Dr. and Mrs. H. M. Stewart, Dyffryn, Dulwich.

WARD-FARMER—CATCHPOLE.—On Feb. 21st, at St. George's Church, Portsmouth, Dr. Paul Ward-Farmer, M.B., M.R.C.P., to Sybil Ethel, the only daughter of Lieut.-Commander and Mrs. T. J. Catchpole, of The Hard, Portsmouth.

DEATHS

BALLANCE.—On Feb. 20th, 1933, at Westfield, Hatfield, Hertfordshire, Alaric Charles Ballance, M.A., M.B., B.Ch. Oxon., dearly loved husband of May Ballance, née Trowel, and only son of Sir Charles and the late Lady Ballance, aged 45.

BULL.—On Feb. 24th, at Clarges-street, London, William Charles Bull, F.R.C.S., in his 75th year.

GALI [illegible] ome in London, Major-General [illegible] K.C.M.G., C.B., late Colonel [illegible] s 81st year.

GRIF [illegible] I. Griffiths, F.R.C.S., aged 34, [illegible] Bristol, dearly loved son of [illegible] of Fairlawn, Portishead, Som.

JOH [illegible] ddenly, at Esslemont-road, [illegible] Johnston, M.D., F.R.C.P.E.,

MANN.—On Feb. [illegible] at [illegible] sby, Lincolnshire, Frederick William Slingsby Mann, M.R.C.S., aged 61.

MARSH.—On Feb. 26th, at Chelmsford, suddenly, Philip Henry Marsh, L.D.S., R.C.S. Eng., of Branwoods, Great Baddow, and Dorset House, [illegible]

O'DONOVAN.—On Feb. [illegible] athedral-road, Cardiff, Marshall J[illegible] L.R.C.S. (I.), L.K.Q.C.P.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths

AND CHESHIRE JOINT SANATORIUM

LECTURE II.—COLLAPSE THERAPY *

Under the term "lung collapse therapy" are included all those methods whereby a collapse of the whole or a part of the lung is produced in order to arrest or heal disease. The most generally used of these methods is artificial pneumothorax, first suggested by Carson of Liverpool in 1822, but not put into actual practice till 1888 by Forlanini. Prior even to this, in 1885, de Cérenville attempted a very limited thoracoplastic operation in an endeavour to arrest hæmorrhage. Thoracoplasty did not, however, become a recognised stereotyped operation till 1911; though Spengler, in 1890, coined the term "extra-pleural thoracoplasty" for his rib-resection operation through a periscapular incision.

"Lung collapse therapy" includes also phrenicectomy and phrenic evulsion; operations which have become rapidly and increasingly popular since the variations in the anatomy of the phrenic nerve and the importance of the accessory phrenic were made clear by Felix in 1922.

Oleothorax, as a means of maintaining collapse of the lung is of even more recent date, and the appreciation of its value is due largely to the pioneer work of Bernou. He, however, was anticipated by de Carle Woodcock, who, as early as 1912, used paraffin oil and air for maintaining lung collapse.

Extrapleural pneumolysis, which is the freeing of the lung together with the parietal pleura from the chest wall in order to obtain a localised collapse, was first tried by Tuffier in 1892. It was not a success, because he relied on the air enclosed in the space to maintain the collapse. In 1910 he obtained satisfactory results by filling the space with fat. Three years later Baer tried paraffin as a filling. It is only recently that, with improved technique, the operation has begun to be regarded with favour by some surgeons.

Yet another operation which is being tried out is that of scalenectomy with division of the first rib, in an endeavour to supplement the effect of hemidiaphragmatic paralysis on the apex.

While there are other methods of producing lung collapse, these are the principal ones.

Objects of Lung Collapse

The most important of the benefits gained by collapsing a diseased lung is the obliteration of cavities, whether these are in the lung substance as in the case of tuberculous cavities and of abscess, or are dilatations of bronchi and bronchioles as in bronchiectasis. Collapse prevents the retention of secretions and the absorption of toxins. This is supplemented by the stasis of the blood and lymph circulations, which reduce absorption and the rate of the circulation of the toxins.

As a result of the lung collapse there is immobilisation of that organ, or a general or local diminution of movement: a state of rest which is particularly valuable in the treatment of tuberculosis. Yet another benefit is the reduction in the size of the lung; this allows of the necessary contraction of the pathological fibrous tissue, which is otherwise kept in a state of tension and therefore of chronic irritation.

It is possible here to give the general indications only for collapse therapy. When a case of pulmonary tuberculosis has been progressing for a certain length of time, mechanical changes develop. There is progressive fibrosis, there is rigidity, thickening, and dilatation of the bronchial tubes, and there is the formation of cavities in the lung substance. These changes can be satisfactorily compensated by the efforts of the body if the disease is arrested in the earlier stages of their development. Once, however, the mechanical changes are established, some form of collapse therapy is necessary if the cavities and other spaces are to be obliterated, and the strain of the contracting, pathological fibrous tissue relaxed. The presence of cavities, whether active and secreting or dry, should always be an indication for collapse therapy, provided there are no contra-indications.

Collapse therapy should be attempted, the condition of the opposite lung permitting, in every case of chronic or subacute pulmonary tuberculosis which is stationary but not healed, or which is progressing despite sanatorium régime; it is indicated even in a few cases of acute infection; it should be attempted also in every case of progressive multilobar, but mainly unilateral bronchiectasis, and in certain cases of lung abscess. Further, collapse therapy is indicated in all cases of hæmoptysis which is endangering life or which is repeated or is persistent.

Collapse therapy must also be considered in connexion with many cases of pulmonary tuberculosis in which it is not necessarily essential in order to save life, and in which sanatorium régime may quite possibly arrest the disease. It must be remembered that many patients, once they leave the sanatorium, cannot continue to lead the sheltered life they have experienced there. Their home conditions may be unfavourable; they may have to return to work before the healing processes have consolidated; the work and climate may be unsuitable. For others the time factor is of immense importance, and it is necessary to return to work or to the family free from infection, and at the earliest moment possible. For yet others, the threshold of resistance is so low that a relapse occurs on the least variation from the strictest routine.

Operations Causing Collapse

The various methods of collapse therapy differ greatly in certain important general principles. By some of the methods, such as phrenicectomy and thoracoplasty, the diminution in the lung volume is produced by a process of collapse only, and the collapse is obtained by a readjustment of the surrounding walls. By others no change is produced in these walls, but the alteration in lung volume is effected by the introduction of a foreign body. Examples of this are artificial pneumothorax, oleothorax, and extrapleural pneumolysis. Of these, the last two produce their result by a compression force. With artificial pneumothorax the effect is by collapse, only when there are no adhesions and no extensive consolidation or dense fibrotic changes in the lung; otherwise, in addition to the collapse, there is often some compression force used.

The diminution of the lung volume by collapse is always preferable to that produced by compression. So long as a compression force is exerted there is a danger of complications. When, further, the

---

* The second George Haliburton Hume lecture for 1933, delivered before the Newcastle-upon-Tyne and Northern Counties Medical Society on Feb. 9th. Lecture I. appeared in our last issue.

By the old method a few very highly skilled surgeons could enucleate a proportion of tonsils with the guillotine, but were never quite sure of it. By the simple process of turning the guillotine round any average surgeon is able to enucleate the great majority of *all* tonsils and to know in which cases this is impossible. The method is more difficult to learn than dissection, it is not so showy, it needs as perfect an anæsthesia. By it, however, the tonsils can be removed as completely and more cleanly than by dissection. It does not, however, remove the lingual prolongation; but with the modern conception for the removal of tonsils not only is this not required, it is definitely considered an unnecessary interference.

I do not propose to discuss the two methods, but want to point out that they put in the hands of surgeons of different frames of mind methods for complete removal of the tonsils, and from that time they began to operate on younger and younger children and the number of operations insensibly went up until in 1914 it was, in my opinion, time "to stay our hands."[5]

The Tonsils as a Source of Sepsis

Why then do we remove tonsils to-day? Not because there is excess of lymphoid tissue but because the tonsils are "a source of sepsis." We postulate that there are living in the tonsil organisms harmful to the individual. It is not a clinical entity that can be diagnosed with accuracy, but a balance of probabilities. It is not a pathological entity, for the organisms present are various ones and cultivation can only show that any special organism was there at that moment. But it is an anatomical entity because it is at the bottom of the crypts that the source of sepsis lies, and removal of anything beyond the tonsil will have no advantage.

What are the criteria upon which you decide that tonsils are a source of sepsis? The criteria are two: the history of the case and the appearance of the tonsil. The history of the case is far more important than appearance of the tonsil. In 1912 Hajek of Vienna was teaching that if a person has three attacks of follicular tonsillitis in the year or two, with joint pains, the tonsils should come out. The older I get the more I am impressed by that teaching. With those cases of recurring follicular tonsillitis you are almost certain to get improvement from the removal of tonsils. When you do not get that history you are never certain that the desired improvement is going to come about. In my opinion children under the age of 5, 6, 7, or 8 should not have their tonsils removed if it can possibly be helped. They do not get acute follicular tonsillitis. They get droplet infection which gives them an inflammation of the upper respiratory tract and the tonsil takes a part in that infection. I do not think there is any doubt that when the tonsil takes its part in resisting that infection it is one of the most important factors in such resistance. I look upon the lymphoid tissue of the upper respiratory tract as one of the most important factors in enabling the child to develop its acquired immunity as distinct from the heredity immunity that it has when it is born. K. H. Digby[6] believes that the lymphoid tissue of the upper respiratory tract and particularly the tonsillar tissue actually makes the antibodies which cause that immunity. Practically it does not matter whether the tonsils are at that age simply filters to hold up the organisms or whether they are actually factories for the production of immune bodies, the result is the same; that they should be left alone. Clinical medicine fits in with theory in that acute follicular tonsillitis rarely occurs in small children.

There comes a time when instead of those tonsils resisting the invasion from without, the organisms have become settled in the bottom of the crypts and are themselves causing trouble. That is what we mean by the statement that the tonsils are "a source of sepsis." It is perfectly true that organisms may reside there and hæmatogenous invasions occur without local reaction, but in my opinion they very seldom do. Therefore, up to the age of 5, 6, 7, or 8 they should not be removed except on those rare occasions in which there is that history of recurring acute follicular tonsillitis.

What then is the best age of selection for that operation? I think the years between 12 and 15. By that time the lymphoid tissue of the tonsil has ceased to have any particular function. The child has developed its acquired immunity and the lymphoid tissue is not absolutely necessary to it as it was to the small child, and I find, personally, that the best results do come at about that age. I think the first two of these years are the better in those that leave school at 14, as once they have left school it is difficult for them to be able to get the time off from their work; but when the child remains at school until 15 or 16 the two latter are the years of selection. There are, however, a definite number of cases in which operation is indicated at the ages of 9, 10, and 11.

Conclusion

We may sum up thus. I do not believe that there is as yet any local treatment of the tonsils that can compare with operative surgery. There are two schools of operative surgery. It is no good trying to persuade the enthusiastic guillotinist that the dissection method is better. Contrariwise it is no good trying to persuade the dissection enthusiast to give up his method and take to the guillotine, no matter how perfect the operation may be. Size is no indication for removing tonsils to-day. The great indication is the history of recurring follicular tonsillitis, and this is even more important than any appearance of the tonsil. Children need lymphoid tissue in their respiratory tracts, and they do not get follicular tonsillitis in the earlier years of life. Therefore, operations on a child up to 5, 6, 7, and 8 should not be done unless it can possibly be helped and the need for it can be proved up to the hilt. After that age you come to the period where operative treatment on tonsils is a practical problem, but I think that the best results come after the age of 12 rather than before.

QUINQUENNIAL APPEAL FOR THE LONDON HOSPITAL.—Sir William Goschen, who succeeded the late Lord Knutsford as chairman, is making his first quinquennial appeal for the London Hospital. He points out that the cost of maintenance is £240,000 a year, but that the income always falls short, and that the hospital looks to the quinquennial appeal to establish an equilibrium. He computes that £200,000 of additional money will be required to maintain the institution for the next five years "and to keep abreast of the continuous developments of medicine and surgery." Last year there were 14,634 in-patients, while out-patients made 501,408 attendances.

THORACIC SURGERY

LECTURE II.—COLLAPSE THERAPY *

Under the term "lung collapse therapy" are included all those methods whereby a collapse of the whole or a part of the lung is produced in order to arrest or heal disease. The most generally used of these methods is artificial pneumothorax, first suggested by Carson of Liverpool in 1822, but not put into actual practice till 1888 by Forlanini. Prior even to this, in 1885, de Cérenville attempted a very limited thoracoplastic operation in an endeavour to arrest hæmorrhage. Thoracoplasty did not, however, become a recognised stereotyped operation till 1911; though Spengler, in 1890, coined the term "extrapleural thoracoplasty" for his rib-resection operation through a periscapular incision.

"Lung collapse therapy" includes also phrenicectomy and phrenic evulsion; operations which have become rapidly and increasingly popular since the variations in the anatomy of the phrenic nerve and the importance of the accessory phrenic were made clear by Felix in 1922.

Oleothorax, as a means of maintaining collapse of the lung is of even more recent date, and the appreciation of its value is due largely to the pioneer work of Bernou. He, however, was anticipated by de Carle Woodcock, who, as early as 1912, used paraffin oil and air for maintaining lung collapse.

Extrapleural pneumolysis, which is the freeing of the lung together with the parietal pleura from the chest wall in order to obtain a localised collapse, was first tried by Tuffier in 1892. It was not a success, because he relied on the air enclosed in the space to maintain the collapse. In 1910 he obtained satisfactory results by filling the space with fat. Three years later Baer tried paraffin as a filling. It is only recently that, with improved technique, the operation has begun to be regarded with favour by some surgeons.

Yet another operation which is being tried out is that of scalenectomy with division of the first rib, in an endeavour to supplement the effect of hemidiaphragmatic paralysis on the apex.

While there are other methods of producing lung collapse, these are the principal ones.

Objects of Lung Collapse

The most important of the benefits gained by collapsing a diseased lung is the obliteration of cavities, whether these are in the lung substance as in the case of tuberculous cavities and of abscess, or are dilatations of bronchi and bronchioles as in bronchiectasis. Collapse prevents the retention of secretions and the absorption of toxins. This is supplemented by the stasis of the blood and lymph circulations, which reduce absorption and the rate of the circulation of the toxins.

As a result of the lung collapse there is immobilisation of that organ, or a general or local diminution of movement: a state of rest which is particularly valuable in the treatment of tuberculosis. Yet another benefit is the reduction in the size of the lung; this allows of the necessary contraction of the pathological fibrous tissue, which is otherwise kept in a state of tension and therefore of chronic irritation.

It is possible here to give the general indications only for collapse therapy. When a case of pulmonary tuberculosis has been progressing for a certain length of time, mechanical changes develop. There is progressive fibrosis, there is rigidity, thickening, and dilatation of the bronchial tubes, and there is the formation of cavities in the lung substance. These changes can be satisfactorily compensated by the efforts of the body if the disease is arrested in the earlier stages of their development. Once, however, the mechanical changes are established, some form of collapse therapy is necessary if the cavities and other spaces are to be obliterated, and the strain of the contracting, pathological fibrous tissue relaxed. The presence of cavities, whether active and secreting or dry, should always be an indication for collapse therapy, provided there are no contra-indications.

Collapse therapy should be attempted, the condition of the opposite lung permitting, in every case of chronic or subacute pulmonary tuberculosis which is stationary but not healed, or which is progressing despite sanatorium régime; it is indicated even in a few cases of acute infection; it should be attempted also in every case of progressive multilobar, but mainly unilateral bronchiectasis, and in certain cases of lung abscess. Further, collapse therapy is indicated in all cases of hæmoptysis which is endangering life or which is repeated or is persistent.

Collapse therapy must also be considered in connexion with many cases of pulmonary tuberculosis in which it is not necessarily essential in order to save life, and in which sanatorium régime may quite possibly arrest the disease. It must be remembered that many patients, once they leave the sanatorium, cannot continue to lead the sheltered life they have experienced there. Their home conditions may be unfavourable; they may have to return to work before the healing processes have consolidated; the work and climate may be unsuitable. For others the time factor is of immense importance, and it is necessary to return to work or to the family free from infection, and at the earliest moment possible. For yet others, the threshold of resistance is so low that a relapse occurs on the least variation from the strictest routine.

Operations Causing Collapse

The various methods of collapse therapy differ greatly in certain important general principles. By some of the methods, such as phrenicectomy and thoracoplasty, the diminution in the lung volume is produced by a process of collapse only, and the collapse is obtained by a readjustment of the surrounding walls. By others no change is produced in these walls, but the alteration in lung volume is effected by the introduction of a foreign body. Examples of this are artificial pneumothorax, oleothorax, and extrapleural pneumolysis. Of these, the last two produce their result by a compression force. With artificial pneumothorax the effect is by collapse, only when there are no adhesions and no extensive consolidation or dense fibrotic changes in the lung; otherwise, in addition to the collapse, there is often some compression force used.

The diminution of the lung volume by collapse is always preferable to that produced by compression. So long as a compression force is exerted there is a danger of complications. When, further, the

---

* The second George Haliburton Hume lecture for 1933, delivered before the Newcastle-upon-Tyne and Northern Counties Medical Society on Feb. 9th. Lecture I. appeared in our last issue.

compression is exerted by a foreign body there is the added danger from the irritation of this foreign body, which may ulcerate through into the lung substance, causing a pleuro-pulmonary fistula. There is also the increased risk of an immediate reaction of the pleural membranes until such time as they acquire tolerance.

With an artificial pneumothorax the irritation of the foreign body, air, is minimal, except occasionally at the induction. If it is done in a case free from adhesions, and in which collapse only is needed, complications, though they may occur, are minimal. They are far more likely to develop if the air is used to compress the lung, and if a stretching force is exerted on the adhesions when present.

The coexistence of a foreign body and of a compression force is particularly exemplified in treatment by oleothorax and extrapleural pneumolysis. The irritation from the foreign body may cause disturbance from the onset, whilst the combination of a foreign substance, and the compression exerted by it, is a source of anxiety which persists indefinitely. With thoracoplasty, on the other hand, the collapse, being produced by a readjustment of the surrounding walls, causes no anxiety once the immediate dangers of the operation are passed. The operation of phrenicectomy is a very minor one in comparison, but the same applies to this also.

ARTIFICIAL PNEUMOTHORAX

It is possible now to consider in greater detail the various methods available for collapse therapy. Except for the operation of phrenicectomy, which can at best effect a partial diminution only of the lung volume, artificial pneumothorax is the simplest of all the methods. It has, moreover, the great advantage that it does not need the surgical training and experience required by all the other procedures. In the absence of pleural adhesions the collapse obtained by artificial pneumothorax is the most complete obtainable by any method. The collapse is not permanent; as the gas is absorbed the lung re-expands. This has the disadvantage that refills are necessary, at first at short intervals but with the passage of months at longer intervals. Another disadvantage is that the constant variability in the degree of collapse allows a repeated partial reopening of cavities. There is, on the other hand, the great advantage that at any time, should it be necessary because of the extension of disease in the opposite lung in cases of pulmonary tuberculosis, partial or complete re-expansion of the lung is possible.

For cases of bronchiectasis involving the larger bronchial tubes, the complete collapse which is possible by artificial pneumothorax is more successful than the collapse obtained by thoracoplasty, unless extensive and multiple operations are done; but for bronchiectasis which involves the smaller bronchi and bronchioles, and for those long-standing cases of pulmonary tuberculosis which are unilateral and have extensive secondary mechanical changes, the permanence of the collapse by thoracoplasty is preferable. Greater initial risks are run, but after that the patient is free from the constant incubus of recurring treatment, the possibility of complications and of the lung re-expanding despite all efforts to maintain the collapse.

The amount of tuberculous disease, either active or healed, which can be present in the contralateral lung and yet permits of collapsing the one lung by artificial pneumothorax, is considerable in selected cases. Massive hilum infection is a contra-indication, but scattered foci or a localised partial lobar lesion is not. In these cases it is often not wise to attempt a complete collapse of the lung.

When the disease is localised to a lobe, advantage can be taken of the contracting force of the pathological fibrous tissue to maintain a localised or selective collapse of the affected lobe. This is particularly advantageous when a bilateral simultaneous collapse by artificial pneumothorax is indicated.

By artificial pneumothorax it is possible to do a complete collapse, a generalised partial collapse, either intentionally or because limited by adhesions, a localised or selective collapse, or a bilateral partial collapse; it is also possible to influence a lesion, such as a cavity which is responsible for hæmoptysis, by a contralateral collapse. In doing this, advantage is taken of the mobile mediastinum which enables the variations in intrapleural pressure on the one side to influence also the pressures on the opposite side.

OLEOTHORAX

The chief use of oils for the production of an oleothorax is in the treatment of effusions, especially tuberculous ones and those complicating artificial pneumothorax. The oil used in these cases is olive oil with 5 per cent. gomenol. Its value lies in its antiseptic property, both olive oil and gomenol being lethal to tubercle bacilli and to pyogenic organisms. The oil and gomenol are, however, foreign bodies and, the gomenol especially, are apt to produce big reactions unless exhibited with the greatest caution until the membranes have acquired tolerance. The tolerance or intolerance must be tested by a maximum preliminary dose of 5 c.cm. only. Subsequent injections depend on the response to the first dose. Olive oil-gomenol is gradually absorbed. This is advantageous as it enables fresh quantities of the oil and gomenol to be introduced. In the presence of pus the oil becomes saponified, and in this state mixes much more intimately with the effusion.

The preliminary step in the treatment of a tuberculous pyothorax is to aspirate the effusion, with air replacement if large, and to adjust the intrapleural pressures. Five cubic centimetres of olive oil-gomenol are then run in. If the reaction is slight 30 c.cm. can be introduced at the next aspiration, and as much as 100 c.cm. at the third. The object is not to fill the pleural cavity with olive oil-gomenol but, by repeated aspiration, if necessary, and replacing with 200 or 300 c.cm. of the oil, to sterilise the cavity and arrest the recurrence of the effusion and the toxic state produced by the absorption therefrom.

Oil and gomenol are also used in cases of artificial pneumothorax either to supplement the collapse by the weight of oil, in the attempt to arrest the progressive re-expansion of the lung, or to replace the air to avoid the frequency of refills. For this purpose some use olive oil with a smaller percentage of gomenol, others, myself included, prefer paraffin with 1 per cent. gomenol. This is very slowly absorbed, but at the start is much more irritating. The maximum dose is 2 c.cm., and the increments are double the preceding amount.

Whilst the use of olive oil-gomenol is a most valuable procedure in the treatment of effusions and, if correctly used, without danger, the use of paraffin-gomenol as an accessory to or a substitute for artificial pneumothorax carries very considerable risks. These risks can, however, be controlled in certain cases; in those wherein it cannot, the paraffin-gomenol must be abandoned. It is so rarely that paraffin-gomenol can be used with safety to increase the compression beyond that possible by air that the attempt is hardly ever justifiable. The substitution of an oleofor a pneumo-thorax is indicated only when there is great difficulty in arranging for the maintenance of refills with air. If the mediastinum is rigid and the oil will be enclosed within unyielding walls there is a considerable possibility that, sooner or later, ulceration will occur at some point on the surface of the lung, and that, a broncho-pleural fistula forming, the oil will escape. Even though the oil is at once withdrawn, infection will pass from the lung into the pleural cavity and an empyema result. This danger of perforation does not appear to exist when there is a mobile mediastinum, and the patients gain considerably from the constancy of the collapse maintained by the oil. Oleothorax is, in my opinion, contra-indicated as a possible means of arresting a progressive, adherent pleurisy.

THORACOPLASTY

Thoracoplasty is the alternative to pneumothorax when a generalised or an extensive localised collapse of the lung is required, and adhesions prevent the separation of the pleural membranes by air. Its use in tuberculous cases must be most strictly limited to those cases in which there is no active disease, and no extensive fibrotic change in the opposite lung.

The paravertebral, extrapleural thoracoplasty consists in the resection of the posterior ends of the ribs right back to the transverse processes of the vertebræ. The standard ten-rib thoracoplasty, which was done whatever the extent of the lesion, is now modified to suit the requirements of the individual case. If the lesion is confined to the upper lobe, an eight-rib operation will suffice; for apical lesions a six-rib or even a five- or four-rib thoracoplasty may produce the necessary collapse. This is a big advance as, with the lesser number of ribs which need resecting, there is a larger proportion of cases in which the operation can be done in one stage; there is also less shock and considerably less risk of pneumonic complications. The reduction in the number of ribs resected makes more feasible and safer yet another modification which is of great practical value. A much greater length of each rib can be removed in the case of large thin-wall or smaller thick-wall cavities. This produces better mobilisation, and therefore a more complete collapse of the affected part of the lung.

In my opinion the operation of thoracoplasty offers less risk to the patient than does the endeavour to convert a pneumothorax collapse, which is incomplete and inefficient owing to multiple adhesions, into a complete one by intrapleural pneumolysis, especially when the adhesions are broad and comparatively sessile.

The very successful results which are obtained by the local thoracoplastic operations makes this operation unquestionably superior to that of extrapleural pneumolysis, which necessitates the introduction of a foreign body and the production of a compression force instead of a collapse.

Most surgeons combine gas-and-oxygen with the local and regional anæsthesia. My own technique is to give nembutal, to do a complete local and regional anæsthetisation of the area, and then to keep the patient unconscious with chloroform vapour; rarely more than two drachms are needed. With this technique there is surprisingly little shock.

The deformity resulting from the operation is small, and, when the patient is dressed, is unnoticeable. The greatest sinking in is in the axilla and at the back. There is no dropping of the shoulder. The prevention of stoop and of obvious scoliosis rest entirely with the patient, and with care need not occur. There is no loss of movement of the arms, and the use of them is limited by the disease only.

The presence of contralateral activity is usually regarded as a definite contra-indication to thoracoplasty. In cases of serious hæmoptysis a localised area of active tuberculous disease in the opposite lung, which is non-progressive, is often a less danger to the patient than is the thoracoplastic operation to anticipate a fatal hæmorrhage. Lately, bilateral localised thoracoplastic operations for bilateral apical lesions have been done with success.

The mortality of the complete thoracoplasty is between 4 and 5 per cent. in selected cases. This is not high considering the seriousness of the alternative if the operation is not done. Of the four cases for which I did a one-stage 10-rib thoracoplasty in 1922 when I again started operating, all especially selected chronic but progressive fibrotic cases, three are still alive and working. The fourth died within a year from tuberculous enteritis.

PHRENICECTOMY

Phrenicectomy has come into vogue because of the simplicity of the operation and the great benefits which may be expected of it in many types of case. It is an expectation not always realised because there are so many factors which influence the result, and those cannot always be correctly gauged. In some cases it is possible to be almost certain of the result of the hemidiaphragmatic paralysis; in others there is considerable uncertainty of success. The operation is justifiable when there is the hope of benefit; should it fail, the worst factor is the disappointment experienced by the patient.

Prior to the researches of Felix on the anatomy of the phrenic and his discovery of the frequency and extent of the variations of the accessory phrenic nerve, the failures due to absence of paralysis of the muscle were so frequent that the gamble entailed was seldom worth the attempt. Our present more exact knowledge and the operations planned to overcome the difficulties ensures the paralysis of the hemidiaphragm in the great majority of cases.

The true phrenic nerve may run a somewhat abnormal course in its relation to the scalenus anticus muscle, but of greater importance are the accessory phrenic bundles. Whilst not always present, there is often one, sometimes two, and on occasion even more separate nerves which course down external to the true phrenic and join it usually shortly after crossing the subclavian vein. The true and accessory phrenics frequently form a loop round the vein, the one crossing in front and the other behind it. Occasionally they loop round the internal mammary vessels. The importance of this when applying traction on the phrenic nerve is obvious.

Destruction of the continuity of the phrenic and accessory phrenic nerves produces paralysis of the corresponding dome of the diaphragm and atrophy of the muscle. The muscle, losing its tone, becomes flaccid and is displaced upwards into the thorax, being pushed up by the intra-abdominal positive pressure and drawn up by the intrathoracic negative pressure. There is frequently a paradoxical movement of the dome. If there is considerable thickening of the pleura and dense basal adhesions, this will greatly limit the displacement.

The benefit derived from hemidiaphragmatic paralysis is twofold. There is the diminution in the hemithorax and corresponding reduction in the lung volume as a result of the rise of the muscle; there is also abolition of the drag on the base of the lung, pleural membranes, and pericardium, as a result of the paralysis. This latter is independent of the extent of the rise and is shown by the reduction or disappearance of such symptoms as pain, drag, dyspnœa, and tachycardia. The extent of the lung collapse is, however, directly dependent on the height to which the dome rises. This collapse is moreover not necessarily limited to the base, it may exert a marked influence on the apex of the lung, for which reason apical lesions and cavitation are among the indications for phrenicectomy.

Briefly stated, phrenicectomy, in order to paralyse the dome of the diaphragm, is indicated—

(1) In those cases for which artificial pneumothorax has been tried but found impracticable, except for those with large cavities or small but thick-wall ones, and those with considerable bronchial changes for which a more extensive collapse as by thoracoplasty is the alternative.
(2) In a few cases as an alternative to artificial pneumothorax, particularly in those in which there is a moderate-sized lesion only with fibrosis either at the base or the apex.
(3) For basal cases of bronchiectasis in the hope of preventing the necessity for a more extensive operation.
(4) In combination with artificial pneumothorax of the contralateral lung, especially when there is a recent basal lesion.
(5) In cases with hæmoptysis which cannot be controlled by pneumothorax and do not necessarily need, or cannot tolerate, a more extensive collapse.
(6) In association with artificial pneumothorax in order to supplement the basal collapse, or to reduce the size of the hemithorax when the lung is re-expanding according or contrary to plan. Occasionally also to help increase the interval between refills.
(7) For the treatment of certain symptoms such as cough due to irritation of the diaphragm and for the same reason of persistent uncontrollable hiccough. For pain and sensation of drag following on old pleurisy or a post-operative scar (as after basal hydatid or lung abscess). Also for tachycardia due to pericardial adhesions, dyspnœa due to pleural adhesions, and vomiting, when repeatedly associated with coughing.
(8) In association and as a preliminary to partial thoracoplastic operations to assist the lung collapse. But not in association with 10- and 11-rib thoracoplastics, because the resulting complete immobilisation of all the walls produces too pronounced a lymph and blood stasis.
(9) As a prophylactic against the development of bronchiectasis after an unresolved pneumonia, and in all cases with excessive basal fibrosis.

There are two ways of destroying the continuity of the phrenic nerve. The nerve can be evulsed, or a length can be cut away from the main nerve and from all accessory branches.

The object when doing a phrenic evulsion is to pluck the nerve out from its attachment to the diaphragm or to remove at least 11 cm. of its length. By so doing, all accessory branches are disrupted from the main trunk. It is only in the most exceptional case that an accessory nerve joins up with the main trunk at a point distal to 10 cm. from the point at which the nerve is found in the neck and cut. Evulsion has certain disadvantages, some of them grave. When the nerve is adherent, it is not infrequent for it to break at a point 7 or 8 cm. from the point of division. It is then not practical and highly dangerous to attempt to find the distal end. If the nerve and a stout accessory branch form a loop round the subclavian vein or the internal mammary vessels, there is the risk that these may be torn, as has happened, with fatal results. The nerve may be adherent to the mediastinal or visceral pleura, and, when ruthlessly evulsed, may tear the membrane and cause a spontaneous pneumothorax, or expose the mediastinal areolar tissue and lead to a serious or fatal mediastinal emphysema. The operation of evulsion, moreover, is always painful when the nerve is adherent.

The radical operation necessitates a slightly longer incision so that, after a length of the phrenic nerve has been cut away, the brachial plexus can be freely exposed, all accessory branches can be found, and lengths of these, and of the nerve to the subclavius, can be excised.

In either case the operation is done under local anæsthesia. The usual incision is a transverse one, but I prefer an oblique one about 2·5 cm. in length along the posterior border of the sternomastoid muscle, extending down to about 1 cm. above the clavicle.

SCALENECTOMY

After the dome of the diaphragm has been paralysed by phrenicectomy, some compensation for the loss of movement may result from an increase in the action of the intercostal muscles, and it is possible, therefore, that part of the advantage gained is thus later again lost. The action of the scalene muscles is antagonistic to that of the intercostal muscles; these muscles brace the first two ribs against the downward pull of the intercostals. After division of the scalene muscles there is a slight downward action of the upper ribs during inspiration, which is enhanced by division of the first rib. This is the raison d'être of the operation of scalenectomy.

The value of phrenicectomy in producing collapse of the apex of the lung, especially when there is localised fibrosis which assists in this selective collapse, is an accepted fact. An apical lesion, especially if there is a thin-wall cavity, is therefore an indication for hemidiaphragmatic paralysis. It is in this type of case when, particularly, it is felt that the rise of the dome alone will not be sufficient to effect the collapse required to obliterate the cavity that scalenectomy has been tried.

Considerable benefit has undoubtedly been obtained in many cases by the combination of these two methods of collapse, which are obtained by the one operation. The number of cases on which it has been tried is, however, few. In my own 11 cases I find it difficult to decide to what extent the improvement has been due to the phrenicectomy alone, or to the added collapse obtained by the division of the scalene muscles and first rib. My impression is that in some of these cases a part, at any rate, of the benefit must be attributed to the scalenectomy, but that its results are not in any way comparable to a four-rib apical thoracoplasty. In a recent paper L. Fisher reports 31 cases of which 18 had had a phrenicectomy done six months to three years previously without satisfactory result. He reports striking improvement after division of the scalene muscles.

Scalenectomy has the advantage of being an operation which can be done entirely under local anæsthesia, and which produces practically no shock.

Access to the muscles is obtained through an incision 5 cm. long, along the posterior border of the sternomastoid muscle, extending down to the clavicle. The scalenus anticus is first exposed, the phrenic nerve and any accessory branches are excised, the muscle is dissected free at its insertion into the first rib between the subclavian vessels, is detached from the rib, and then 2 cm. of its length are excised. The brachial plexus is drawn inwards, the greatest care being taken not to damage the long thoracic nerve which traverses the scalenus medius muscle. This muscle is traced to its insertion into the neck of the first rib from which it is detached, at first with the knife and then with the raspatory. A length of this muscle also is cut away. The neck of the first rib is now exposed at the bottom of the wound and is freed from its periosteum, bearing in mind the close relationship of the eighth cervical and first dorsal and first intercostal nerves.

EXTRAPLEURAL PNEUMOLYSIS

The importance of treating, the imperative necessity of obliterating, cavities is still unrealised to a grave extent. Every cavity, whether actively secreting or dry, is a menace to the patient. It is estimated that 90 per cent. of cases with cavities die within five years, Thin-wall cavities will sometimes heal with sanatorium treatment alone. When the walls are fibrosed some form of collapse is essential. The value of artificial pneumothorax and of multiple rib resections has already been discussed. For small apical cavities phrenicectomy alone, or supplemented by scalenectomy, may in some cases suffice. The operation of choice for apical cavities, in unilateral cases, is unquestionably, in my opinion, the localised apical thoracoplasty with extensive resection of the upper ribs, made possible by stripping the origin of the second and third digitations of the serratus magnus muscle off the second rib.

This, however, is not a practicable operation when there is active disease in the contralateral lung, nor when the patient is over 45 years of age. It is for these cases essentially that the operation of extrapleural pneumolysis must be considered. By this operation the lung is collapsed together with the parietal pleura; the space thus formed between the membrane and the ribs being filled with a foreign substance. That most frequently used is paraffin, but occasionally living grafts of the pectoralis muscle or of the breast are made use of. Whilst less irritating than paraffin, they do not maintain their volume. Paraffin may cause ulceration through the fused pleural membranes into the lung cavity at any time during the succeeding months or even years. Should this happen, the paraffin must be removed and the wound packed with gauze until the hole becomes filled with granulation tissue.

The insertion of the paraffin wax, which should have a melting point of about 50° C., is best done after resecting a short length of the second rib, supposing a collapse of the apex is required (apicolysis). The posterior layer of the periosteum is divided and then the parietal pleura and lung are stripped off the endothoracic fascia. Great care must be taken that the lung is not torn or the cavity opened.

A paraffin filling is also used as an alternative to a supplementary rib resection after a thoracoplasty, when a sufficient collapse has not been obtained by the original operation.

What Collapse Therapy Can Do

When used in conjunction with sanatorium régime for the treatment of pulmonary tuberculosis, collapse therapy will arrest the disease in a considerable number of cases doomed otherwise to a lingering illness, terminating in death.

The value of surgical treatment is long past the experimental stage. Collapse therapy will save life in many cases, restoring the individual to working capacity. For many it will enable healing to take place, and will shorten the period of treatment; for some it will make life possible among home surroundings, which would otherwise be denied because of the risk of infection; whilst for yet others it will protect or offer greater or a longer period of protection against recurrence. The more drastic forms of collapse therapy in the treatment of pulmonary tuberculosis take a certain toll from individuals who are permanent invalids, but give to the greater number life and a state of health otherwise unobtainable.

This country is still sadly behind America, Scandinavia, and other countries on the continent. Wales and some counties of England and Scotland give their tuberculous patients every modern aid in treatment. It is time that all follow this example, and offer to their patients those opportunities for the restoration of health and the saving of life which are available by collapse therapy.

AN ADVANCE IN THE SURGERY OF CLEFT PALATE *

By David Levi, M.S. Lond., F.R.C.S. Eng.

SURGEON TO THE INFANTS HOSPITAL, LONDON; DEMONSTRATOR OF ANATOMY, ST. MARY'S HOSPITAL MEDICAL SCHOOL

About 500 children are born each year in England with either a cleft palate or a hare-lip. In France, Peron [1] reviewed 100,000 births and found that one child in 942 was born with a similar deformity. Davis [2] in America found one malformation in every 915 births. These failures of embryonic fusion occur in connexion with the superior maxilla and may be classified, according to Brophy,[3] into:—

1. *Clefts of the soft palate only.*—The cleft may vary from a bifid uvula to a complete cleft extending through the whole substance of the soft palate. This type occurs in 20·8 per cent. of these malformations, according to Veau's [4] statistics.
2. *Clefts of the soft and hard palate,* which occur in 30·8 per cent. of patients.
3. *Complete unilateral cleft of the palate associated with a hare-lip;* the commonest type of malformation, which accounts for 38·8 per cent. of patients. The cleft of the palate involves the alveolar arch and extends through into the anterior nares. There are many variations of this type of deformity; they depend in the main on the degree of approximation of the cleft hard palate with its fellow of the opposite side.
4. *Complete bilateral cleft palate and double hare-lip;* the rarest type, present in only 9·6 per cent. of patients. Many variations of this type exist. It is essentially a deformity associated with maldevelopment and malposition of the premaxilla, and may or may not be associated with clefts of the hard palate itself.

The clinical manifestations of these conditions—the ugly face, the difficulty in eating, and the poor quality of the speech—are so well known and obvious that they do not warrant further description. In 1861 M. Langenbeck, a German surgeon, described his operation for closure of the gap in cleft palates. The essential steps of this method consist of:—

1. An incision is made in the muco-periosteum of the hard palate internal to the alveolar arches. Care must be taken not to injure the posterior palatine artery.
2. The muco-periosteum is stripped from the hard palate.
3. The internal borders are pared.
4. The buccal mucosa is sutured.

This operation, which has now become one of the classical procedures of surgery, has stood the test of over half a century, and is still the operation performed by many surgeons in England to-day, but it does not give universally satisfactory results. Many have been disappointed at the frequency with which the palate breaks down. Those who have followed their patients through childhood to adult life cannot have failed to be uneasy at the poor functional result, the nasal intonation of the voice, and the inability to pronounce many of the consonants.

Many attempts have been made to supplant Langenbeck's operation, and the names of Brophy and Arbuthnot Lane have already passed into history. Brophy advocated closing the cleft by forced apposition of the superior maxillæ, and substitutes a deformed alveolar arch for a deformed palate. Lane's flap operation was planned without due regard to the blood-supply of the flap and, if the child recovers from the initial severity of this procedure, the flap which forms its new palate nearly always sloughs away. Thus Langenbeck's operation has, until to-day, remained the operation of choice for cleft palate.

---

* Post-graduate lecture delivered at the Infants Hospital.

VEAU'S OPERATION

Victor Veau has contributed a valuable step to the advance of cleft-palate surgery, and his operations have been performed at the Infants Hospital. In principle, they consist of suture of the nasal mucosa, suture of the muscles of the soft palate, and suture of the buccal mucosa. Referring to these three rows of sutures he states that "La première est utile, la deuxième est indispensable, le troisième est superflue." Veau epithelialises the raw surface of his flaps, and thus reduces cicatricial contraction to a minimum.

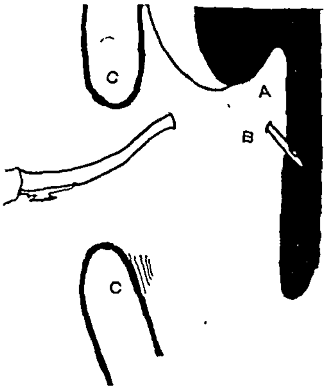

FIG. 3.—Cleft palate with Reverdin needle in place.
A = soft palate; B = Reverdin needle; C = alveolar arches.

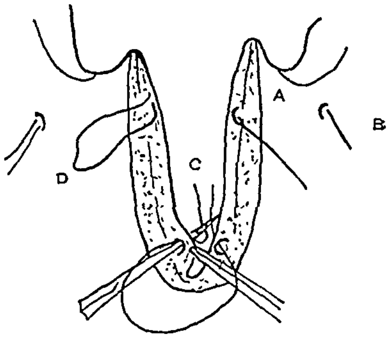

FIG. 5.—Cleft palate. Margins of cleft have been split. Muscle suture placed in right-hand side.
A = soft palate; B = muscle suture in place on right; C = nasal mucosal suture; D = silk loop.

It is our practice at the Infants Hospital, and I think it is an almost universal one, to repair the hare-lip soon after the infant has recovered from the shock of its birth and has become acclimatised to its new surroundings. The practice with regard to the repair of cleft palates varies widely, but the tendency has been to suture these clefts early in the infant's life. Langenbeck's operation was performed when the child reached the age of 2 or 3 years. Now palates are repaired when the infant is ten months to a year old, before it has been taught to speak.

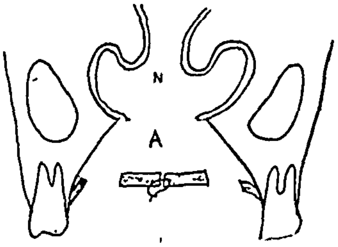

FIG. 7.—Langenbeck's operation. Note dead space A.
N = nose. A = dead space.

Veau does not consider it necessary to remove either the tonsils or the adenoids, as he thinks that both these structures fulfil a useful purpose in helping to close the post-nasal space, but if they show signs of infection, as exemplified by enlarged glands at the angle of the jaw or muco-pus in the post-nasal space, then the tonsils should be dissected out and the adenoids curetted. It is our practice here to remove the tonsils in all cases, at least two months before the contemplated attack on the palate. This interval enables the structures operated upon to return to their pristine suppleness. All signs of inflammation in the bed of the tonsil should by then have disappeared. A clean mouth is a very material asset to the suture line in the palate. Any carious teeth must be removed. Nursing plays an important part in the success or failure of the operation. Often the mother makes a most successful nurse, but this depends entirely upon her temperament. In all circumstances the child must be familiar with its surroundings and attendants, and thus must be admitted to the hospital several days before the operation. Operation should if possible be planned to take place in the spring or summer.

Veau has devised four main types of operation, one type for each subdivision into which cleft palates have been classified. Two of these operations will be described in detail.

OPERATION FOR CLEFT SOFT PALATE

The child is given an injection of antiscarlatiniform serum (Dick) and is allowed barley-sugar and glucose before operation; it is neither starved nor purged. Anæsthesia is induced with ethyl chloride, and this is followed by ether. The child is put in the dorsal position with a sandbag under its shoulders and its head extended. Care must be taken not to hyper-extend the head, as this may interfere with respiration. The mouth is kept open by means of a Waugh's gag, and the anæsthetic—oxygen blown through ether—is delivered through a tube placed in one nostril.

The surgeon sits at the head of the table. The aim of the operation is to suture the soft palate in three layers. The first layer is composed of the nasal mucous membrane (Fig. 1); the second is a muscular tension suture (Fig. 2); and the third closes the buccal mucosa.

A curved Reverdin's needle is entered on the buccal surface of the soft palate near the little depression made

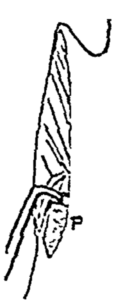

FIG. 10.—Method of separating muscle from posterior surface of hard palate.
P = hard palate.

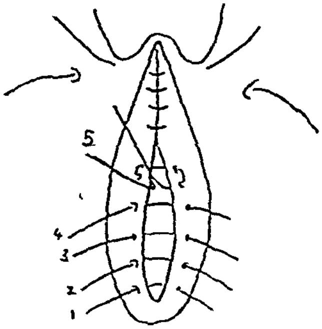

FIG. 11.—Nasal mucosa sutured. Fifth knot to be tied on nasal surface of palate.

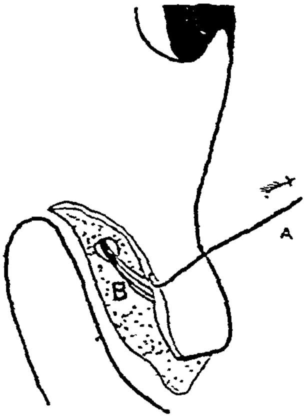

FIG. 12.—Arterial pedicle, B. Hook, A. The pedicle is stretched by pulling the hook inwards and downwards.

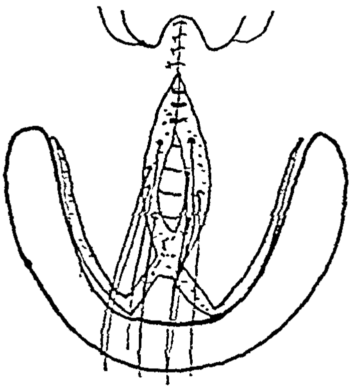

FIG. 13.—Soft palate sutured. Sutures in nasal mucosa before insertion through the palatal flaps.

by the upper end of the anterior pillar of the fauces and the side of the inferior maxilla (Fig. 3). The needle is pushed deep to the muscles of the palate, between them and the nasal mucosa. The index-finger is placed on the nasal aspect of the soft palate to guide the needle point. The point of the needle is brought out on the buccal surface of the palate 1 mm. from its internal free edge. The surgeon must make sure the needle envelops the muscles by palpating its concavity with the index finger which was placed on the posterior surface of the soft palate; if the muscles are superficial to the needle they are readily felt. It may be necessary to make three or four attempts before the needle has been correctly placed. This manœuvre is easier in large muscular palates than in the palates of young infants. The needle must be passed when the soft palate is flaccid. The right suture is easier to pass than the left. Before passing the catgut the edge of the soft palate should be incised. The incision is not a paring operation (Fig. 4). The edges are not cut away and the mucosa is not resected. After the incision has been made the edges of the wound open out and all tissues are thereby conserved. It is my practice to detach the muscular elements of the soft palate from the posterior end of the bone of the hard palate with the crochet. Unless this is done there is an undue amount of tension at the anterior extremity of the wound.

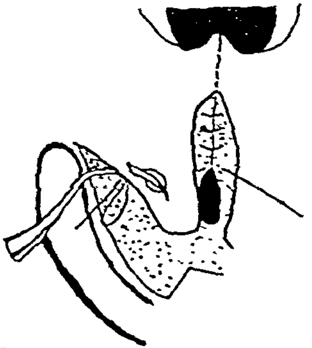

FIG. 14.—Showing method of passing the suture to hold palatal flap to nasal mucosa.

Incision of the uvula is difficult. It is made first while the palate is steadied by the needle, and is then carried up towards the cleft. If the cleft is short the knife may be carried to its summit. If the cleft is a long one it is not wise to incise the edges with the needle in place, as the tissues are fixed by the bone as well. The incision should be confined to the buccal mucosa and a few fibres of the muscle. A piece of wire† without kinks or twists in it is now placed in the eye of the Reverdin needle and drawn into position. Similar measures are carried out on the left side. The only point of difference between the two sides is the manner in which the catgut is passed. On the left side a silk loop is left in place (Fig. 5). The summit of the cleft is now split. In clefts of the soft palate the edges tend to come together in front. The crochet is used to pull the buccal edge out and the incision is completed with the knife.

Suture of the nasal mucosa is an important step in the operation. Ophthalmic silkworm gut is used, and the stitches are passed with a Reverdin needle. The silk must be tied on the nasal side of the *soft palate*. and with this object in view the Reverdin needle is passed threaded. The needle pierces the cut edge of the mucosa at 1 mm. *from* its free border, and the silk is caught and pulled from the eye of the needle on the nasal side of the palate with a pair of forceps. The knots are tied as shown in the diagram (Fig. 6). It is important when tying the knot to avoid lifting the soft palate by pulling the ends of the silk upwards. In small mouths one thread may be fixed over a finger in the nasopharynx while the other is tightened by a hand outside the mouth. These nasal mucosal sutures are carried back to the base of the uvula. The uvula is difficult to suture. A suture should be placed through its tip. This

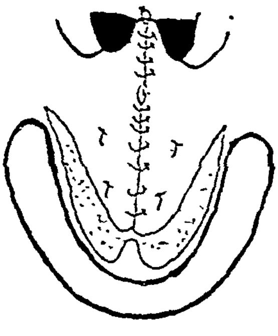

FIG. 15.—The completed palate.

---

† We use No. 00 catgut instead of wire.

suture is not tied but is used as a retractor, and the remaining sutures are inserted *in the posterior or nasal surface* of the cleft. Sutures should now be placed along the anterior aspect of the uvula. These sutures should be placed by a needle which takes both edges of the cleft at one thrust.

The *muscular suture* is the most important step in the operation. It surrounds the muscles of the soft palate (Figs. 1 and 2). Many of these muscles lie in the pharynx—e.g., the tensor palati and levator palati muscles—and only their tendons are inserted into the soft palate. Hence a suture of this muscular element in the soft palate does not strangle the muscles but draws some of their tendinous fibres tightly together. It is essential to make quite certain that all the muscles and tendons in the soft palate are encircled by the suture, and the suture does not include either buccal or nasal mucosa (Fig. 1).

One end of the suture is placed in the silk loop, which has already been passed through the left side of the soft palate. Care is taken to make quite certain that the catgut is free, and it is then drawn through the left half of the palate.

The ends of the catgut should now be passed between the buccal mucosa and the muscle, so that the suture may be knotted in the midline to include only the musculature of the palate. This is done by passing the needle through the orifice from which the catgut is projecting and passing it inwards immediately below the buccal mucosa. The needle is withdrawn with a silk loop in it. The catgut is placed in the silk loop and is thus made to encircle the muscles. The same manœuvre is carried out on the opposite side of the palate, and the ends of the catgut are tied as for the first stage of a reef knot. The knot is pulled tightly and tied.

Buccal suture.—When the catgut suture has been tightened the buccal mucosa suture is inserted. Nothing, however, is asked of this suture.

OPERATION FOR CLEFTS OF THE HARD AND SOFT PALATES

The constituents of the soft palate are elastic, those of the hard palate are not. The great drawbacks to Langenbeck's operation are the large dead space A (Fig. 7) which is left, and the manner in which the palatal flaps are left with large exposed raw areas which heal with much cicatrisation.

Veau's operation is not a copy of Langenbeck's operation, for Veau overcomes these two fundamental objections. *He obliterates the dead space and he covers the raw area in his palatal flaps with nasal mucosa* (Fig. 8). The closure of the soft palate is a suture operation, that of the hard palate is an autoplastic flap operation. These flaps are lined on each side by mucosa, and come together easily in front, but there is a little tension posteriorly.

A technique similar to that previously described is used.

The operator commences by attacking the soft palate. The incisions of the edges of the cleft are carried up to the cleft in the hard palate. As the bone is approached and passed, this procedure becomes progressively more difficult. It is important not to split the mucosa, which is bound down to the underlying bone, so that when an incision is made in it the wound does not gape as the incision in the soft palate does; also the field is obscured by hæmorrhage.

For these reasons *it is better to separate the mucosa* of the hard palate with the crochet rugine before incising it. The crochet is introduced into the wound at the posterior end of the hard palate and is kept in close apposition to the bone (Fig. 9). The detachment of the mucosa is facilitated by the presence of a few muscle-fibres in the submucosa round the edge of the cleft hard palate (Fig. 10). This muscle of the cleft has been described and emphasised by Veau. As each 5 mm. or so of mucosa is raised by the crochet it is incised with the knife. The mucosa is detached from both nasal and buccal surfaces of the palate.

The nasal mucosa becomes more adherent anteriorly and is liable to get pricked by the crochet. Therefore the crochet must always be kept close to the superior aspect of the palate. The mucosa is stripped by movements of the crochet as a whole and not by the irregular motion of its point alone.

The left edge of the cleft should be incised first and then the right. It is essential for the operator to be ambidextrous. The right hand is used to incise one side and the left hand for the other. The mucosa becomes more adherent to the bone anteriorly, and difficulty may be experienced in making the incision meet round the front edge of the cleft.

Nasal suture.—When the edges of the cleft have been incised and the nasal mucosa has been elevated, the cut edge of the mucosa will be found to overlap the edges of the cleft in the bone by 2 to 3 mm. The sutures of the nasal mucosa of the hard palate are placed so that the knots are tied in the buccal surface, for these sutures act as points to which the palatal flaps are fixed. As a routine four stitches are employed, and are passed with a small curved needle on a holder. The sutures are not tied and the ends are left long (Figs. 11 and 13). The catgut suture in the soft palate is then completed and tied, and a fifth suture, placed in the nasal mucosa at the junction of the hard and soft palate, is tied so that the knot lies on the nasal surface of the palate (Fig. 11).

The operation has been relatively bloodless, but when the palatal flaps are raised hæmorrhage is sharp; it may be controlled by compression of the flap against the bony resistance of the palate. It is useless to attempt to ligate bleeding points. An incision is made round the alveolar margin very near the teeth, starting just posterior to the alveolar process of the superior maxilla and carried forwards external to the posterior palatine foramen. The flap thus delineated is raised from before backwards, care being taken *to avoid injury to the vascular pedicle coming from the* posterior palatine foramen. Hæmorrhage is severe but should be ignored. The crochet should be passed just external to the vascular pedicle and this pedicle should be elongated by gentle traction (Fig. 12). The pull should be steady and progressive. When this has been done the flap is compressed by means of the ball of the thumb against the hard palate. This pressure should be maintained for half a minute at least, to ensure hæmostasis. The procedure is repeated on the opposite side (Fig. 13).

The flaps are now placed in position by means of the four untied sutures which have been passed through the nasal mucosa. The most posterior of these four nasal sutures is isolated and the ends are passed through the buccal flap of one side behind the arterial pedicle (Fig. 14). The next succeeding suture is fixed in a like manner through the opposite buccal flap. The next suture is passed much more anteriorly through the buccal flap originally treated. Thus each buccal flap has two sutures—an anterior and a posterior—which tie it to the nasal mucosa. All four sutures are placed in position before any are tied. All that now remains is to suture the palatal flaps in the midline. Anteriorly this is very easy; posteriorly there is a little tension, the amount varying with the efficiency with which *the arterial pedicles have been elongated.* If a small gap persists it is of no very great moment (Fig. 15).

COMPLETED PALATE

Careful after-treatment should be instituted. The child should be kept quiet with a little tincture of opium for the first 24 hours, and glucose and sodium bicarbonate may be given per rectum. Slops and soft foods should be allowed, and after each feed some sterile water should be given. The palate is not inspected until the eighth or tenth day. Small holes in the new suture line should not occasion undue alarm, for they tend to close spontaneously. I have so far been unable to judge the functional result of this procedure as all the infants operated upon have been too young to talk.

WORK OF EYE HOSPITALS.—A number of eye hospitals have recently held their annual meetings. Of the Glasgow Eye Infirmary it was reported that the out-patient department is "tremendously overcrowded," but that an appeal for £25,000 for extensions had produced only £7000, with which it is proposed to do work imperatively necessary.—Last year the Birmingham and Midland Eye Hospital prescribed nearly 10,000 pairs of spectacles. There is "considerable physical and monetary strain," and great need for a scholarship or fund for research to enable younger surgeons "to study at home or abroad, or to investigate some special question in ophthalmology in the laboratory or clinic."—Bristol Eye Dispensary (which is said to be the only institution of the kind open on Sunday) last year treated 1775 new patients.—At Southampton Free Eye Hospital in 1932 there were 377 in-patients and over 9000 out-patients. More than half the cost of running the institution is paid by the patients. The medical staff is asking the committee to consider the desirability of establishing a clinic for the ocular training of children who squint.

A CASE OF DYSINSULINISM

BY W. J. GRIFFITHS, PH.D. LOND.
ASSISTANT IN THE DEPARTMENT OF CHEMICAL PATHOLOGY, ST. THOMAS'S HOSPITAL
AND
O. L. V. DE WESSELOW, D.M. OXF., F.R.C.P. LOND.
DIRECTOR OF THE MEDICAL UNIT AT THE HOSPITAL

APART from those described by Ramsbottom and Eastwood, and by Moore and O'Farrell, no cases of spontaneous hypoglycæmia appear to have been reported in this country. The total number recorded in America and elsewhere is still small, but the condition is probably frequently overlooked and the symptoms are likely to be regarded as the product of the patient's imagination. We are indebted to Dr. J. J. Spira for the opportunity of studying the following case in which he had diagnosed the hypoglycæmia syndrome.

CASE RECORD

The patient is a married woman, 44 years of age. Her mother suffered from hypertension and died from a stroke at 47. There is no family history of glycosuria or diabetes.

The patient has had three healthy children and six early miscarriages, the miscarriages alternating with the normal pregnancies.

Her medical history has been eventful. At 25 she was curetted for dysmenorrhœa; but the periods are still irregular and usually accompanied by attacks of sickness, epigastric and lumbar pain, and abdominal distension.

At 30 she was operated on for epigastric hernia. At 38 she had an attack of typhoid. In 1930 her tonsils were enucleated. For six years she has suffered from frequent and painful micturition, and in 1931 had a definite attack of pyelitis for which she was treated with ureteric catheterisation and pelvic lavage. Later in the same year an ischiorectal abscess developed and was incised. Since the age of 30 she has suffered from mucous colitis and has passed mucous casts. This condition has been somewhat improved by colonic lavage.

In 1926, shortly after her attack of typhoid, an abnormality of her sugar metabolism was first noticed. A Swiss physician whom she had consulted found a reducing body in the urine. She was treated by him for "glandular anæmia" with thyroid and parathyroid, and was given a course of insulin, 10 units on alternate days. During this treatment she experienced several insulin reactions.

The maximum weight which she has ever attained was 10 st., at the age of 19. Since her miscarriages she has lost weight steadily, and in 1928 she was only 6 st. 3 lb. At the time of writing her weight is 7 st. 9 lb., and her height 5 ft. 5 in.

The attacks of which she now complains can be traced back for at least four years and probably longer. At first intermittent, they have become steadily more frequent and more severe. Noticeably severe reactions occurred at the time of the ischiorectal abscess (1931). She is now getting a slight reaction almost every day. They usually occur at about 12 noon but occasionally before tea, at 10 P.M., and in the early hours of the morning. They are aggravated by exercise and are relieved by rest in bed. She describes them as resembling the results of an overdose of insulin. At the onset of the reaction there is a feeling of intense depression. This is succeeded by an attack of giddiness, breathlessness, and a sense of impending dissolution. The memory and intelligence are temporarily impaired. There is marked tremor of the hands, pallor, tachycardia, and sweating. She becomes ravenously hungry. The reaction clears up in ten minutes after taking glucose in solution, rather more slowly if it is ingested in solid form.

Sugar was found in the urine in January, 1932. In May, 1932, a high blood-sugar was found on two occasions by two different consultants, and she was put on insulin. In June, 1932, a blood-sugar of 0·038 per cent. was noted by a third consultant, with a "lag curve" after glucose ingestion, and frequent doses of sugar were advised. Recently she has been taking up to 44 units of insulin, in two doses, daily, with a good deal of sugar at the time when reactions are expected to occur. On this she has gained 12 lb. in weight.

She was first seen by us in September, 1932. At that time the blood-sugar three hours after a normal breakfast was 0·077, and an hour later had fallen to 0·054, signs of a reaction developing. She had had no insulin for 24 hours. Sugar, which was ravenously consumed, rapidly relieved her symptoms.

On Oct. 12th, 1932, she was admitted to a small ward for observation, having taken no insulin for 48 hours. Physical examination was negative except for slight epigastric tenderness. Blood pressure 120/82. She presented no clinical signs of endocrine dysfunction. She was put on a diet of 2000 calories, containing 200 g. carbohydrate, divided equally over the four meals. The blood-sugar on Oct. 13th ran the following course. Breakfast: 50 g. carbohydrate at 8 A.M. Blood-sugar 10 A.M., 0·048; 11 A.M., 0·048; 12 noon, 0·058; 1 P.M., 0·077. Lunch: 50 g. carbohydrate; 2 P.M., 0·113; 3 P.M., 0·122; 4 P.M., 0·092; 5 P.M., 0·072. Tea: 50 g. carbohydrate; 6 P.M., 0·139. The urine, passed hourly, showed traces of glucose (glucosazone) throughout the test, but no acetone.

The results of two glucose-tolerance tests are given in the accompanying Table. Test I. was followed by a severe attack of hypoglycæmia.

	TEST I (20/10/32)				TEST II (15/10/32)			
	B.S. per cent.	Urine.		R.Q.	B.S. per cent.	Urine.		R.Q.
		Amount	Sugar per cent.			Amount	Sugar per cent.

,,	0·065	45 c.cm.	Trace.	0·77	0·062	60 c.cm.	Nil.	0·83
	Glucose 50 g.				Glucose 50 g.			
30′	0·154	—	—	0·84	0·139	—	—	0·86
60′	0·227	—	—	0·89	0·345	45 c.cm.	0·8	0·86
90′	0·201	65 c.cm.	2·05	0·94	0·152	—	—	0·91
120′	0·141	—	—	0·96	0·171	50 c.cm.	2·5	0·89
170′	0·109	28 c.cm.	2·20	0·92	0·122	30 c.cm.	1·5	0·88
210′	0·056	10 c.cm.	Trace.	0·84	—	—	—	—

With a view to determining the extent of peripheral sugar storage, the capillary-venous sugar difference was estimated while the patient was hypoglycæmic: Blood-sugar, capillary (finger-prick), 2½ hours after breakfast at 10.30 A.M., 0·085; at 11 A.M., capillary 0·054, venous 0·040. Considerable peripheral storage was therefore going on at hypoglycæmic levels of blood-sugar.

As the patient had been taking large doses of insulin without any apparent aggravation of her symptoms, the effect of 30 units of insulin on the blood-sugar was examined. The patient was on the same diet under the same conditions as on Oct. 13th. The insulin was injected immediately before her breakfast which contained 50 g. carbohydrate, and was taken at 8 A.M. Blood-sugar: 10.30 A.M., 0·079; 11 A.M., 0·048; 11.30 A.M., 0·054; 12 noon, 0·077; 12.30 P.M., 0·067, 1 P.M., 0·041. Hypoglycæmic symptoms were noticed between 11.30 A.M. and 12 noon, but passed off without administration of sugar. Exogenous insulin did not appear to depress her usual blood-sugar level to any appreciable extent. After injection of 0·5 c.cm. 1 : 1000 adrenaline, the blood-sugar rose in the course of two hours from 0·067 to 0·100, which we regard as a normal response.

The results of the lævulose-tolerance test gave no indication of any grave impairment of liver function. Blood-sugar before: 0·081; 30 min., 0·125; 60 min., 0·095; 90 min., 0·095; 120 min., 0·087; 150 min., 0·077. The basal metabolic rate determined on three occasions gave rates of —26 per cent., —22 per cent., —18 per cent.; but apart from this no signs of thyroid inadequacy were present.

Radiographic examination showed a sella turcica of normal size and appearance, and a normal gastric outline and emptying time. The fæces on a mixed diet contained 20·8 per cent. of fats, and showed a good digestion of muscle-fibres and no excess of starch microscopically. The urinary diastatic index was 10·0. There was therefore no evidence of impairment of the external secretion of the pancreas. A further blood-sugar curve after 50 g. glucose was obtained on Feb. 3rd, 1933, and the results were as follows: blood-sugar: 11 A.M., 0·068; 11.30 A.M., 0·167; 12 noon, 0·151; 12·30 P.M., 0·130; 1 P.M., 0·070; 1.30 P.M., 0·037. From this it appears that, in comparison with the previous curves, the rise of blood-sugar is less marked; the terminal hypoglycæmia is, however, accentuated.

DISCUSSION

Hypoglycæmic attacks not due to injection of exogenous insulin have been reported in patients suffering from gross lesions of the liver, lesions of the adrenals, adenomata or adenocarcinomata of the islands of Langerhans, and the "pluriglandular syndrome." There was no evidence in our case of a gross liver damage. A tumour large enough to destroy almost the entire liver parenchyma can hardly have been present for the length of time during which the attacks had occurred, and should have been easily detected on clinical examination. It is common knowledge that in conditions of hepatic disorder, such as cirrhosis, no hypoglycæmic symptoms usually occur. The few cases of hepatic hypoglycæmia which have been described have been associated with almost entire destruction of the liver by growth: of this there can be no question in this patient in view of the four years' history of symptoms. On the other hand, with insular adenomata or adenocarcinomata, gross irregularities of blood-sugar, both in the upward and downward direction, have been observed. The case reported by Wilder and his co-workers is one of the earliest on record. This patient gave high blood-sugar curves with a terminal hypoglycæmia practically identical with those obtained in our case. There was no evidence of hepatic disorder. Laparotomy and a subsequent post-mortem examination revealed that the metabolic disturbance was associated with an adenocarcinoma of the pancreas, with small secondary nodules in the liver. The tumour tissue, which contained insulin, had apparently arisen from the islets of Langerhans. Abundant glycogen was present in the liver. Adrenal hypoglycæmia due to destructive lesions of the adrenal medulla, as in the case reported by Rabinovitch, is a rarity, and the disease is of short duration. In our patient the absence of Addisonian pigmentation, the normal blood pressure, and the length of history, appear to negative this possibility.

The syndrome met with in our patient most closely resembles that associated with definite adenomata or adenocarcinomata of the insular tissue or diffuse hyperplasia of the islands of Langerhans. The most curious feature of the condition is the tendency to extremely low blood-sugar levels on a normal starch-containing diet, coupled with a blood-sugar response to glucose, ingested in solution, resembling that of the diabetic. In view, however, of the rise in the respiratory quotient which follows the ingestion of glucose there can be no question of inadequate oxidation of glucose, as in the diabetic. The absence of ketosis is further evidence of the satisfactory oxidation of sugar. The marked terminal hypoglycæmia also differentiates these curves from those of the diabetic.

Similar findings have been reported by other observers. Glucose-tolerance tests were performed in 12 of 20 pancreatic cases collected by Gammon and Tenery; in 8 instances high curves were obtained. In a quarter of the recorded cases glycosuria had been noted.

No explanation of this anomalous response to glucose can be given. We have as yet no definite knowledge as to the mechanism by which the output of insulin from the pancreas is controlled. For the present, in view of the association of high blood-sugar curves after glucose ingestion with hypoglycæmic levels of blood-sugar on a normal diet, the condition is perhaps better termed dysinsulinism than hyperinsulinism. The findings suggest a failure to adjust the insulin output to the needs of the body rather than a constant excessive output.

Other unexplained features of the case are the tolerance of exogenous insulin and the low basal metabolic rate. In the latter respect our case resembles that reported by Pettersson, in which atrophy of the thyroid and adrenals was found post mortem in association with an increase in the number of the islands of Langerhans.

Differentiation between diffuse hypertrophy of the insulin-producing tissue and localised adenomata or adenocarcinomata of the islands of Langerhans is with our present knowledge impossible. The indications for operative interference are therefore uncertain. In default of surgical treatment two possible lines of treatment present themselves. We may attempt to avoid stimulation of the insulin-producing tissue by placing the patient on a diet poor in carbohydrate; or we may aim at keeping the blood-sugar at a normal level by frequent carbohydrate feeds. Successful results have been reported from both methods.

Good bibliographies of the condition are to be found in the papers by Harris, and by Gammon and Tenery.

COMMENT ON THE ABOVE CASE

By Dr. P. J. Cammidge and Dr. E. P. Poulton

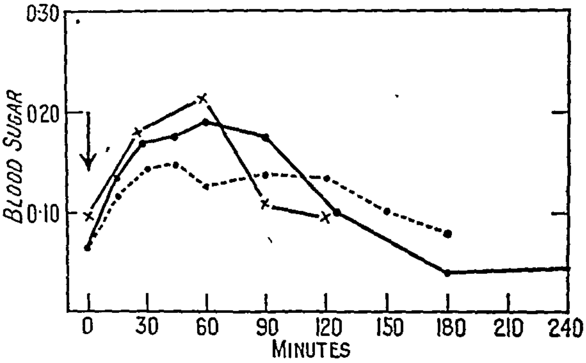
Dr. Griffiths and Prof. de Wesselow have kindly shown us their notes so that we can comment on this case, with which we were also concerned. Dr. G. L. Eastes has kindly allowed us to publish the first sugar-tolerance curve carried out on the patient on Feb. 5th, 1932. This one and the curve obtained by E. P. P. on June 29th, 1932 (Hagedorn-Jensen method) resembled in a general way de Wesselow's curves (MacLean's method) obtained in the latter part of October, 1932, except for the very high value of 0·345 per cent. obtained on one occasion by Griffiths and de Wesselow. But the curve obtained by P. J. C. on Dec. 7th, 1932, for the carbohydrate of the blood after hydrolysis was much lower, since the maximum value was 0·147 per cent. at three-quarters of an hour, and the curve for the "true" sugar was, of course, lower still. This suggests that the condition had varied in the course of the year. This was also borne out by the epinephrine test; on July 20th, 1932. E. P. P. found that the blood-sugar was 0·04 per cent. at 12.15 P.M. 1 c.cm. of 1 in 1000 epinephrine was injected, and the results obtained were at 20 min., 0·05 per cent.; 52 min., 0·04 per cent.; 75 min., 0·05 per cent.; 95 min., 0·05 per cent.; a negative result. Griffiths and de Wesselow, on the other hand, at a later date obtained a positive result with half the quantity of epinephrine.

At the moment the tendency in medicine is to diagnose any case of spontaneous hypoglycæmia with corresponding symptoms as due to hyperinsulinism caused by a tumour, hyperplasia, or merely increase of function of the islands of Langerhans. A study of the published cases tends, in our opinion, to throw doubt on this conclusion.

PANCREATIC ADENOMA OR HEPATIC DEFICIENCY?

The first case of adenoma of the islands of Langerhans was described by Nichols[1] in 1902, and Schneider[2] has collected 13 cases dealing with the literature up to 1922. This paper has evidently escaped the notice of many recent writers on this subject. Where clinical notes are available for these cases there does not appear to be any history of the hypoglycæmic symptoms recently described. Of course, it is possible that the symptoms were present, but not noted. This may sometimes have been the case, but it is difficult to believe that these symptoms were present in all the cases. For instance, Morse's cases were acute peritonitis and cerebral hæmorrhage. Rollett's case died of tuberculosis of the lungs and peritoneum, and the tumour in the pancreas was a chance finding post mortem. In Lecomte's case there was a tumour of the cerebellum with definite symptoms of cerebellar disease. Priesel's case was one of lobar pneumonia. We would suggest that these adenomas can occur without producing hypoglycæmic symptoms.

There have been described at least eight cases of the hypoglycæmic syndrome associated with adenoma and three cases with carcinoma. In McClenahan's and Morris's case,[3] the only case where the data are available, we have calculated that the size of the adenoma was 2·2 per cent. of the whole pancreas, a very small body to be solely responsible for such marked symptoms. Again in the cases described by Wilder and others[4] and Howland and others,[5] in spite of the hypoglycæmia the sugar-tolerance test gave a diabetic type of curve, a fact which requires some explanation. The suggestion put forward by Wilder that the liver was so full of glycogen that it could not store any more sugar so that the blood-sugar rose is partially supported by the work of Boller and Überrack,[6] who found that the blood-sugar did rise abnormally high when dextrose was given at the end of a period of insulin administration; but there was no hypoglycæmia at the beginning or end of the tests as occurred in the cases under review, and when the dextrose was given at the time of hypoglycæmia there was no very marked extra rise in the blood-sugar. Then, if hyperinsulinism leads to hyperglycæmia after sugar, why in all the other cases of spontaneous hypoglycæmia should the sugar-tolerance curve have been normal? A still greater difficulty is the response to epinephrine or pituitrin. In three out of eight cases the blood-sugar did not rise in response to injections of these substances; but a rise would be expected if the liver was full of glycogen which was demonstrated by Wilder to be so in his case. His suggestion that there was so much insulin in the blood that the effect of the epinephrine was swamped is not convincing, because where a low sugar results from a balance between an excess of insulin and any epinephrine secreted secondarily (? by reflex action) a dose of epinephrine should have its usual action and raise the blood-sugar.



×——× R. Easte's curve, 5/2/32.
•——• E. P. P.'s curve, 29/6/32.
•-----• P. J. C.'s curve, 7/12/32 (total carbohydrates estimated).

The fact is all these biochemical changes are found in rabbits when the liver has been poisoned by phosphorus[7]; the blood-sugar is low because its supply from the liver is interfered with; there is a bigger rise than usual after a dose of dextrose combined with insulin, and the blood-sugar level is not affected by epinephrine, because the glycogenic function of the liver is interfered with. Cammidge and Howard[8] also found that by poisoning the liver with hydrazine phosphate the disturbance of glycogenic function was indicated by an increase in the dextrins which were liberated into the circulation. If hypoglycæmia in man is usually due to impairment of glycogenic function it is quite likely that the latter might be followed secondarily by some increased activity of the islands of Langerhans, which might take the form of an adenoma or even a carcinoma of the pancreas. Such increased activity would have the advantage of keeping up the load of glycogen in the liver cells, though it would also deplete the peripheral circulation of sugar, and in this respect aggravate the effect of the primary hepatic disease.[*] On this view operation would also be expected to bring relief, and in this connexion it is of particular interest that our patient obtained most relief by large doses of insulin and glucose; this may have helped the liver because the islands had not yet hypertrophied sufficiently—the patient never actually fainted, a symptom usually present in the pancreatic cases.

In favour of the hepatic deficiency point of view is the fact that in Wilder's case and in Finney's case[9] (where a normal pancreas was partly removed) there was a long-standing history of alimentary symptoms which might well affect the liver, and there is a similar history in the present case; and Cammidge [10] and Gammon and Tenery [16] have commented on the frequency of this kind of history in hypoglycæmia.

---

[*] That this sequence of events in pathology is not fanciful is shown by congenital heart disease which is benefited by the polycythæmia: the latter, however, sometimes increases the viscosity of the blood so much that other undesirable effects are produced.

Such a view makes it necessary to postulate a dissociation of hepatic function—an interference with glycogenic function without disturbances of biliary, urea forming, and uric acid destroying functions, &c. Experimentally this dissociation takes place when most of the liver is removed from a dog.[11] In Nadler and Wolfer's [12] case of carcinoma involving most of the liver the sugar-tolerance curve was very similar to the earlier curves in the present case, and epinephrine did not cause a rise of blood-sugar. Clinically, the patient had typical hypoglycæmic attacks which were hardly controlled with 270 g. of dextrose a day; there was no jaundice or other sign of hepatic deficiency. In Crawford's [13] case of carcinoma of the liver as much as 2000 g. of carbohydrate were given to prevent hypoglycæmic symptoms; the rise of blood-sugar after dextrose was not abnormal, and the van den Bergh test was negative. In Wagner and Parnas's much quoted case,[14] a girl with a large liver, who sometimes passed fatty stools in the morning, had hypoglycæmia and ketosis while fasting without symptoms. Glycosuria occurred after giving sugar and starch, and the maximum blood-sugar was 0·43 per cent. two hours after the dose, and the ketosis disappeared. Epinephrine did not cause a rise of blood-sugar.

These examples are enough to show that the symptoms of impairment of hepatic hypoglycæmia may imitate closely the syndrome of hyperinsulinism as ordinarily understood.

THE PRESENT CASE

The case recorded above falls rather into the hepatic than into the pancreatic group of hypoglycæmic cases. Griffiths and de Wesselow's lævulose-tolerance curve indicates some degree of hepatic deficiency (cf. Kimball [15]), while P. J. C. on Dec. 7th, 1932, found that the non-protein nitrogen was 50 mg., which is distinctly above normal, and the "difference values" between the total reducing substances and the true sugar in the blood following the administration of dextrose were increased—both indications of hepatic deficiency. The low values for the basal metabolism obtained by de Wesselow can be correlated with P. J. C.'s finding that the iodine content of the blood was low (Kottmann's reaction); hence there was some associated thyroid deficiency. We did not advise operation.

We have written at some length on this interesting case, because we do want to emphasise the fact that hyperinsulinism may not always be the primary cause of the hypoglycæmic syndrome, arising spontaneously. As Cammidge has pointed out, the liver is more likely to be at fault in these cases.

SEDIMENTATION-RATE AND ULTIMATE PROGNOSIS IN TUBERCULOSIS

AN INVESTIGATION INTO THE AFTER-HISTORY OF FIVE HUNDRED CASES

By R. R. Trail, M.D. Aberd., M.R.C.P. Lond.
MEDICAL SUPERINTENDENT OF KING EDWARD VII. SANATORIUM, MIDHURST

In a previous paper [1] the value of the sedimentation-rate as a reflection of the immediate benefits of sanatorium treatment was investigated on the experience of 318 clinically tuberculous cases, watched over a period of residence of not less than four months. The technique used was that of the late Dr. Arthur Inman, and was described in the paper; it has been used in all cases admitted since November, 1926.

It is now possible to follow 500 cases over a period of from two to six years after discharge, and therefore to inquire into the value of this test as a factor in estimating ultimate prognosis. These cases are the first 500 consecutive admissions in which a diagnosis of pulmonary tuberculosis was made on a combination of physical and X ray findings and sputum tests. No case is counted positive unless it was positive in the sanatorium and no case has been counted negative on discharge unless there were at least three consecutive negative sputum tests at fortnightly intervals before such date of discharge; 362 of the 500 were T.B.+ and 138 were T.B.− on admission. All cases have been divided into groups according as their sedimentation-rates fall between 1–10, 11–20, 21–30, 31–40 per cent. and over, both on admission and on discharge.

Table I.—*Sedimentation-rates on Admission*

Sed.-rates.	T.B. + cases.			T.B. − cases.		
	Alive. (%)	Dead. (%)	Total	Alive. (%)	Dead. (%)	Total
1–10	36 (94·7)	2 (5·3)	38	53 (100)	—	53
11–20	88 (87·1)	13 (12·9)	101	46 (90·2)	5 (9·8)	51
21–30	61 (60·4)	40 (39·6)	101	18 (85·7)	3 (14·3)	21
31–40 and over	68 (55)	54 (45)	122	9 (69·2)	4 (30·8)	13

Table I. gives the after-history according to the sedimentation-rates on admission, both in T.B.+ and T.B.− cases, the rates given being the mean of the first two readings taken within three weeks of the date of admission.

There is a marked rise in the death-rate with each successively higher reading. This is more evident in the positive cases but the results in negative cases march with them; a figure above 20 in positive cases and above 30 in negative cases means a grave prognosis in that more than 30 per cent. are dead in two to six years after discharge. The totals in each group are also worthy of note, and if the per-

16. Gammon, D., and Tenery, W.: Arch. Internal Med., 1931, xlvii., 829.

centage of gross total is worked out, it is found that 61·6 per cent. of positive cases enter the sanatorium with a sedimentation-rate over 20, while 9·4 per cent. of negative cases are over 30 on admission.

Table II. follows the after-history to date; (*a*) follows 216 cases who were positive on admission and discharge, (*b*) 146 cases who were positive on admission and negative on discharge, (*c*) 138 cases who were negative throughout their stay. The average duration of treatment was four months. If the results of sections (*a*) and (*b*) of this table are compared, it is seen that there is a close approximation in prognosis where the sedimentation-rate was under 20 per cent. As in Table I. there is a marked rise in the death-rate where the figure is over 20 per cent., and it is much more marked in those that remain positive until it reaches 52·9 per cent. where the figure is above 30. On the other hand, the prognosis is more than twice as good in those who remained positive and left at a figure under 10 than in those who lost the tubercle in their sputum but left with a sedimentation over 10.

A comparison of sections (*b*) and (*c*) will show the value in prognosis of sedimentation-rates in cases who became negative as against those who had at no time during their residence produced positive sputum. It happens that the gross totals in these sections are almost the same—(*b*) 146 and (*c*) 138—and that the totals in each subgroup are practically the same, so that a comparison of formerly "open" as against "closed" tubercle cases can be read in conjunction with the sedimentation-rates. The prognosis on the whole is not so good in (*b*) as in (*c*). It is interesting to note, however, that there is no marked difference in the prognosis provided the sedimentation-rate on discharge is under 10, while it seems that the prognosis is almost four times better (4·3 : 15·4 per cent.) in those who lost the tubercle in their sputum and left with a sedimentation-rate under 10, as against those who never were positive but left with a sedimentation-rate of over 20.

TABLE II.—*Sedimentation-rates on Discharge*

Sed.-rates.	(*a*) T.B. + on admission and on discharge.			(*b*) T.B. − on admission. T.B. − on discharge.			(*c*) T.B. − on admission and on discharge.		
	Alive. (%)	Dead. (%)	Total	Alive. (%)	Dead. (%)	Total	Alive. (%)	Dead. (%)	Total
1–10	34 (87·2)	5 (12·8)	39	67 (95·7)	3 (4·3)	70	75 (97·4)	2 (2·6)	77
11–20	39 (70·9)	16 (29·1)	55	33 (71·7)	13 (28·3)	46	36 (90)	4 (10)	40
21–30	25 (48·1)	27 (51·9)	52	15 (75)	5 (25)	20	11 (84·6)	2 (15·4)	13
31–40 and over	33 (47·1)	37 (52·9)	70	7 (70)	3 (30)	10	4 (50)	4 (50)	8

Of the 500, 121 (24·2 per cent.) are dead. Sanatorium records show that on discharge 29 of these 121 were on rest as having raised temperatures, and that they had gained no appreciable benefit by their residence; the remaining 92 had normal pulse and temperature and were on exercise varying from attendance at meals to walking exercise up to six miles per day, and they seemed, on the usual critéria of physical signs, pulse, temperature, and "exercise tests" to be making satisfactory progress. These 92, therefore, would appear to warrant closer investigation, with a view to ascertaining whether their sedimentation-rates give any hint as to their liability to break down; 82 of them had been positive on admission, and 60 of these 82 had remained positive; the remaining 10 had never had tubercle in their sputum during treatment. When adjustments are made by subtracting the 29 according to their position in the groups of sedimentation-rates on discharge, Table III. emerges from Table II.

TABLE III

Sed.-rates.	T.B. + on admission. T.B. + on discharge.		T.B. + on admission. T.B. − on discharge.		T.B. − on admission and on discharge.	
	Total.	Dead (%)	Total.	Dead (%)	Total.	Dead (%)
1–10	37	3 (8·1)	70	4 (5·7)	77	2 (2·6)
11–20	52	14 (27)	46	12 (26)	40	4 (10)
21–30	46	19 (41·3)	20	5 (25)	13	2 (15·4)
31–40 and over	56	24 (43)	8	1 (12·5)	6	2 (33·3)

This Table shows, as former Tables, the comparatively small number of patients who lose the tubercle in their sputum and leave the sanatorium at a figure over 20 per cent. Allowing for this, there is a sharp rise in the death-rate of all groups with a sedimentation-rate of over 10. Positive sputum has a decided bearing, but its effect is most seen in readings over 20 per cent., and it is clear that it is far better for a patient to remain T.B. + and leave the sanatorium with a reading under 10 than to become T.B. − and leave with a reading over 10; indeed, such a patient has a better prognosis than one who has never had positive sputum but is discharged with a sedimentation-rate of over 10.

CONCLUSIONS

This investigation appears to show that considerable value must be given to the sedimentation-rate in assessing ultimate prognosis. It is usual to assess such prognosis on physical signs, temperature, pulse, sputum tests, and fitness for exercise judged on the results of "exercise tests." It is well known how such criteria can lead the observer astray; the sedimentation-rate may be a decided help, since the prognosis becomes increasingly grave with the higher rates of sedimentation. To enter the sanatorium with a figure of over 20 and to leave with a figure over 10 means a grave prognosis; this applies to all cases of clinical tuberculosis, "open" and "closed," and while the gravity increases with "open" cases and in particular with those who remain so in spite of treatment, it appears that it is better to remain positive and secure a fall in the sedimentation-rate to under 10, than to be a "closed" case with a discharge figure of over 10.

One method of treatment that reduces the sedimentation-rate was mentioned in the last paper—artificial pneumothorax; the average fall in 20 cases was from 31 per cent. to 14 per cent. Further experience with this treatment has borne out this result. Other methods such as tuberculin (B.E.) are being tested, but the old lesson seems obvious: rest is the best of all treatments. Once the patient has been assessed, as only sanatorium observation can assess him, during his first month's residence, the amount of rest required, the capacity for increasing movement in "graduated rest," and the fitness for return to work ought to be founded as much on the movements of his sedimentation-rate as on his pulse, temperature, "exercise tests," and sputum results. Both immediate and after-history results may be benefited and the physician may be distinctly aided in his difficulty of the evaluation of prognosis.

was a long-standing history of alimentary symptoms which might well affect the liver, and there is a similar history in the present case; and Cammidge [10] and Gammon and Tenery [16] have commented on the frequency of this kind of history in hypoglycæmia.

Such a view makes it necessary to postulate a dissociation of hepatic function—an interference with glycogenic function without disturbances of biliary, urea forming, and uric acid destroying functions, &c. Experimentally this dissociation takes place when most of the liver is removed from a dog.[11] In Nadler and Wolfer's [12] case of carcinoma involving most of the liver the sugar-tolerance curve was very similar to the earlier curves in the present case, and epinephrine did not cause a rise of blood-sugar. Clinically, the patient had typical hypoglycæmic attacks which were hardly controlled with 270 g. of dextrose a day; there was no jaundice or other sign of hepatic deficiency. In Crawford's [13] case of carcinoma of the liver as much as 2000 g. of carbohydrate were given to prevent hypoglycæmic symptoms; the rise of blood-sugar after dextrose was not abnormal, and the van den Bergh test was negative. In Wagner and Parnas's much quoted case,[14] a girl with a large liver, who sometimes passed fatty stools in the morning, had hypoglycæmia and ketosis while fasting without symptoms. Glycosuria occurred after giving sugar and starch, and the maximum blood-sugar was 0·43 per cent. two hours after the dose, and the ketosis disappeared. Epinephrine did not cause a rise of blood-sugar.

These examples are enough to show that the symptoms of impairment of hepatic hypoglycæmia may imitate closely the syndrome of hyperinsulinism as ordinarily understood.

THE PRESENT CASE

The case recorded above falls rather into the hepatic than into the pancreatic group of hypoglycæmic cases. Griffiths and de Wesselow's lævulose-tolerance curve indicates some degree of hepatic deficiency (cf. Kimball [15]), while P. J. C. on Dec. 7th, 1932, found that the non-protein nitrogen was 50 mg., which is distinctly above normal, and the "difference values" between the total reducing substances and the true sugar in the blood following the administration of dextrose were increased—both indications of hepatic deficiency. The low values for the basal metabolism obtained by de Wesselow can be correlated with P. J. C.'s finding that the iodine content of the blood was low (Kottmann's reaction); hence there was some associated thyroid deficiency. We did not advise operation.

We have written at some length on this interesting case, because we do want to emphasise the fact that hyperinsulinism may not always be the primary cause of the hypoglycæmic syndrome, arising spontaneously. As Cammidge has pointed out, the liver is more likely to be at fault in these cases.

SEDIMENTATION-RATE AND ULTIMATE PROGNOSIS IN TUBERCULOSIS

AN INVESTIGATION INTO THE AFTER-HISTORY OF FIVE HUNDRED CASES

By R. R. Trail, M.D. Aberd., M.R.C.P. Lond.
MEDICAL SUPERINTENDENT OF KING EDWARD VII. SANATORIUM, MIDHURST

In a previous paper [1] the value of the sedimentation-rate as a reflection of the immediate benefits of sanatorium treatment was investigated on the experience of 318 clinically tuberculous cases, watched over a period of residence of not less than four months. The technique used was that of the late Dr. Arthur Inman, and was described in the paper; it has been used in all cases admitted since November, 1926.

It is now possible to follow 500 cases over a period of from two to six years after discharge, and therefore to inquire into the value of this test as a factor in estimating ultimate prognosis. These cases are the first 500 consecutive admissions in which a diagnosis of pulmonary tuberculosis was made on a combination of physical and X ray findings and sputum tests. No case is counted positive unless it was positive in the sanatorium and no case has been counted negative on discharge unless there were at least three consecutive negative sputum tests at fortnightly intervals before such date of discharge; 362 of the 500 were T.B.+ and 138 were T.B.− on admission. All cases have been divided into groups according as their sedimentation-rates fall between 1–10, 11–20, 21–30, 31–40 per cent. and over, both on admission and on discharge.

TABLE I.—*Sedimentation-rates on Admission*

Sed.-rates.	T.B. + cases.			T.B. − cases.		
	Alive. (%)	Dead. (%)	Total	Alive. (%)	Dead. (%)	Total
1–10	36 (94·7)	2 (5·3)	38	53 (100)	—	53
11–20	88 (87·1)	13 (12·9)	101	46 (90·2)	5 (9·8)	51
21–30	61 (60·4)	40 (39·6)	101	18 (85·7)	3 (14·3)	21
31–40 and over	68 (55)	54 (45)	122	9 (69·2)	4 (30·8)	13

Table I. gives the after-history according to the sedimentation-rates on admission, both in T.B.+ and T.B.− cases, the rates given being the mean of the first two readings taken within three weeks of the date of admission.

There is a marked rise in the death-rate with each successively higher reading. This is more evident in the positive cases but the results in negative cases march with them; a figure above 20 in positive cases and above 30 in negative cases means a grave prognosis in that more than 30 per cent. are dead in two to six years after discharge. Douthwaite.[6] With the case here described this makes a total of 47 cases; but the list is probably by no means complete.

A striking feature of the more recent cases, and one well exemplified in our case, is the rapidity of progress once improvement is established. How far this is due to the use of the various sera it is difficult to say, but it seems more than likely that they exercise a very potent influence on the course of the disease.

Source of infection.—The great majority of cases arise as the result of some septic condition in the ears, usually a purulent otitis media. Of the cases mentioned above, almost 70 per cent. could be traced to this source. A primary infection in the throat is rare. In Solomon's case meningitis followed an injury to the posterior wall of the pharynx caused by a blow from a curtain pole. In the cases of Vining and Thompson,[7] Cassel, Trounce and Douthwaite, and in Rosenberg and Nottley's own patient, the source of infection appeared to lie in the throat. In our case a somewhat trivial tonsillitis was apparently responsible for the condition. It seems probable that in these cases the meningitis is due to a blood-borne infection, but the possibility of a spread upwards from the nose through the cribriform plate of the ethmoid cannot entirely be excluded.

Type of organism.—In the reports of most of the recovered cases the type of streptococcus is not specified. In ten of Rosenberg and Nottley's series, and in the cases of Leishman and of Trounce and Douthwaite, the causative organism is recorded as being a hæmolytic streptococcus. In five cases, including that of Ebert, the *Streptococcus viridans* was obtained on culture. *S. pyogenes and S. mucosus* have also more rarely been identified.

Treatment.—Lumbar puncture either alone or in combination with some other method is the procedure most generally adopted. Operative measures—e.g., mastoidectomy and labyrinthotomy—have of course been employed, but only where the source of infection lay in the ear. Where a block in the spinal canal has taken place and little fluid has been obtained by lumbar puncture, cisternal puncture has been resorted to (Rosenberg and Nottley). In several cases antiseptics were used to wash out the spinal canal: acriflavine (Neal and Jones [8]) and 1 per cent. mercurochrome (Leishman). More recently, however, serum has been administered in addition to any other procedure. Of the sera employed the antimeningococcal has been that most frequently used in the first instance before a report on the cerebro-spinal fluid has been obtained; and in one case (Ebert) recovery followed the use of this serum alone. Once the true state of affairs has been recognised polyvalent antistreptococcal serum has been extensively used, and results have certainly been better since its introduction. As is shown in the accompanying Table and in the history of this case, its administration can be of great value. In streptococcus antitoxin (scarlatina) globulins, which has more recently become available, we have probably a much more potent agent. Trounce and Douthwaite, using this preparation intravenously and intrathecally, report the most dramatic change in their patient's condition.

In the case here recorded it is difficult to assess its value accurately, since it was not administered until the sixth day of hospital residence and followed the administration of large doses of polyvalent serum, but recovery was so extremely rapid thereafter that it is difficult to avoid the conclusion that the scarlatinal serum was in large measure responsible. More data are, of course, required before any definite conclusions can be drawn concerning the most effective method of administration, but these results appear to us to be most encouraging.

We are indebted to Dr. R. E. Robinson, pathologist to the hospital, for the reports on the cerebro-spinal fluid in this case.

Clinical and Laboratory Notes

CLICKING KNEE IN CHILDHOOD

By Eric I. Lloyd, M.B. Camb., F.R.C.S. Eng.

SURGEON TO THE HOSPITAL FOR SICK CHILDREN GREAT ORMOND STREET, AND TO THE PRINCESS LOUISE HOSPITAL FOR CHILDREN; ORTHOPÆDIC SURGEON TO THE ROYAL NORTHERN HOSPITAL

In spite of their great activity, children hardly ever damage their semilunar cartilages, and consequently rarely suffer from internal derangement of the knee-joint. This is perhaps odd because it seems likely that the twisting strains of the playground are as great as those of the football field. The common adult injuries are caused by the momentum (*kinetic energy*)—i.e., half the mass multiplied by the square of the velocity of the moving body—and though the velocity may be equal, the mass of the adult is much greater than that of the child. Where the velocity is a constant, the expression $\frac{1}{2}mv^2$ varies directly as the mass and consequently the *kinetic energy* of a moving body of 160 lb. is twice that of one of 80 lb. Probably this is the explanation of childhood's immunity.

There is, however, a small but interesting group of children whose knees are at fault owing to a congenital abnormality. Symptoms are very occasionally delayed (see Case 3), but the same thing happens with a hernial sac of the inguinal canal and both are congenital lesions. It is probable that more than one condition is included in the term "clicking knee," but from a clinical standpoint it is at present impossible to distinguish them.

The following are recent examples from three hospitals:

Case 1.—Hilda A., aged 8½. (Hospital for Sick Children, Great Ormond-street.) Clicking of left knee since birth. She could make it click, and kept herself awake by doing so. Operation (Dec. 31st, 1931): external cartilage appeared normal, and was not disc-like; internal cartilage seemed to be unduly mobile posteriorly and was removed. Thirteen months later there was no disability, and her knee has not clicked since the operation.

Case 2.—Lucy B., aged 12. (Princess Louise Hospital for Children.) Child had suffered from extensive poliomyelitis of both lower limbs for many years, and both knees had clicked ever since she could remember. Operation (July 12th, 1932): removal of right external semilunar cartilage, which was more or less of a disc. Operation (July 19th): removal of left external semilunar cartilage; the knee was seen to "jump" over the outer part of the cartilage; a large and disc-like cartilage was removed. She never clicked her knee again, and was apparently cured of the condition when seen six months later.

Case 3.—Ronald C., aged 12½. (Royal Northern Hospital.) Onset of symptoms referred to a gymnastic display three

CASE OF STREPTOCOCCAL MENINGITIS
WITH RECOVERY

By J. K. Rennie, *M.C.*, B.Sc., M.D. Glasg.
PHYSICIAN, ST. LUKE'S HOSPITAL, BRADFORD
AND
W. S. Craig, B.Sc., M.B. Edin.
LATE HOUSE PHYSICIAN, ST. LUKE'S HOSPITAL, BRADFORD

Streptococcal meningitis, except as a complication of some otitic infection, is rare, and recovery in any event is uncommon. The following case illustrates both these phenomena and is therefore regarded as worthy of record.

HISTORY OF THE CASE

A labourer, aged 23, was admitted to hospital on Oct. 20th, 1931, complaining of severe headache which had persisted since its onset on Oct. 15th. Associated with this headache there had been periods of mild delirium, giving place to marked drowsiness. Vomiting occurred only once and that at the commencement of the illness. On the evening of Oct. 19th a rise in temperature was first noted, and complaint was made of aching pain in the back and of diplopia.

When first seen in hospital the patient was conscious but extremely drowsy. He answered questions correctly, but speech was slow and drawling. Respirations were sighing and irregular, 20 per minute. The temperature was 102° F.; the pulse-rate was regular, 80 per minute. Very definite nuchal rigidity, slight opisthotonos, and bilateral Kernig's sign were present. Ptosis of the left upper eyelid and a pronounced convergent strabismus were evident. The pupils reacted to light and on accommodation. The right pupil was larger than the left. Both external recti were paralysed. Other eye movements were normal. The right knee-jerk and both ankle-jerks could not be elicited. All other deep reflexes were active. The plantar reflexes were both flexor. There were no spots anywhere on the skin, but *tache cérébrale* was very marked. The tongue was dry and glazed, and there was much sordes around the lips but no herpes. Nothing was found in the ears or in the accessory sinuses. The tonsils were enlarged and inflamed.

TABLE SHOWING PATHOLOGICAL CHANGES WITH SERUM

Day of disease.	Chlorides mg. per 100 c.cm.	Sugar per cent.	Protein per cent.	Globulin.	Gold curve.	Culture.	C.S.F. amount c.cm.	Cell count per c.mm.	Serum.		Leucocyte count.

A.M. = Antimeningococcus serum.
P.A. = Antistreptococcus (polyvalent) serum.
S.A. = Streptococcus antitoxin (scarlatina) globulins.
I.T. = Intrathecally.
I.M. = Intramuscularly.
C.S.F. = Cerebro-spinal fluid.

On admission a diagnosis of basal meningitis was made; lumbar puncture was performed with no great relief, and morphia was required on account of persistent headache. The cerebro-spinal fluid was faintly turbid but contained no organisms; 60 c.cm. was withdrawn. Next day there was no change. The patient had had no sleep despite morphia, and intense headache persisted. The temperature was 103° and the pulse-rate 90. Lumbar puncture was again performed; 60 c.cm. was withdrawn, and 35 c.cm. of antimeningococcus serum was *injected intrathecally*. The fluid withdrawn gave a growth of non-hæmolytic streptococcus on culture. A throat swab gave streptococcal and staphylococcal growths.

Headache was rather less severe next day (Oct. 22nd), when again 60 c.cm. of cerebro-spinal fluid was withdrawn, and 35 c.cm. of antistreptococcus (polyvalent) serum was administered intrathecally and 20 c.cm. intramuscularly. He was quiet during the 23rd. Photophobia was present. At lumbar puncture 60 c.cm. of fluid was obtained, more yellow and turbid than previously, but not markedly under pressure; *35 c.cm. of antistreptococcus serum was again* given intrathecally. At night severe epistaxis occurred, and the patient became violently, almost maniacally, delirious. His mental condition appeared clearer in the early part of the next day (Oct. 24th), but towards afternoon he fell into a low muttering delirium. Nevertheless he recognised relations and carried on a brief rational conversation with them. Headache was still severe. Antistreptococcus serum (20 c.cm.) was given intramuscularly. Mild delirium was present during most of the 25th, and 25 c.cm. of antistreptococcus serum was injected intramuscularly. At midnight a sudden worsening of his condition occurred, delirium becoming more pronounced and breathing distinctly Cheyne-Stokes. Lumbar puncture next morning at first *yielded no fluid, but by gentle aspiration a number of thick,* purulent, fibrinous flakes were obtained and afterwards about 7 c.cm. of yellow fluid. Streptococcus antitoxin (scarlatinal, B. W. and Co., 20 c.cm.) was given intramuscularly, *and on the following day he was talking* rationally and taking an interest in his surroundings. Pain was still acute in the back of the neck and head. The antitoxin was repeated on this and the two subsequent days. On Oct. 28th the nuchal and head pains were less severe and diplopia was much less pronounced. The patient demanded more nourishment.

The temperature had fallen to normal on Oct. 29th and there was a dramatic change in the picture. The patient was ravenous and he was able to read the morning paper. A very profuse serum rash appeared and lasted four days but rapid improvement continued. The nuchal rigidity was practically absent on Oct. 30th and he could easily nod his head. Sleep was prolonged and natural. The plantar reflexes were extensor on Oct. 31st. On Nov. 2nd lumbar puncture yielded 15 c.cm. clear fluid, not under pressure.

On Nov. 12th Kernig's sign was still present, and staphylococci and streptococci were found on a throat swab. On Dec. 12th there was still a tendency to rapid pulse and pain in the region of the fourth lumbar spine. The right plantar reflex was extensor, the left flexor. Diplopia was still present on Dec. 20th and the right plantar reflex still gave a dubious extensor response. He could now touch his toes with his fingers. He was discharged on Dec. 24th.

On March 8th, 1932, he was readmitted to hospital for tonsillectomy. A throat swab gave sparse streptococcus culture, also staphylococcus growth. He ran a post-operative temperature for 12 days and was not fit for final discharge until March 26th, at which time examination revealed no sign of organic disease or permanent damage. There was no evidence of weakness of the ocular muscles.

DISCUSSION

Recovery in these cases is, as already stated, comparatively rare. Rosenberg and Nottley[1] have collected 41 cases from the literature, and further cases have been recorded by Solomon,[2] Cassel,[3] Ebert,[4] Leishman,[5] and recently by Trounce and the involved ear. I made a diagnosis of zygomatic mastoiditis.

On Oct. 26th the child was admitted to the nursing home. The mastoid was exposed by the usual incision, the tissues were separated over the zygoma and a quantity of pus flowed out, revealing a mouse-eaten appearance of the zygomatic process and squama of the temporal bone anterior to the auricle. On removing the cortex, a small-celled mastoid was uncovered, showing pus in the cells around the antrum, and a general osteomyelitis of the whole process, extending up to the dura and behind and around the lateral sinus; the cells at the tip were small (and were not macroscopically involved). The sinus wall was not involved. The incision was then prolonged along the zygoma and the posterior half of the zygomatic process was removed. This part did not appear to contain any large cells. The necrosed squama anterior to the auricle was chiselled away, exposing the dura. The wound was Bipped, gauze was applied to a bleeding dura vessel, and two drainage-tubes were inserted.

On Nov. 15th pressure on the healed mastoid wound resulted in sero-pus filling the external auditory meatus, so a small drainage-tube was introduced into the lower angle of the wound, and the patient was discharged to her home on a farm.

On Nov. 30th the wound had healed except for a drainage-tube track. There was no discharge into the ear on pressure.

MEDICAL SOCIETIES

ROYAL SOCIETY OF MEDICINE

SECTION OF TROPICAL MEDICINE

At a meeting of this section on March 2nd, with the president, Dr. Hugh S. Stannus, in the chair, a discussion on the

Diagnosis of Chronic Diarrhœas

was opened by Dr. Robert Hutchison. Diarrhœa, he said, was a symptom and not a disease. He classified the chronic non-tropical diarrhœas into five groups:

(1) The *gastrogenic group,* in which diarrhœa was associated with achlorhydria, though the relation between the two was obscure. In these cases, administration of dilute hydrochloric acid cured the diarrhœa; if this treatment proved unsuccessful, the diarrhœa was not gastrogenic in origin.

(2) The *fatty diarrhœas.* This group included those conditions in which there was an excess of unsplit fat in the stools—namely, congenital steatorrhœa, pancreatic diarrhœa, cœliac disease, non-tropical sprue, and cases in which obstruction of the lacteals, for example by tuberculosis, interfered with the absorption of fat.

(3) Diarrhœa due to *enteritis* or catarrh of the small intestine. This might be due to some irritant such as alcohol, to gross errors of diet, to the toxins of disease such as tuberculosis (which might cause catarrh quite apart from ulceration), or possibly to the elimination of poisons, as in uræmia. Putrefactive and fermentative diarrhœa were varieties of enteritis due to the maldigestion of proteins and carbohydrates respectively. Catarrh of the small intestine could be diagnosed by the finding of bile-stained mucus in the fæces on microscopic examination.

(4) The *colonic diarrhœas* included catarrhal conditions which might become chronic, giving rise to morning diarrhœa; ulcerative colitis of the dysenteric and non-dysenteric varieties; obstructive diarrhœa due to new growth, or sometimes in elderly people to scybala.

(5) *Neurogenic diarrhœa* might be of the reflex type seen in children, in which the gastro-colic reflex seemed to be set on a hair trigger; or the psychogenic type, in which emotional excitement fired off the bowel. The neurogenic type of diarrhœa might be engrafted on an organic type, owing to loss of confidence on the part of the patient. Diagnosis, in every case, demanded a careful history; physical examination of the whole patient; naked-eye and microscopic examination of the stools and possibly estimation of their fat content; digital examination of the rectum and perhaps sigmoidoscopy; and sometimes the administration of a test-meal and sometimes an X ray examination following a barium enema. In many cases the diagnosis would remain uncertain, and any given case might fall into one or more categories.

DIARRHŒA IN THE TROPICS

Dr. P. H. Manson-Bahr said that diarrhœa of some kind was the almost invariable concomitant of life in the tropics, and it was dangerous to assume that most of the tropical diarrhœas were due to amœbic dysentery. The result of this assumption was that every case was dosed with emetine, and as one of the symptoms of emetine poisoning was diarrhœa the last case of the patient might be worse than the first. Bacillary dysentery was much commoner than had been supposed, and the chronic form of the disease often went unrecognised. In amœbic dysentery the onset was usually insidious, there was little pyrexia, the course was prolonged, emaciation was rare, and leucocytosis moderate; in chronic bacillary dysentery the onset was often acute, pyrexia marked, the course prolonged, emaciation extreme, and there was no leucocytosis. Sigmoidoscopy in cases of chronic bacillary dysentery showed the mucous membrane to be corrugated and eroded; the colon formed a rigid tube with granulations on the surface which bled when touched; the diagnosis was made on the history and by serum agglutination. Idiopathic ulcerative colitis might occur in the tropics, and was usually diagnosed as dysentery; the prolonged use of emetine was harmful in this condition and in chronic bacillary dysentery. In idiopathic ulcerative colitis the mucous membrane looked like red plush and bled easily; diagnosis from bilharzia could be made by finding the eggs of the parasite in scrapings from a granulating patch. Polyposis might be a sequel of chronic bacillary dysentery or ulcerative colitis. Chronic malarial diarrhœa was often diagnosed as dysentery; the parasite could be found in the stools and treatment must be directed against the malaria. In sprue, emaciation was always marked; the condition was liable to be confused with pernicious anæmia and pancreatitis. Cœliac disease occurred among children in the tropics; it should not be confused with sprue, which he was convinced did not occur in young children.

SPURIOUS DIARRHŒA

Mr. Lionel Norbury said that diarrhœa might be true or spurious; it was with spurious diarrhœa that the surgeon was concerned—by which he meant months previously, when patient was kneeling. On attempting to stand, his knee would not go straight for a time and had often clicked since. Operation (May 11th, 1932): the external cartilage formed almost a complete disc, and was removed. Six weeks later he had normal range of movement, and was quite unable to make his knee click. Seven months after operation he was able to play football, and has had no trouble at all with his knee, which has not clicked since his operation.

The usual adjective applied to these knees is not particularly well chosen. It quite wrongly calls to mind the clicks which we all hear from time to time in our own healthy joints, and of which the bonesetter is a notorious exploiter. The clicking knee of childhood always evinces itself on the outer side of the joint, and generally about three-quarters of the way from flexion to active extension. Passive movement sometimes fails to elicit the click but at other times is successful. The patient is often better than the surgeon at producing it but this need not surprise us.

If this matter of the click is pursued a little further it will be found to resolve itself into the audible click and, in addition, a visible and palpable bump. The sound is often the least conspicuous part of it, for as the limb passes towards extension the external tuberosity of the tibia is seen and felt suddenly bumping and jolting forward on the femur like the wheel of a train running over an obstacle. It may be thought folly to strain at a click and swallow a bump, but it is difficult to find a word which better describes the simultaneous perceptions of three sense organs.

I have paid particular attention to this matter of the click, bump, or jolt, because radiograms are normal and a history of injury is generally absent. We are confronted simply and solely with a knee which clicks.

It is true that other symptoms are absent except an occasional complaint of weakness in the joint, and that the disability is generally slight, nevertheless, operation should be advised in view of the following considerations: (1) It is unbelievable that such a condition will right itself. (2) It may predispose to osteo-arthritis in later years. (3) It may be the precursor of one of the more familiar injuries of adult knees. (4) It is cured by the removal of the affected external semilunar cartilage if that structure is found to be a complete disc instead of the normal shape. If this condition is not present the click is caused by less well-defined abnormalities which may be discovered and remedied at operation. (See Case 1.)

ZYGOMATIC MASTOIDITIS

BY W. S. THACKER NEVILLE, M.D. DUB., F.R.C.S. EDIN.

I AM reporting the following case because there were no symptoms or signs of mastoid involvement, although pus was found in the mastoid as well as around the zygoma.

The involvement of the base of the zygomatic process is so common in acute mastoiditis that, just as one never performs an operation for acute mastoiditis without opening the cells at the tip of the mastoid, so one always chisels superiorly and anteriorly forwards in order to explore the cells in the base of the zygoma. This step, however, may not expose the infected cells, for Mollison, quoting Holmgren, says that the cells in the squamo-zygomatic mastoid portion of the temporal bone may be separated into two groups, an anterior group quite separated by non-cellular bone from a posterior group.

Of the five cases of zygomatic mastoiditis reported by Mollison, three presented the same features as this case. As in four of Mollison's cases, this patient had an otorrhœa and also was markedly deaf, which Mollison considers to be a valuable sign pointing to involvement of the mastoid even in the absence of an otorrhœa. MacCuen Smith, in his article on the method of involvement of the zygoma, shows a typical photograph of zygomatic mastoiditis with absence of swelling and tenderness on the mastoid. This case is unlike the cases reported by Nicol Rankin in that his cases showed swelling over the mastoid as well as over the temporal region. Horgan's cases were also unlike this one in that they followed a mastoiditis on which a Schwartze operation had been done. Watt's case resembled Nicol Rankin's cases in that it was an example of disease of the mastoid extending along the zygoma. His case, however, was peculiar in that the whole zygomatic process, including the cells on the outer aspect of the orbit, was involved.

Muecke described two types of zygomatic mastoiditis; the first, seen in children, resembles a parotitis but reveals itself as a true mastoiditis in a few days by signs appearing over the mastoid. The case reported here corresponds to this type in its resemblance to parotitis, but differs in that the mastoid signs were absent. Muecke's second type appears in adults and is similar to the first, except that there is less likelihood of signs on the mastoid, but rather there is pain and swelling over the orbit, simulating a frontal sinusitis.

Bernstein's case closely resembled the one reported below, for the swelling extended anteriorly as far as the eye. However, on the second day it also extended back over the mastoid. In his case the diagnosis was rendered more difficult, as the puncture of a dull tympanic membrane did not reveal pus. Mill's case resembled the case reported here in that the zygoma was bare and the swelling appeared in the parotid region, but in his case there was a marked tenderness of the mastoid and so there was no difficulty in diagnosing the case as one of mastoiditis.

CASE RECORD

A girl, aged 11, was seen by the family physician on June 11th, 1932, for earache following a feverish cold. On Oct. 8th she went to the doctor's surgery, as the ear had been discharging for six days.

On Oct. 10th, 11th, and 12th she was seen in her home. Her temperature was 102° F., and the ear was discharging and very painful. On Oct. 13th a swelling appeared over the zygoma, but there was no swelling or tenderness of the mastoid, which was repeatedly examined.

The temperature remained at 102° F. for the first week and then fell to normal during the second week, and the swelling over the zygoma subsided. On Oct. 25th the temperature rose to 102° F., and the swelling over the zygoma suddenly increased. I was asked by the family physician to see the child in order to open an abscess in front of the ear.

Examination (Oct. 25th) showed that the tympanic membrane was perforated and discharging a small quantity of pus. A large non-fluctuating swelling was seen over the left parotid region, reaching to the outer angle of the left eyebrow. Neither fluctuation nor tenderness was present on the tip or on the base of the mastoid. An acutely tender spot was present above the left auricle. Tuning fork tests demonstrated middle-ear disease. A 60 in. watch was heard at 60 in. by the good ear but only at 1½ in. by the involved ear. I made a diagnosis of zygomatic mastoiditis.

On Oct. 29th the child was admitted to the nursing home. The mastoid was exposed by the usual incision, the tissues were separated over the zygoma and a quantity of pus flowed out, revealing a mouse-eaten appearance of the zygomatic process and squama of the temporal bone anterior to the auricle. On removing the cortex, a small-celled mastoid was uncovered, showing pus in the cells around the antrum, and a general osteomyelitis of the whole process, extending up to the dura and behind and around the lateral sinus; the cells at the tip were small (and were not macroscopically involved). The sinus wall was not involved. The incision was then prolonged along the zygoma and the posterior half of the zygomatic process was removed. This part did not appear to contain any large cells. The necrosed squama anterior to the auricle was chiselled away, exposing the dura. The wound was Bipped, gauze was applied to a bleeding dura vessel, and two drainage-tubes were inserted.

On Nov. 15th pressure on the healed mastoid wound resulted in sero-pus filling the external auditory meatus, so a small drainage-tube was introduced into the lower angle of the wound, and the patient was discharged to her home on a farm.

On Nov. 30th the wound had healed except for a drainage-tube track. There was no discharge into the ear on pressure.

MEDICAL SOCIETIES

ROYAL SOCIETY OF MEDICINE

SECTION OF TROPICAL MEDICINE

At a meeting of this section on March 2nd, with the president, Dr. HUGH S. STANNUS, in the chair, a discussion on the

Diagnosis of Chronic Diarrhœas

was opened by Dr. ROBERT HUTCHISON. Diarrhœa, he said, was a symptom and not a disease. He classified the chronic non-tropical diarrhœas into five groups:

(1) The *gastrogenic group*, in which diarrhœa was associated with achlorhydria, though the relation between the two was obscure. In these cases, administration of dilute hydrochloric acid cured the diarrhœa; if this treatment proved unsuccessful, the diarrhœa was not gastrogenic in origin.

(2) The *fatty diarrhœas*. This group included those conditions in which there was an excess of unsplit fat in the stools—namely, congenital steatorrhœa, pancreatic diarrhœa, cœliac disease, non-tropical sprue, and cases in which obstruction of the lacteals, for example by tuberculosis, interfered with the absorption of fat.

(3) Diarrhœa due to *enteritis* or catarrh of the small intestine. This might be due to some irritant such as alcohol, to gross errors of diet, to the toxins of disease such as tuberculosis (which might cause catarrh quite apart from ulceration), or possibly to the elimination of poisons, as in uræmia. Putrefactive and fermentative diarrhœas were varieties of enteritis due to the maldigestion of proteins and carbohydrates respectively. Catarrh of the small intestine could be diagnosed by the finding of bile-stained mucus in the fæces on microscopic examination.

(4) The *colonic diarrhœas* included catarrhal conditions which might become chronic, giving rise to morning diarrhœa; ulcerative colitis of the dysenteric and non-dysenteric varieties; obstructive diarrhœa due to new growth, or sometimes in elderly people to scybala.

(5) *Neurogenic diarrhœa* might be of the reflex type seen in children, in which the gastro-colic reflex seemed to be set on a hair trigger; or the psychogenic type, in which emotional excitement fired off the bowel. The neurogenic type of diarrhœa might be engrafted on an organic type, owing to loss of confidence on the part of the patient. Diagnosis, in every case, demanded a careful history; physical examination of the whole patient; naked-eye and microscopic examination of the stools and possibly estimation of their fat content; digital examination of the rectum and perhaps sigmoidoscopy; and sometimes the administration of a test-meal and sometimes an X ray examination following a barium enema. In many cases the diagnosis would remain uncertain, and any given case might fall into one or more categories.

DIARRHŒA IN THE TROPICS

Dr. P. H. MANSON-BAHR said that diarrhœa of some kind was the almost invariable concomitant of life in the tropics, and it was dangerous to assume that most of the tropical diarrhœas were due to amœbic dysentery. The result of this assumption was that every case was dosed with emetine, and as one of the symptoms of emetine poisoning was diarrhœa the last case of the patient might be worse than the first. Bacillary dysentery was much commoner than had been supposed, and the chronic form of the disease often went unrecognised. In amœbic dysentery the onset was usually insidious, there was little pyrexia, the course was prolonged, emaciation was rare, and leucocytosis moderate; in chronic bacillary dysentery the onset was often acute, pyrexia marked, the course prolonged, emaciation extreme, and there was no leucocytosis. Sigmoidoscopy in cases of chronic bacillary dysentery showed the mucous membrane to be corrugated and eroded; the colon formed a rigid tube with granulations on the surface which bled when touched; the diagnosis was made on the history and by serum agglutination. Idiopathic ulcerative colitis might occur in the tropics, and was usually diagnosed as dysentery; the prolonged use of emetine was harmful in this condition and in chronic bacillary dysentery. In idiopathic ulcerative colitis the mucous membrane looked like red plush and bled easily; diagnosis from bilharzia could be made by finding the eggs of the parasite in scrapings from a granulating patch. Polyposis might be a sequel of chronic bacillary dysentery or ulcerative colitis. Chronic malarial diarrhœa was often diagnosed as dysentery; the parasite could be found in the stools and treatment must be directed against the malaria. In sprue, emaciation was always marked; the condition was liable to be confused with pernicious anæmia and pancreatitis. Cœliac disease occurred among children in the tropics; it should not be confused with sprue, which he was convinced did not occur in young children.

SPURIOUS DIARRHŒA

Mr. LIONEL NORBURY said that diarrhœa might be true or spurious; it was with spurious diarrhœa that the surgeon was concerned—by which he meant months previously, when patient was kneeling. On attempting to stand, his knee would not go straight for a time and had often clicked since. Operation (May 11th, 1932): the external cartilage formed almost a complete disc, and was removed. Six weeks later he had normal range of movement, and was quite unable to make his knee click. Seven months after operation he was able to play football, and has had no trouble at all with his knee, which has not clicked since his operation.

The usual adjective applied to these knees is not particularly well chosen. It quite wrongly calls to mind the clicks which we all hear from time to time in our own healthy joints, and of which the bonesetter is a notorious exploiter. The clicking knee of childhood always evinces itself on the outer side of the joint, and generally about three-quarters of the way from flexion to active extension. Passive movement sometimes fails to elicit the click but at other times is successful. The patient is often better than the surgeon at producing it but this need not surprise us.

If this matter of the click is pursued a little further it will be found to resolve itself into the audible click and, in addition, a visible and palpable bump. The sound is often the least conspicuous part of it, for as the limb passes towards extension the external tuberosity of the tibia is seen and felt suddenly bumping and jolting forward on the femur like the wheel of a train running over an obstacle. It may be thought folly to strain at a click and swallow a bump, but it is difficult to find a word which better describes the simultaneous perceptions of three sense organs.

I have paid particular attention to this matter of the click, bump, or jolt, because radiograms are normal and a history of injury is generally absent. We are confronted simply and solely with a knee which clicks.

It is true that other symptoms are absent except an occasional complaint of weakness in the joint, and that the disability is generally slight, nevertheless, operation should be advised in view of the following considerations: (1) It is unbelievable that such a condition will right itself.. (2) It may predispose to osteo-arthritis in later years. (3) It may be the precursor of one of the more familiar injuries of adult knees. (4) It is cured by the removal of the affected external semilunar cartilage if that structure is found to be a complete disc instead of the normal shape. If this condition is not present the click is caused by less well-defined abnormalities which may be discovered and remedied at operation. (See Case 1.)

ZYGOMATIC MASTOIDITIS

BY W. S. THACKER NEVILLE, M.D. DUB.,
F.R.C.S. EDIN.

I AM reporting the following case because there were no symptoms or signs of mastoid involvement, although pus was found in the mastoid as well as around the zygoma.

The involvement of the base of the zygomatic process is so common in acute mastoiditis that, just as one never performs an operation for acute mastoiditis without opening the cells at the tip of the mastoid, so one always chisels superiorly and anteriorly forwards in order to explore the cells in the base of the zygoma. This step, however, may not expose the infected cells, for Mollison, quoting Holmgren, says that the cells in the squamo-zygomatic mastoid portion of the temporal bone may be separated into two groups, an anterior group quite separated by non-cellular bone from a posterior group.

Of the five cases of zygomatic mastoiditis reported by Mollison, three presented the same features as this case. As in four of Mollison's cases, this patient had an otorrhœa and also was markedly deaf, which Mollison considers to be a valuable sign pointing to involvement of the mastoid even in the absence of an otorrhœa. MacCuen Smith, in his article on the method of involvement of the zygoma, shows a typical photograph of zygomatic mastoiditis with absence of swelling and tenderness on the mastoid. This case is unlike the cases reported by Nicol Rankin in that his cases showed swelling over the mastoid as well as over the temporal région. Horgan's cases were also unlike this one in that they followed a mastoiditis on which a Schwartze operation had been done. Watt's case resembled Nicol Rankin's cases in that it was an example of disease of the mastoid extending along the zygoma. His case, however, was peculiar in that the whole zygomatic process, including the cells on the outer aspect of the orbit, was involved.

Muecke described two types of zygomatic mastoiditis; the first, seen in children, resembles a parotitis but reveals itself as a true mastoiditis in a few days by signs appearing over the mastoid. The case reported here corresponds to this type in its resemblance to parotitis, but differs in that the mastoid signs were absent. Muecke's second type appears in adults and is similar to the first, except that there is less likelihood of signs on the mastoid, but rather there is pain and swelling over the orbit, simulating a frontal sinusitis.

Bernstein's case closely resembled the one reported below, for the swelling extended anteriorly as far as the eye. However, on the second day it also extended back over the mastoid. In his case the diagnosis was rendered more difficult, as the puncture of a dull tympanic membrane did not reveal pus. Mill's case resembled the case reported here in that the zygoma was bare and the swelling appeared in the parotid region, but in his case there was a marked tenderness of the mastoid and so there was no difficulty in diagnosing the case as one of mastoiditis.

CASE RECORD

A girl, aged 11, was seen by the family physician on June 11th, 1932, for earache following a feverish cold. On Oct. 8th she went to the doctor's surgery, as the ear had been discharging for six days.

On Oct. 10th, 11th, and 12th she was seen in her home. Her temperature was 102° F., and the ear was discharging and very painful. On Oct. 13th a swelling appeared over the zygoma, but there was no swelling or tenderness of the mastoid, which was repeatedly examined.

The temperature remained at 102° F. for the first week and then fell to normal during the second week, and the swelling over the zygoma subsided. On Oct. 25th the temperature rose to 102° F., and the swelling over the zygoma suddenly increased. I was asked by the family physician to see the child in order to open an abscess in front of the ear.

Examination (Oct. 25th) showed that the tympanic membrane was perforated and discharging a small quantity of pus. A large non-fluctuating swelling was seen over the left parotid region, reaching to the outer angle of the left eyebrow. Neither fluctuation nor tenderness was present on the tip or on the base of the mastoid. An acutely tender spot was present above the left auricle. Tuning fork tests demonstrated middle-ear disease. A 60 in. watch was heard at 60 in. by the good ear but only at 1½ in. by

Chronic exhausting diseases. such as phthisis. were stated to have some connexion with the condition.

Dr. J. F. CUNNINGHAM considered that Dr. Solomons had been fortunate in being able to make the diagnosis fairly early. as Cæsarean section became necessary. In an ordinary case. he thought. the diagnosis would be difficult until an attempt was made to remove the placenta.

Dr. A. H. DAVIDSON said he had seen one case. He wondered if the condition were connected with some failure of the corpus luteum. Occasionally. in cases where manual removal of the placenta was needed. it proved possible to get a portion separated. while other portions would not come away. The chief difficulty was to know when to stop trying to take out the placenta. Radical treatment appeared to be the only treatment for the condition.

Dr. NINIAN FALKINER said he regarded placenta accreta in somewhat the same light as an ectopic pregnancy. because it undoubtedly was ectopic. The end-result of placenta accreta was that the chorionic elements were intertwined with the muscles of the uterine wall. This was the condition met with in ectopic pregnancy. He thought that in Dr. Solomon's case there must have been pre-existing inflammation.

Dr. SOLOMONS. in reply. said that the placenta was in the upper segment. When he said that the diagnosis should be made as soon as possible. he meant that in a case of pelvic delivery efforts to remove the placenta should not be persisted in. and radical treatment should be undertaken. as soon as the diagnosis of placenta accreta was made. Among explanations of the condition failure of the corpus luteum might always be thought of. but it was more probably due to an inflammatory condition of the endometrium by which chorionic elements could get between the glands to the muscle.

Dr. O'DONEL BROWNE read a paper on the Use of Pituitary Extract in Labour. and Dr. CUNNINGHAM a paper on Late Ectopic Pregnancy.

Chorion-epithelioma of Fallopian Tube

At a meeting of the section of pathology on Feb. 10th. with Dr. J. MCGRATH. the president. in the chair. Prof. T. T. O'FARRELL showed a specimen and reported the following case :—

A woman. aged 35. had been married 15 years and had two children, the last having been born 11 years previous to the present illness. Menstruation had been of the 28-day type and of five days' duration. the amount being heavy. Last period, Oct. 14th. Present illness: uterine hæmorrhage began on Dec. 5th. 1932; was not heavy. and lasted 14 days. There was no pain at this time, but there was slight pain in the lower abdomen during the following seven days. Hæmorrhage during this time became more marked. and before admission to hospital there was acute pain in the lower abdomen for 12 hours.

On admission (Dec. 26th) the patient was in a condition of shock; pulse-rate 125. temp. 97 F. There was acute tenderness and rigidity over the lower half of the abdomen. especially in the left iliac fossa. On vaginal examination the uterus was found to be small. hard. and in good position. A vague cystic mass was felt behind and on both sides of the uterus. At operation the pelvic cavity was seen to be filled with blood clot with a little fresh blood. The fimbriated end of the right tube looked as if an ectopic pregnancy had ruptured through the end. The right tube was removed. A large pyosalpinx was observed on the left side. The abdomen was closed. leaving a drainage-tube in position. Subsequent history: the lungs were radiographed with a negative result. The patient refused further operation and. after an uneventful recovery, left hospital in three weeks. not returning subsequently.

The lumen of the tube. Prof. O'Farrell said. contained chorionic villi of about the fourth week type. and at one point there was definite invasion of the musculature. At this spot typical villi were scanty, there was marked proliferation of Langhans's cells. many of which contained mitotic figures, and there were comparatively scanty syncytial masses. These structures occupied about four low-power fields of the microscope and were indistinguishable from chorion-epithelioma malignum. In discussing the case. Prof. O'Farrell asked his hearers by what criteria they would judge whether the specimen was an early malignant tumour or a benign condition.

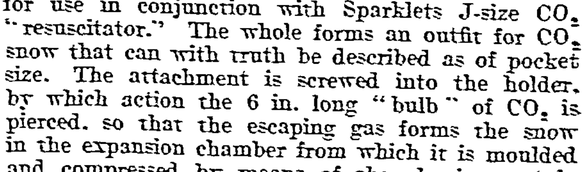
The PRESIDENT said that cases of tubal pregnancy were frequently seen. and if chorionic villi were malignant. then all these cases would be malignant—which was not so. But he thought the present specimen was a chorionic epithelioma.—Prof. J. T. WIGHAM said it was usual to find some cystic condition of the ovary in cases in which there was chorionic epithelioma. He thought that if the ovary was found to have a normal corpus luteum on the affected side, that it would be rather against the idea that the condition was becoming malignant. He thought that chorionic epithelioma was either very rapidly malignant or else that it could be readily removed, when it proved to be histologically malignant but clinically non-malignant.—Dr. R. M. CORBET said he thought the luteinisation of the ovary was the effect of too much trophoblast. It was the deciduum which influenced the ovary, and not the ovary which influenced the deciduum.—Dr. BETHEL SOLOMONS thought it looked as if the condition were definitely locally malignant. and that the patient would not be troubled again. He had almost never, he said, seen malignancy after a simple hydatidiform mole.

Other specimens were shown.

NEW INVENTIONS

A NEW POCKET CO_2 SNOW OUTFIT

THE use of carbon dioxide snow in general practice for the treatment of nævi. warts. and other skin conditions has been greatly hampered by the inconvenience of obtaining the requisite supplies of CO_2, even the most "portable" apparatus being cumbersome. involving the carriage and transportation of heavy cylinders. This deficiency has been remedied by a small attachment in nickelled brass and ebonite for use in conjunction with Sparklets J-size CO_2 "resuscitator." The whole forms an outfit for CO_2 snow that can with truth be described as of pocket size. The attachment is screwed into the holder, by which action the 6 in. long "bulb" of CO_2 is pierced. so that the escaping gas forms the snow in the expansion chamber from which it is moulded and compressed by means of the ebonite spatula supplied. Each "bulb" of CO_2 will provide a rod of solid snow about 1½ in. long and ⅝ in. in diameter. The apparatus is held pointing vertically downwards, so that the CO_2 may be emitted into the expansion chamber in its liquid form. The bulbs are inexpensive. empties are returnable for refilling and—most important—can be sent by post. The whole apparatus measures about 10 in.. and the accompanying illustration shows its essential simplicity.



The attachment is made by Sparklets, Angel-road, Upper Edmonton, N.18.

S. SHONE. M.D.. M.R.C.P.

diarrhœa in which the patient passed mucus, blood, and pus, perhaps mixed with fæcal matter. The most common lesions causing these symptoms which the surgeon was called upon to treat were ulcerative colitis and proctitis and their sequelæ, tumours of the colon, and colonic diverticulitis. In ulcerative colitis there were frequent motions with the passage of blood, mucus, pus, and sloughs. It was a disease of early adult life, and was sometimes supposed to be of dysenteric origin because Flexner's bacillus had been found in a case. At St. Mark's Hospital routine culture from the stools had invariably given negative results, and in no case had the patient's serum agglutinated Flexner's or Shiga's dysentery bacilli. Sigmoidoscopy showed œdema in the early stages and later irregular areas of ulceration covered with bleeding granulations and mucous sloughs. The mucous membrane between the ulcers might become polypoid, and healing might be followed by stricture formation. The ulcers were distributed in three bands, opposite the three longitudinal bands of muscle running along the intestinal wall. Diagnosis was suggested by the symptoms and confirmed by sigmoidoscopy; the sigmoidoscope should be passed with care owing to the danger of perforation. Achlorhydria had been demonstrated in some cases and symptoms had improved when dilute hydrochloric acid was given by mouth; calcium deficiency was also blamed, but calcium therapy had produced little benefit. Ulcerative proctitis might coexist with ulcerative colitis, or might occur separately. Stricture might follow ulcerative proctitis. Treatment of carcinoma of the cervix with radium might cause proctitis, with liability to stricture formation. Gonorrhœal proctitis might be diagnosed by finding the organism in a smear in the early stages. Syphilitic or gonorrhœal proctitis might give rise to multiple strictures associated with ulceration above and below. The possibility that these so-called gonococcal and syphilitic strictures were due to the virus responsible for lymphogranuloma inguinale had to be borne in mind. Tuberculous proctitis was rare. Simple tumours of the colon and rectum might give rise to spurious diarrhœa and so might polyposis intestini, a familial disease affecting young adults, in which there was a tendency to malignant transformation. Carcinoma of the colon or rectum could be diagnosed by sigmoidoscopy and removal and section of a portion of the growth. A barium enema was of little use in the diagnosis of carcinoma of the recto-sigmoid because this region was masked by the presence of barium in the rectum itself.

DISCUSSION

Mr. E. T. C. MILLIGAN differentiated between non-tropical ulcerative proctocolitis and granular proctocolitis. In ulcerative proctocolitis, he said, there was deep ulceration, much discharge, and loss of elasticity of the bowel wall, with a tendency to deformity and stricture; digital examination was painful; microscopic examination showed leucocytic infiltration and disappearance of lymphoid tissue. The temperature was usually high and the patient anæmic and emaciated; the prognosis was uncertain. In granular proctocolitis, on the other hand, there was redness of the bowel mucosa but no ulceration, and no loss of elasticity or deformity; digital examination was not painful; microscopic examination of a snipping showed no destruction of lymphoid tissue. Temperature and pulse were little raised, and the patient was robust and able to work. Ultimate resolution was complete.

Dr. G. VILVANDRÉ said that if radioscopy was properly performed carcinoma of the recto-sigmoidal region could be demonstrated perfectly. The rectum loaded with barium had to be pushed to one side. Moreover, a radiogram taken after evacuation of the bowel showed the anatomy of the sigmoid delicately outlined in barium.

Dr. N. HAMILTON FAIRLEY asked whether the cases mentioned by Dr. Hutchison in which there was achlorhydria were cases of true achylia gastrica, and whether any of them had shown symptoms of subacute combined degeneration. It was rare, he said, for the bacillus to be isolated from so-called cases of chronic dysentery in this country. He considered that some cases of proctitis fell between the two groups portrayed by Mr. Milligan.

Dr. M. A. ARAFA said that he had recently seen cases of catarrhal enteritis in Vienna where diagnostic significance had been attached to the presence of a tender spot to the left of the umbilicus, and to large amounts of split fat in the stools.

Dr. JULIUS BURNFORD pointed out that Dr. Hutchison's classification was based partly on ætiology and partly on symptomatology.

The PRESIDENT said that he had been unable to find any proof that stricture of the rectum was ever due to syphilis or tuberculosis, and the evidence in favour of gonorrhœa or chancroid as causal factors was negligible. It was doubtful whether this condition was due to any of the causes to which it had been attributed in the past.

In replying, Dr. HUTCHISON said that any classification of diarrhœas could be criticised. There had been no signs of pernicious anæmia or subacute combined degeneration among his achlorhydria cases. Dr. MANSON-BAHR and Mr. NORBURY also replied.

ROYAL ACADEMY OF MEDICINE IN IRELAND

A MEETING of the section of obstetrics was held on Feb. 3rd, with Dr. D. G. MADILL (in the absence of the president) in the chair. A communication on

Placenta Accreta

was made by Dr. BETHEL SOLOMONS and Dr. F. S. BOURKE. The cause of the condition, they said, was unknown, and it was very rare; there had not been one example at the Rotunda Hospital in the last 25,000 births. It could be diagnosed only when efforts to remove the placenta had failed, there being no line of cleavage. The consensus of opinion was that hysterectomy is the best treatment.

The case reported was that of a woman, aged 41, who in her first confinement lost a baby after a long and dry labour. The baby had died in utero about two days before it was born. On the present occasion she was about 36 weeks pregnant when liquor amnii began to come away. This loss continued for three days, but the cervix remained closed. After a consultation Cæsarean section was decided on. All attempts to remove the placenta failed entirely. There was no line of cleavage, and hysterectomy was done. The convalescence was without incident.

The CHAIRMAN said that placenta accreta had been described only in the last ten years, and he had never seen a case. He asked if the placenta in this case was low down in the uterus, or if it was in the fundal region. The only treatment in these cases was radical treatment. He thought it would be very difficult to make a diagnosis with the naked eye.

Malassez is only one of the factors involved in the ætiology of this widespread and troublesome affection.

The section on the treatment of syphilis remains unaffected by recent controversy, for, as the author says, "there is no routine treatment for syphilis." A schedule of treatment is unfortunately necessary, but it must not be too closely followed, and the interests of the individual patient must always be paramount. For this reason some dermatologists may criticise the suggested administration of six consecutive weekly injections of 0·9 g. N.A.B. to the average adult male as being rather a strain on the liver and the excretory mechanism, and apt to lead to exfoliative dermatitis, the "formidable complication . . . most likely to occur in cases subjected to intensive treatment." Similarly, the treatment of chronic sycosis barbæ by painting small patches at a time with the liquid acid nitrate of mercury (p. 53) seems rather a drastic measure to recommend to the practitioner. Dr. Mackenna has published several interesting observations on the treatment of lupus erythematosus by bismuth salts, which, in his opinion, is the method of choice. Gold compounds should be reserved for the cases which fail to respond to the bismuth therapy, which has at least the advantage of comparative safety. This section and the illustrations which accompany it are well worthy of consideration and study.

This text-book is well up to modern standards, and will doubtless remain popular.

Classic Descriptions of Disease

By RALPH H. MAJOR, M.D., Professor of Medicine, University of Kansas School of Medicine. London: Baillière, Tindall and Cox. 1932. Pp. 630. 30*s*.

THIS book is a collection of classical descriptions of disease selected by Prof. Major, and biographical sketches of the authors are included. The choice is mainly on clinical grounds and is a very wide one, as it embraces the work of 179 different authorities ranging from Hippocrates and the Papyrus Ebers to observers still alive. There are 130 illustrations.

The subject matter is arranged under ten headings. The first section deals with infectious diseases—namely, syphilis, tubercle, plague, tetanus, diphtheria, typhus, typhoid, scarlet fever, small-pox, measles, influenza, sweating fever, chicken-pox, whooping-cough, rheumatic fever, relapsing fever, sleeping sickness, Schönlein's disease, and finally focal infection and Hodgkin's disease. Diseases of metabolism include diabetes, thyroid disease, tetany, gout, pernicious anæmia, Paget's disease, achondroplasia, osteomalacia, myositis ossificans, acromegaly, Fröhlein's disease, and persistent thymus. The next section deals with lead poisoning and the remaining ones with diseases of the circulatory system, the blood, kidney diseases, respiratory diseases, deficiency diseases, and diseases of the digestive tract.

In the preface Prof. Major makes a graceful acknowledgment of the help he has received from others in his formidable task. Largely no doubt through the labours of Sir Humphry Rolleston, Caleb Hillier Parry of Bath here receives the just merit due to him for having been the first to describe hyperthyroidism. It may interest English readers also to hear that William Cowper, while not the first to describe the urethral glands named after him, appears to have been the first to describe and figure disease of the aortic valves in a paper contributed to the Philosophical Transactions of 1706. The notice of Richard Morton (1637–1698) omits to mention his recognition of herpes simplex as a specific febrile disease—a very remarkable achievement to which Levaditi has drawn attention. We are told that Kussmaul in 1874 was the first to employ thoracentesis, but the late Sir Norman Moore used to ascribe that honour to John Locke, the great philisopher, who was an M.B. of Oxford, and at one time had charge of a patient suffering from a pleural effusion.

Prof. Major's book was evidently a labour of love. It is compiled with much care and will be of considerable service to those who wish to have historical contributions to clinical medicine in a readily accessible form.

L'année thérapeutique

By Dr. A. RAVINA. Sixth and seventh years, 1931 and 1932. Paris: Masson et Cie. Pp. 182 and 176. Fr.16 per vol.

THE series of "L'année thérapeutique" has now reached its seventh year, having been started in 1921, but interrupted in 1924 by the death of the former editor, Dr. Cheinisse. The object of these little volumes is to provide a summary of new work in treatment, of new methods, and of changes taking place in the whole field of therapeutics. Dr. Ravina has not limited himself to one branch of medicine, but has divided the subject into three sections: the first on diseases and symptoms, the second on methods of treatment, and the third on new drugs. In all such works the difficulty lies essentially in evaluating recent work. Dr. Ravina has, for the most part, contented himself with summarising numerous papers published, principally in France and Germany, without offering criticisms or judgment upon their value. Many of the papers referred to will be new to English readers, and the results recorded will not be too readily accepted.

In the last volume (1932) the "new" drugs mentioned include the mercurial diuretics, nembutal, hæmolytic and antistreptococcal sera, and extracts of convallaria and adonis in heart disease. In pulmonary tuberculosis Dr. Ravina regards sanocrysin treatment as established. Other methods described include the use of atebrin in malaria, suprarenal cortical extracts in Addison's disease, liver extract injections in pernicious anæmia, and many other less well-known innovations. Some of these such as the apple cure in infantile diarrhœa, ovarian extract treatment of hæmophilia, the use of pancreatic extracts in scleroderma and Ménière's disease will strike the English reader as requiring further confirmation.

Books in this series contain information that cannot easily be found elsewhere in collected form, and if read with proper caution and perspective should be of real help to practitioners.

Animal Diseases in South Africa

By M. W. HENNING, Professor of Veterinary Science, University of Pretoria. South Africa: Central News Agency. 1932. 2 vols. Pp. 405 and 469. 50*s*.

THESE volumes are confined entirely to animal diseases of economic importance, including bacterial, protozoal, and virus diseases, those due to poisonous plants, and deficiency diseases. For the greater part Prof. Henning has followed the orthodox teaching given at the laboratories for veterinary research established under the department of agriculture of the Union of South Africa at Onderstepoort. The work has indeed been produced primarily for veterinary students in South Africa, who have already studied pathology and bacteriology in detail, since familiarity with these subjects is assumed. It should also be

REVIEWS AND NOTICES OF BOOKS

Pastoral Psychiatry and Mental Health

By JOHN RATHBONE OLIVER, D.D., M.D. London: Charles Scribner's Sons. 1932. Pp. 330. 8*s.* 6*d.*

THE issue of such a book as this will not meet with universal approval among doctors. It is addressed to "persons without definite medical training and experience whose work brings them in touch with the mental illnesses and maladjustments of their fellow men," in the hope that it will help them to recognise and handle such cases. It certainly provides a fairly sound and simple account of the familiar mental disorders, their causes and treatment. It is particularly meant for clergymen, and the author's qualifications for writing it are that he is a Catholic priest as well as a practising psychiatrist. The value of religion in the prevention and treatment of mental disorder is constantly stressed. The exposition of psychiatry here is for the most part in conformity with modern teaching, and would be of assistance to the chaplain of a mental hospital or to a court missionary. Spiritual directors of the Roman Catholic church already have their manuals, here enumerated in an excellent bibliography. The author often expresses his debt to these works, most of them written by Jesuits. There is much clinical documentation throughout the book. There are two temperate chapters on sexual factors and a final chapter on religious faith and practice.

It is probable that the book will be used by many untrained social workers, attached to churches and charitable bodies, who will accept the statement on its dust-cover that it can be easily and thoroughly understood, and that it will enable them to "supply accurate scientific help to the bewildered, the mentally sick, and the profoundly maladjusted." This is certainly not a safe assumption: amateur book-learnt therapy is as risky and ineffective in psychiatry as in other branches of medicine.

The Physical Mechanism of the Human Mind

By A. C. DOUGLAS, M.D., Ch.B. Edinburgh: E. and S. Livingstone. 1932. Pp. 251. 15*s.*

THE pursuit of neurological explanations of behaviour continues to occupy the minds of observers who attempt a unification of all the data concerning living things. It is only natural that those who have been brought up on anatomy and physiology should find it irresistible to picture behaviour in terms of neural process. The growth of our knowledge of the nervous system has produced such a nicely woven fabric of neural paths, from the simple mechanisms governing digestion and the expression of emotion to the mechanism of speech itself, that it would appear sufficient to rest all explanations of behaviour upon neural mechanisms. It certainly introduces a simplicity which the logical mind desires for the sake of economy in the use of concepts. The use of concepts, however, belongs to the world of ratiocination and when we turn from logic of thought to the logic of values, whether they be moral or æsthetic, we find that the neural explanation becomes little more than a diagrammatic scheme of a process which is constantly concerned with growth as new situations are faced.

In the first half of this admirable neurological exposition the reader feels completely satisfied, but when the author enters the domain of perception, association, belief, will, and imagination, the scheme breaks down, and what was at first a translation of mind into the language of physiology becomes little more than a synopsis, a skeleton from which the essential structures have been removed. The author does not reach the first manifestations of behaviour in reflex actions, but finds the reflex actions precipitations of purposes which have become stereotyped along neural paths. The concept of Value, which so frequently appears in the last 50 pages of this book, can have no neurological counterpart. It is not that neurology is by any means mistaken in its description but that it is insufficient as an explanation. It may be methodologically sound to separate mind from body, but it is a gross elimination of the facts of experience to ignore the processes which have no physiological counterpart and which cannot be squeezed into a neurological scheme the very vocabulary of which is so frequently borrowed from the world of psychology.

Entstehung, Erkennung, und Behandlung innerer Krankheiten

I. Band. *Pathologische Physiologie.* XIVth Edition. By LUDOLF KREHL, Professor in Heidelberg. Berlin: F. C. Vogel. 1932. Pp. 716. R.M.39.60.

Prof. Krehl's momentous work has now reached its fourteenth edition. The whole field of human physiology is covered from the standpoint of variations and disorders. The processes that underlie the causation of disease and form the foundation of all diagnosis and treatment are fully discussed. Throughout the work the author's critical refusal to accept unproved hypotheses stamps him as one whose sincerity of purpose fits him to be a teacher of advanced students. He does not hesitate to express his own views with emphasis, though without dogmatism, but the opinions of others are carefully reviewed. Over 2000 references to original papers are supplied. This work on the origins of disease provides a link between physiology and clinical medicine. It may not lessen the difficulties of the practitioner in understanding and explaining the production of symptoms and signs, but it will emphasise in his mind the gaps in our knowledge, and will prevent him from drawing facile conclusions from insufficient data.

This work is a standard reference book of a kind which clears the way for the advance of medicine.

Diseases of the Skin

By the late ROBT. W. MACKENNA, M.A., M.D., B.Ch. Edin. Third edition, revised and enlarged by ROBT. M. B. MACKENNA, M.A., M.D., B.Ch. Camb., Hon. Dermatologist, Liverpool Heart Hospital and Stanley Hospital. London: Baillière, Tindall and Cox. 1933. Pp. 506. 25*s.*

WE reviewed the second edition of this now standard work six years ago; the revision and amplification of his father's work necessitated by advances in dermatology since that time have been admirably carried out by Dr. R. M. B. Mackenna. Some 50 pages have been added to the text, and the number of coloured plates and illustrations has been increased. The section on the seborrhoides and seborrhœic dermatitis (p. 189) has been rearranged according to modern ideas and to alteration of bacteriological nomenclature, and it is to be hoped that biochemical discoveries will demand further amendment of this section in a future edition, for the pityrosporon of

THE LANCET

LONDON: SATURDAY, MARCH 11, 1933

SPONTANEOUS HYPOGLYCÆMIA

THE level of the blood-sugar at any given time depends on the amount of sugar entering and leaving the blood stream, and it is maintained within normal limits principally by the action of adrenaline and insulin—the thyroid and pituitary hormones probably playing a less important part. Thus a rise of blood-sugar due to absorption of glucose from the alimentary tract, or from any other cause, will result in a secretion of insulin which will rapidly bring the blood-sugar back to normal or slightly subnormal levels, whilst a fall in blood-sugar, or increased peripheral oxidation—e.g., in active exercise—will call for liberation of more adrenaline. The action of adrenaline is to mobilise the glycogen stored in the liver, and where the functional activity of the liver is much impaired—as in severe ketosis or toxæmia, or extensive hepatic disease—there may be both an abnormally poor response to adrenaline and also delay in storing carbohydrate absorbed from the gut. Similarly, when the glycogen stores of the liver have become depleted—which readily happens in most young animals, including children—increased calls for glucose may cause a temporary breakdown of the sugar-regulating mechanism, and the result will be a moderate degree of hypoglycæmia. The reason why the breakdown is only partial, even after prolonged starvation, is that the liver obtains glycogen from sources other than carbohydrate (glyco-neogenesis), and this method of "living on capital" prevents the blood-sugar from falling too far.

It will be clear that over-secretion, or unopposed action, of insulin or adrenaline will tend to produce hypoglycæmia or hyperglycæmia respectively. The clinical features of hyperglycæmia have been familiar to physicians since the dark ages, because at a certain point excess of sugar passes into the urine, where it may be recognised by the sense of taste or by more modern tests. Hypoglycæmia, on the other hand, provides no such simple clue, and its occurrence has only been known since injection of insulin has made it possible to appreciate the symptoms. These prove to be very various, and it is evident that minor degrees of hypoglycæmia are likely to remain undiagnosed unless the clinician is on the watch for them. Amongst the commonest are sweating, incoördination, and an inexplicable sense of fear; sometimes the incoördination may be so conspicuous as to suggest alcoholic intoxication. Dr. HECTOR CAMERON[1] has pointed out that in children night terrors, nervous instability, and disturbances of sleep may sometimes be alleviated by the judicious administration of glucose, and in adults it is more than probable that the wide popularity of the cocktail before a meal is in part due to the relief of hypoglycæmia which it brings. The exhaustion of athletes, again, often responds rapidly to the administration of easily assimilable carbohydrate. Here, of course, we are dealing with more or less physiological variations; but the theoretical prediction that a pathological state of hyperinsulinism, comparable to hyperthyroidism or hyperpituitarism, would be recognised has now been justified and a number of examples have been described. Where post-mortem examination or operation has shown the condition to be due to lesions of the pancreas, these lesions have usually proved to be malignant. In other cases, however, such as the one just reported by DERICK and others,[2] an adenoma of island-of-Langerhans type was found and was removed with relief of symptoms. In our present issue, Dr. W. J. GRIFFITHS and Prof. O. L. V. DE WESSELOW record an example of what they regard as "dysinsulinism," and give reasons for thinking that the symptoms are most easily explained by new growth or diffuse hyperplasia of the islet tissue of the pancreas—in spite of an anomalous response to the glucose test-meal. These conclusions are criticised by Dr. P. J. CAMMIDGE and Dr. E. P. POULTON, who put their emphasis on the hepatic element in this and some other cases.

The reader in search of a general survey of hypoglycæmia will find it in the current issue of the *Quarterly Journal of Medicine* (p. 117), where Dr. GLADYS M. WAUCHOPE reviews the subject as a whole. She classifies it in the following categories:—

1. *Excess of insulin,* arising from therapeutic injections, tumours and hyperplasia of the pancreas, and so-called functional hyperinsulinism.
2. *Lack of opposing secretions* from disease of the suprarenal glands, pituitary tumours, and myxœdema.
3. *Lack of glycogen* owing to destruction of the reservoirs—viz., hepatic disease or wasting of muscles—abnormal excretion of sugar due to a lowered renal threshold or lactation, depletion of glycogen stores from active exercise, and failure to replenish them from starvation.
4. *Interference with the regulating centre,* as in nervous disorder affecting the pons, or overaction of the vagus.

In several of these conditions it is admittedly difficult to prove cause and effect, and the interpretation is somewhat speculative. It appears clearly that there is no blood-sugar level at which symptoms of hypoglycæmia regularly manifest themselves, and that a rapid fall in blood-sugar will produce them at a much higher level than if the fall is gradual. Indeed, chronic hypoglycæmia may be associated with very little disturbance, or may be found only on routine examination, whilst an excessive dose of insulin may produce symptoms in a diabetic if it results in a rapid fall of blood-sugar to a level that would normally be considered hyperglycæmic. It is surprising to find that WAUCHOPE gives as high a level as 0·08 to 0·07 per cent. as the usual level for the onset of clinical hypoglycæmia, although it is pointed out that the welcomed by field veterinary officers, and its easy style and interesting historical descriptions of diseases should give it a wider public among stockowners. Much of the material has hitherto been available only in journals; this applies more particularly to the filtrable virus and plant poison sections.

[2] Derick, C. L., Newton, F. C., Schulz, R. Z., Bowie, M. A., and Pokorny, N. A.: New Eng. Jour. Med., Feb. 9th, p. 293.

The pattern adopted for each disease is to discuss causal organism, susceptible animals, methods or suggested methods of transmission, geographical distribution in South Africa, and their symptoms, course, lesions, diagnosis, treatment, and prevention. Considerable space is devoted to prophylactic inoculation. Measures for State control are included in descriptions of "scheduled" diseases, and the reasons of their enforcement are explained. If farmers would take the trouble to read these sections they might grow more eager to coöperate with the Ministry of Agriculture. Throughout the book disease control is regarded from the point of view of the State and of the herd, very little space being allotted to the treatment of individual animals. This doctrine is in keeping with the ranching type of farming practised in South Africa. It is unfortunate that a subject of such economic importance as parasitology should have been omitted entirely. A third volume repairing this omission would be a valuable addition.

A text-book dealing with disease economically important in one country must have a message outside its range. This work is of real value in collecting and setting forth the results which have been attained by Sir Arnold Theiler and his co-workers at Onderstepoort. The section on plant poisons forms an excellent addition to the literature of a subject much neglected in veterinary works.

The Early History of the Infant Welfare Movement

By G. F. McCLEARY, M.D. Cantab., D.P.H., formerly a Deputy Senior Medical Officer, Ministry of Health; Medical Officer of Health, Battersea. London: H. K. Lewis and Co., Ltd. 1933. Pp. 176. 6s.

BROADLY speaking, the infant welfare movement came into being at about the end of the nineteenth century, and Dr. McCleary, one of the pioneers of the movement in this country, has written an illuminating account of its early history, which he divides into two periods, the first up to June, 1906, when the first conference on Infantile Mortality was held in London, and the second up to the next conference in 1908. A concluding chapter summarises the events between 1908 and 1914. Dr. McCleary wins the reader's gratitude by an admirable gift of selection; he has produced an essentially complete record without ever becoming tedious or overloading his chapters with unnecessary detail. Amongst forerunners of the infant welfare movement, William Cadogan (1711–1797) and George Armstrong, who in 1769 founded a "Dispensary for the relief of the Infant Poor," are quoted for their modern views and active work on behalf of infancy, while John Brunnell Davis (1780–1824) was the first advocate of health visiting. The great debt of child welfare to French physicians, among whom Pierre Budin will always hold first place, is well set out, as is the contribution of America towards securing a satisfactory milk-supply, the two outstanding figures in this campaign being Nathan Straus, the apostle of pasteurisation, and Henry Leber Coit, to whom the introduction of certified milk was due. Dr. McCleary was himself responsible for the first infants' milk depôt in London, opened in Battersea in 1902, when he was medical officer of health of that borough. The inception and development of a health visiting service, of schools for mothers, infant consultations, meals for nursing mothers, and other features of child welfare work make an interesting record, and the reader is introduced to an imposing gallery of pioneers—Alderman Benjamin Broadbent, Drs. A. K. Chalmers, Drew Harris, J. W. Ballantyne, J. F. J. Sykes, Sir George (then Dr.) Newman, Dr. S. G. Moore, Sir Arthur (then Dr.) Newsholme, Dr. Eric Pritchard, and others whose names are household words among child welfare workers. In his final chapter Dr. McCleary discusses the question how far the decline in infantile mortality in the period covered by his record may be attributed to the infant welfare movement, and makes out a good case for regarding this as probably the most potent, though certainly not the only, cause for the improvement achieved. A double index, one under names and the other under subjects, adds to the value of this well-written book.

British Journal of Children's Diseases

To the January–March number Dr. W. G. Wyllie and Dr. Bernard Schlesinger contribute a paper based on 80 cases on the Periodic Group of Disorders in Childhood, in which they include bilious attacks, cyclical vomiting, ketogenic or acetonæmic vomiting, recurrent pyrexial attacks, and migraine. The periodic attack is manifested clinically by a syndrome composed of vomiting, abdominal pain, headache, and fever. In some instances vertigo, rise of blood pressure, lapses of consciousness, and convulsions are observed. In a large number of cases there is a history of a similar complaint in other members of the family or in the childhood of one or other parent. The latter may suffer from biliousness or migraine in adult life. The influence of heredity is more often found on the maternal side, though in the writers' series migraine in the father was not uncommon. Asthma occurs in a considerable proportion of such families, so that the question of an allergic factor in the make-up of children suffering from the periodic group of disorders has been raised. From a study of the effects of a ketogenic diet and the results of liver function tests in normal children and subjects of the periodic syndrome the writers conclude that the primary factor underlying the occurrence of the syndrome is of nervous origin.—Dr. F. Parkes Weber and Dr. T. R. Hill relate a Case of Cerebral Obesity Due to Chronic Encephalitis Lethargica in a boy aged 11, with a description of the appearance of the brain after death, which was characteristic of long-standing cases of the disease as described by other writers.—Dr. W. M. Feldman and Dr. A. Chalmers report a Case of Complete Transposition of the Great Vessels of the Heart with a Patent Foramen Ovale, in which the points of interest during life were the variable intensity of the cyanosis which at times was very slight, the relatively slight polycythæmia, and the comparative paucity of the leucocytes.—Dr. W. J. Rutherfurd records a Case of Hereditary Knock-knee, with Recurrent Dislocation of Patella and Aplasia of Nails in Fingers and Toes. The knock-knee was not rickety but was inherited, five cases having occurred in three generations. Every affected member of the family showed aplasia of the finger- and toe-nails, but other members of the family had similar affections of the nails without the bony deformity. Hereditary aplasia of the nails though rare was mentioned by Theophrastus in the third century B.C. in his description of the Nasty Fellow.—Dr. E. W. Goodall gives an account of three cases in which an Eruption of Petechiæ Followed Attacks of Vomiting.—The abstracts from current literature are devoted to tuberculosis.—A preliminary programme of the Third International Pædiatric Congress, which will be held in London from July 20th to the 22nd, will be found in this issue.

CARRIERS OF ENTERIC

In Great Britain the abolition, with rare exceptions, of gross contamination of water-supplies has reduced morbidity and mortality from enteric fever to small proportions. But this fall in incidence has, if possible, enhanced the importance of chronic carriers who are now the chief causes of epidemic outbreaks both in the community at large and in institutions. Prof. C. H. Browning and his associates in Glasgow have therefore rendered a valuable service in undertaking to report[1] upon this problem in the light of their own researches and those of others.

Enteric carriers may be classified according to the duration of the carrier state, and also according to the route of excretion of the specific organisms. It has been shown that, in paratyphoid B infections especially, the incidence of *temporary* carriers in convalescence is high, and the report therefore lays stress on precautions against the spread of infection during the convalescent period. In some cases the carrier state may set in several months after convalescence, and its occasional intermittency is also a factor which adds to the difficulties of control; intervals of infectivity "may be separated by non-infective periods of years." Most of those who continue to excrete bacilli for six months after the acute attack will continue to do so. Those who still excrete after a year, fortunately a small proportion only, will not clear spontaneously; the carrier state becomes *chronic* or permanent. The chronic carrier after a known attack of enteric fever is sufficiently dangerous, but in the investigation of an outbreak the history of the illness at least provides a clue to a possible source of infection. More dangerous, because more elusive, is the chronic carrier who has had no known attack or whose carrier state is intermittent. The two main routes of excretion are fæcal and urinary; it is also well recognised that bone sinuses, or subcutaneous abscesses, may continue to yield pure cultures for long periods. The chronic fæcal carrier or excreter is "usually a married woman of 30 years of age or upward." Female chronic carriers exceed male carriers in the proportion of four or five to one. Children rarely become chronic carriers, but are important agents in dissemination because the attack is so often mild and atypical. Fæcal carriers, who are occasionally "mixed" carriers of *B. typhosus* and *paratyphosus*, are far the most numerous class and may be further subdivided into the biliary carrier (gall-bladder or liver and bile-ducts, or both) and the rare true intestinal carrier. Although chronic cholecystitis, usually but not always associated with gall-stones, has been found in a large proportion of fæcal carriers, cases have occurred in which the biliary system could be held blameless, the focus being strictly intestinal. Not only may gall-stones be absent but the gall-bladder may show comparatively slight naked-eye changes such as thickening of the mucosa. Histologically, the most marked change observed by the authors of the report consisted in "localised and diffuse collections of cells in the mucosa, which are mainly plasma cells and lymphocytes with scanty eosinophiles." They think there is considerable support for Garbat's view that the gall-bladder in these carriers acts as "a test-tube containing the bile medium in which the typhoid bacteria propagate without affecting the gall-bladder itself." Urinary carriers, although less numerous, are clearly more dangerous than fæcal carriers. Not only are the opportunities for spreading infection greater, but the organisms occur in large numbers in the urine and not uncommonly in pure culture. The nidus of infection appears to be "most commonly situated in the kidney or kidney pelvis." That one kidney only may be infected has been shown by means of ureteral catheterisation and the clearance of the carrier state after the removal of the unilateral lesion.

Apart from careful treatment and nursing and the provision of a high calorie diet during the acute and convalescent stages, is it possible to prevent or lessen the possibility of the patient becoming a carrier? Prophylactic inoculation diminishes the incidence of clinical attacks. When attacks do occur in the inoculated they tend to be slight, and it has been held by some that carriers after such modified attacks are less numerous. Others, however, have not been able to confirm this. General anti-enteric inoculation of any population liable to exposure is not practicable in peace-time. But the same measure applied to closed communities such as the staff and inmates of mental hospitals is not only practicable but highly desirable. Prof. Browning and his colleagues point out that although this measure be adopted the carrier must still be searched for and treated, since amongst the recently vaccinated massive infection may yet result in an epidemic. It is well known also that the protection afforded by inoculation with T.A.B. tends to wane after a year, and to secure full protection thereafter the process must be repeated. It is advised that in addition to bacteriological evidence of freedom from infection before discharge of a case from hospital, examinations should again be made six to twelve months later, compulsory powers being exercised by all authorities in order to obtain the necessary specimens from convalescents and suspects. In Scotland, under Article 13 of the Public Health (Infectious Diseases) Regulations, 1932, it is possible to notify and to remove compulsorily a carrier, subject to the certificate being renewed every three months. In England powers exist merely to prevent enteric carriers from being concerned in the preparation or handling of food or drink for human consumption. In America regulations for the control of carriers are much more comprehensive and drastic. The authors of the report consider that the existing accommodation, usually an isolation hospital, for the investigation and difference in methods of blood-sugar estimation makes it difficult to compare the results of different observations, and that the level is generally lower in childhood.

---

[1] Chronic Enteric Carriers and their Treatment. By C. H. Browning, with H. L. Coulthard, R. Cruickshank, K. J. Guthrie, and R. P. Smith: Medical Research Council, Spec. Report Series No. 179. London: H.M. Stationery Office. 1933. Pp. 80. 1s. 6d.

Though certain broad generalisations are being formed it is obvious that the interpretation of the individual case of hypoglycæmia will remain largely a matter of medical polemic until the action of the hormones regulating carbohydrate metabolism is more precisely understood.

◆

THE PHARMACY AND POISONS BILL

CHANGES in the profession of pharmacy and in the law of poisons are projected by the Pharmacy and Poisons Bill (H.M. Stationery Office, 6*d.*) which has been introduced in the House of Lords. The report of the Departmental Committee of 1926 regretted that these two subjects were so curiously entangled in the statute-book. The new Bill seeks to simplify the law. Like its predecessor in 1931, it is based on the draft Bill appended to the 1926 report; but there are occasional new features—e.g., the proposed prohibition of the sale of any poison from an automatic machine. The 1931 Bill passed through the House of Lords in spite of opposition from Lord DAWSON OF PENN, who complained that there had been too little consultation of the medical profession, and that the control of poisons, hitherto managed with success by the Pharmaceutical Society, was being handed over to a new bureaucratic body imperfectly acquainted with the needs of medicine. In the Commons the Bill made no headway. Its successor deserves a better fate, for the existing law is full of anomalies. Last September a man was found dead on Porlock Hill in Somerset with enough arsenic in his pockets to kill 642 persons. He worked for a paint firm, and poison was easy to get. "I could not go to a chemist's and buy 5 grains of arsenic without giving a convincing explanation," said his employer; "but I can write an order for 5 hundredweight and have it delivered here in a couple of hours without having to answer a question."

The pharmacy clauses early in the new Bill give membership of the Pharmaceutical Society to registered pharmacists; it will no longer be a matter of election. Names will be removed from the register for good cause through the agency of a Statutory Committee, subject to a right of appeal to the High Court. In this part of the Bill the Privy Council remains the central authority. A registered pharmacist who retails drugs will become an "authorised seller of poisons," provided that he or another registered pharmacist is in personal control of the premises, and of each set of premises, where the retailing is carried on, and provided that the name and certificate of registration of the person in control is conspicuously exhibited. No unregistered person is to call himself "pharmaceutical chemist," "chemist and druggist," "druggist," or "pharmacist." The difficulty of thus restricting the title of "chemist," which members of the Institute of Chemistry have a right to share, is met by legislating only as to that title if used in connexion with the sale of goods by retail. The clauses about poisons, later in the Bill, propose considerable changes. As the departmental committee proposed, and in spite of Lord HEWART's suspicions of encroachment upon Parliamentary functions, the Poisons List is to be taken out of the statute-book and left to be settled by a Poisons Board of 16 or more members including representatives of the Pharmaceutical Society, the Royal Colleges of Physicians, the General Medical Council, British Medical Association, and Institute of Chemistry, as well as nominees of the Home Office, Scottish Office, and Ministries of Health and Agriculture. The Poisons List, to be prepared by the Poisons Board and confirmed by the Home Office, will be in two parts. Part I. poisons will be saleable only by "authorised sellers of poisons"; Part II. will contain those which can be sold only by such "authorised sellers" or by persons on the local authority's list, the latter list corresponding to the present list of persons locally authorised to sell poisonous preparations used for agricultural and other non-medical purposes. The Poisons Board will have a free hand; their sole statutory guidance is the suggestion that they shall restrict Part II. to articles which are in common use "for purposes other than the treatment of human ailments," and which the public should have adequate facilities to obtain.

The proposed restrictions on the sale of poisons are partly set out in the Bill and partly left to Home Office rules. Except as provided by the rules (a rather vague exception which will require vigilant scrutiny), this part of the Bill is not to interfere with the sale of articles to duly qualified doctors or to registered dentists or veterinary surgeons for professional use or with sales to approved hospitals or to research workers for use in research. Amongst other conditions, it will be unlawful to sell a poison unless its container is labelled with the name of the poison, the proportion of the poisonous ingredient to the total ingredients, the name and address of the seller, and the word "poison" *or other prescribed indication of the character of the article.* The words which we have italicised seem to be new law. Unless rules relax the requirement, a Part I. poison must not be sold to anyone unless he is either "certified in writing" (more new law) or known to the seller to be a person to whom the poison may properly be sold. The seller of the Part I. poison must not deliver it until he has entered in a book (with the purchaser's signature) the name and address of the purchaser and of the person who certifies the purchaser. These special provisions as to sale of Part I. poisons however, are not to apply to medicine supplied by duly qualified doctors, registered dentists, and registered veterinary surgeons for professional treatment. A rather complicated subclause about book entries of all prescriptions containing poisons has a saving for medicine supplied on prescription under the National Health Insurance Acts. The Bill seeks to protect the public; poisons are not to find their way too easily into the wrong hands. At the same time, Parliament must so fashion the Bill that medical practice and research are not made too difficult.

a Government commission was appointed to investigate. The work of this commission was completed last November, and its report has just been published. Much of it is a summary of observations made abroad, but the members of the commission have all the time kept in mind the bearings these observations may have on their own country. In *Nordisk Medicinsk Tidskrift* for Feb. 4th Prof. A. Lichtenstein, one of the commissioners, publishes a summary of the report, and in the same issue of the journal appears a paper by Dr. E. Abramson of Stockholm on the problem of vaccination in Sweden. It appears from Prof. Lichtenstein's summary that while vaccination legislation has been extensively revised in many countries since the Great War, there has been a general tendency to retain compulsory vaccination for children. In answer to the question: Should compulsory vaccination be retained? his commission has replied by pointing out the inefficacy of isolation alone against small-pox, and by emphasising the difficulties associated with vaccination deferred till small-pox has broken out in the neighbourhood. The commission finds that obligatory vaccination in childhood is at present the best protection against small-pox. On account of the age-distribution of post-vaccination encephalitis, the commission is in favour of early obligatory vaccination, preferably during the first year of life. In certain communities in Sweden there seems to have been a general revolt against compulsory vaccination, with legal consequences distressing for all concerned. To face this psychological problem of mass suggestion the commission urges more effective health education in connexion with vaccination. Swedish legislation of 1916 had a "conscientious objection" clause which, between 1917 and 1926, was so strictly interpreted by the authorities that they admitted only one claim. In the period 1926–1931, as many as 145 out of 406 claims under this clause were admitted. The remedy for inconsistency of this kind is popular education.

MEDICAL AND DENTAL REGISTERS

THE Medical Register for 1933 contains 56,096 names, being 492 more than last year and 14,156 more than in 1913. The numbers added during 1932 by registration in the several divisions of the United Kingdom do not differ much from the last five-year average; 19 more in England, 8 less in Scotland, 3 less in Ireland. The addition of 196 to the Colonial list is 17 in excess of the average. There is only one removal from the Register on ceasing to practise, and only six under the penal sections of the Medical Act, the average being five over a long period of years; the smallness of this number may come as a surprise to those accustomed to take their views of professional integrity from the headlines of the daily press. Removals on evidence of death (960 last year) steadily rise in number; an increase which, although a perfectly natural happening, must be borne in mind when considering replacements. Other than these figures, the introductory pages of the Register are little changed. There is a small addition to the documents in the signing of which the practitioner is asked to observe care. The six pages containing names of present and past officers and members of the Council contain not a single name of a woman, a fact that would more readily have escaped notice had it not been for recent correspondence in our columns. Colonel Norman C. King will be signing warning notices for the last time, as his well-earned retirement is nearly due. The tables showing reciprocity with British possessions and foreign countries seem to have remained unchanged and may signify a state of equilibrium; if so, it may give food for thought that among all the countries of the world Italy and Japan are the only ones who accept our medical degrees and whose medical degrees we accept in exchange. Those who have hitherto not found much use for the Register we may remind that under the Medical Act of 1858 a copy of the Register for the time being is evidence in all courts of law, and before all justices of the peace and others, that the persons specified therein are registered according to the provisions of this Act; and that the absence of the name shall be evidence, until the contrary be made to appear, that such a person is not so registered. Moreover the Register has the merit for ready reference that it is almost a single alphabetical list—with the lamentable exception of the Colonial and Foreign lists at the end, the separate publication of which, although admittedly serving no useful purpose, remains because it would require an Act of Parliament to merge them. Finally we offer tribute to the accuracy of a list whose only misprint—in a place name, detected last year—no longer appears, although, to be honest, it was deleted by death and not by correction.

The Dentists Register for 1933 contains 14,528 names, being 56 more than last year, and 1766 more than in 1922, when for the first time dentists without qualifications were included. As an inset to the Register is issued a list of dental companies and the names of directors of companies carrying on the business of dentistry.

The lists of Medical and Dental Students registered during the year 1932, published under the direction of the General Medical Council, show that 1947 medical students registered during the year, a number larger than in any year since 1920, and 322 dental students, a number larger than in any year since 1922. All three Registers are published for the General Medical Council by Messrs. Constable and Co., 10, Orange-street, London, W.C.2.

THE PRODUCTION OF QUININE

WE noted recently[1] that the amount of quinine necessary—20 g.—to give to every patient suffering from malaria throughout the world was estimated by the Health Organisation of the League of Nations as 1,387,000 kg. yearly. The question has naturally been raised whether such a demand could be met by the quinine industry. Messrs. Howards and Sons inform us that it could, as the normal sales of the 14 principal factories, excluding those of the Indian and Italian Governments, are about 500,000 kg. yearly, and it may be assumed safely that their existing plant could give an output twice as great. Moreover these factories always hold very large stocks of quinine to meet any sudden need; for a more permanent demand sufficient plant could rapidly be erected, probably within a few months, to increase their present maximum output by 50 or even 100 per cent. Huge stocks of bark are also held, while the cinchona plantations are at present collecting only about half of their possible harvest and could greatly increase their present output at short notice. There is, then, ample quinine to meet not only present needs but all that can be foreseen. No world shortage of the drug exists, but the position noted in our columns five years ago[2] still persists—that is, a shortage of quinine at a price which would make it available for general tropical use. The difficulty is wholly economic. The great mass of those who treatment of carriers involving bacteriological, radiological, urological, and operative procedures is not adequate. This is certainly true of many small fever hospitals, but several of the large institutions already possess, or can readily provide, the necessary facilities.

---

[1] THE LANCET, Jan. 28th, p. 206.
[2] Ibid., 1928, i., 87.

In the treatment of the chronic fæcal carrier chemotherapy, physiotherapy, and the administration of *B. acidophilus*, with a view to changing the reaction of the intestinal flora, alike proved ineffective. Vaccine therapy, including Besredka's oral bile-vaccines, produced no better results. Where the gall-bladder is the site of infection cholecystectomy has been successful in terminating the carrier state in 75 per cent. of cases. Failures may have been due to the fact that the patients were purely intestinal carriers who cannot be detected with certainty before operation. It seems clear that just as the chronic carrier state in diphtheria is most certainly terminated by the removal of infected tonsils and adenoids, so surgical measures offer by far the best chance of success for the cure of the chronic enteric carrier. In both conditions much expenditure of time and money will be saved when this fact is generally recognised.

ANNOTATIONS

THE HUME LECTURES

In opening the review, of which we publish the conclusion this week, Mr. H. Morriston Davies said it seemed to him a fitting tribute to the memory of George Haliburton Hume that the subject matter selected for the first lecture on surgery under his name should be thoracic surgery. A contemporary of Lauder Brunton and a pupil of Syme, Hume witnessed the complete development of Listerian methods; to his knowledge obtained in this country, he added that acquired by prolonged visits abroad, notably in Berlin and Vienna. Hume was on the active staff of the Royal Infirmary, Newcastle-upon-Tyne, for 34 years, and as chairman of the staff took a prominent part in the building of the new Infirmary, being instrumental in obtaining a gift of £100,000 from Mr. John Hall and many other contributions. He was three times president of the Northern Counties Medical Society, and the esteem in which he was held was manifested by the society commemorating his name by endowing the George Haliburton Hume lectures. The interest taken by Hume in surgery and in its progress made it right, said Mr. Morriston Davies, to pause a moment to consider why the advance of chest surgery lagged so far behind the surgery of other parts of the body. The first real advance in surgical treatment was made possible by the discoveries of Lister; the terrors were in great part allayed by the introduction of antiseptics and of narcotics. Operative treatment became a practical science and advanced with rapidly increasing strides. Operations on the abdomen, on the limbs, and on the head and neck, ceased to be those only of urgent necessity.

The brain alone, other than the thorax, resisted for a time an increasingly successful response to surgical skill. Soon however the mechanical conditions of the skull and brain became understood while the thorax remained not Victorian but pre-Victorian in its imperviousness to modern methods; unresponsive to surgical skill, repaying usually by the death of the patient any efforts more heroic than those of previous decades—one might almost say centuries. The last 15 to 20 years had, however, seen a change almost incredible in its rapidity. The surgery of the chest had suddenly ceased to be a dark reproach on this science; it had become instead an illuminating example of what could be accomplished once the fundamental principles of anatomy, of physiology, and of the mechanical peculiarities of the region, in addition to the pathology of the disease, were understood.

In pulmonary tuberculosis the value of surgical treatment has long passed the experimental stage. Collapse therapy, as Mr. Morriston Davies remarks in his summing up, will save life, in many cases restoring the individual to working capacity. For many it will enable healing to take place and will shorten the period of treatment. The more drastic forms of this therapy may give individuals life and health otherwise unobtainable, but in the matter of thoracic surgery, he adds, this country is still sadly behind America, Scandinavia, and other continental countries. Only Wales and a few counties, it seems, give their tuberculous patients every modern aid in treatment, but there are indications of a rapid change. A recent meeting of the West London Medico-Chirurgical Society was given up entirely to discussing artificial pneumothorax and Dr. F. E. Saxby Willis laid down clearly the indications for its employment. The director of the Michigan State sanatorium for tuberculosis has recently given his conclusion[1] that the majority, not the minority, of cases of active pulmonary tuberculosis are suitable for collapse therapy in some form; and very striking is the allocation of two whole numbers[2] of an important French journal to the surgical treatment of pulmonary tuberculosis, one of these numbers containing an admirable summary of the work of Prof. J. Sebrechts at the Hôpital St.Jean at Bruges. The editorial committee of the journal points out that the experience of the last few years is pointing in rather a new direction. The surgeon, instead of embarking at once on a total thoracoplasty, is attempting to achieve various forms of partial collapse more strictly adapted to the particular lesion before him. At Bruges in particular Sebrechts has concentrated on the obliteration of apical cavities by apicolysis; in Davos where the technique of collapse has been brought to a high degree of efficiency by intrathoracic division of adhesions, Dr. G. Maurer never omits to emphasise the fact that every method must be considered in every case. It is no longer a question of the routine application of the method of Forlanini or the method of Sauerbruch. The Hume lecturer has given a lead in the application of means to ends in the practice of thoracic surgery.

THE SMALL-POX PROBLEM IN SWEDEN

During the last few years the problems of small-pox and vaccination have been considered in Sweden in view of the occurrence there of cases of small-pox and the doubts raised by certain untoward incidents associated with vaccination both at home and abroad. These events were the subject of comment in the Swedish Riksdag as well as in the press, and in 1930 its success, however, depends entirely on the efforts of the patient. As Mr. Mullins said, many criminals offend because they like it; some are so lazy and feeble that they like prison; some are so bored that they like crime. These people would never be cured by psychology as it is to-day.

---

[1] Jour. Amer. Med. Assoc., Feb. 4th, p. 315.

[2] Arch. Méd.-Chir. de l'Appareil Respiratoire, 1932, Nos. 5 and 6.

Mr. Mullins went on to deprecate the treatment of criminals as sick people and the deletion of punishment from the penal system. He strongly believes in punishment as a deterrent, and brought forward examples to show its value to the State. He assured his audience that considering the circumstances of the time the number of criminals was astonishingly low—and was decreasing. But the suggestion that the prisons would soon be empty if the psychologists had their way was nonsense. He would like to press on with a better probation system, and the appointment of a doctor psychologist to every prison. He would take steps to ensure that those responsible for handling law-breakers had had special training in psychology as well as in law, and that the prison authorities should be allowed to make a report on every case—and even to advise the judge or magistrate as to sentence. "The task of getting these reforms," he concluded, "will be rendered more difficult by uninstructed abuse and wholesale condemnation, and also by theoretical proposals that cannot stand the test of experiment."

ANÆSTHETICS IN BRAIN SURGERY

THE discussion on anæsthesia in intracranial surgery, at the Royal Society of Medicine on March 3rd, brought out instructive differences of opinion among experts. Mr. Norman Dott, speaking from an experience of 700 cerebral operations, described his use and disuse of ether vapour by inhalation; the addition of local infiltration; rectal ether with paraldehyde; luminal and ether vapour as adjuvants, and local anæsthesia with morphia. Later he had tried avertin and ether, and his present choice was avertin and morphia. Besides conferring stillness and safety, the ideal anæsthetic for these operations must discourage bleeding. Any anæsthetic which caused swelling or congestion of the brain was to be avoided; and herein lay the first notable difference of opinion, for, whereas Mr. Dott disapproved of ether for this reason, Dr. Z. Mennell, Mr. Ryan and others claimed that, given through an endotracheal tube, ether does not increase the size or the vascularity of the brain during operation. Endotracheal nitrous oxide and oxygen, after cocainisation of the throat, was endorsed by Mr. J. Challis, and Mr. Hugh Cairns had been well pleased with the results of this procedure employed by experts in passing the tracheal tube. Mr. Cairns described the danger of tachycardia following on withdrawal of the anæsthetic from patients in whom the sympathetic control centres had been interfered with at the operation, and queried whether the anæsthesia should not be continued for many hours to give the centres time to recover. Apart from the possibility of maintaining unconsciousness after operation is over, the time question is a serious matter for the anæsthetist. Some surgeons now may require four hours or more, up to seven or eight, for removal of a cerebral tumour. The anæsthetist working with these deliberate operators, as Dr. Mennell pointed out, is confronted with problems different from those of association with the rapid type of operator, of whom the late Sir Percy Sargent was the most brilliant example. For an operation lasting from half an hour to one and a half hours, ether given through an endotracheal or endopharyngeal catheter may be a satisfactory agent to employ, and even chloroform can be used with advantage when there is great intracranial tension. But these anæsthetics are out of the question when the operation is to last the best part of a working day. None of the speakers expressed himself satisfied with local analgesics for this kind of work. The patient must be unconscious, unless he is an infant, when a local injection fortified by the distraction of a feeding bottle during operation has given Mr. Dott all that he wanted. An additional objection to novocain, pointed out by Mr. Julian Taylor, is the febrile reaction which often follows its use. Mr. Taylor was impressed with the importance of avoiding cough, and this made him apprehensive of the endotracheal tube. Mr. C. P. G. Wakeley favoured avertin with local analgesia. The good results obtained in America with light ether anæsthesia were also mentioned.

LISTER TO SHARPEY

THERE is no finality in biography; when everything has been said about a man that can be said, a fortunate accident may open up new points and lead to fresh discoveries. Such an accident has happened in the case of Lister. Mr. C. R. Rudolf has found, in the shop of a second-hand bookseller, eight long letters written by Joseph Lister to William Sharpey who had taught him physiology when he was a student at University College in London. These letters Mr. Rudolf has transcribed, annotated, and published.[1] Six of the letters are of extreme interest because they show Lister's method of working, the great care he took to be accurate in his facts, and his desire to submit to expert criticism before he made his results public. The six letters were written between November, 1857, and November, 1858, at a time when Lister was doing the original work on the early stages of inflammation and the inhibitory action of the visceral nerves which he afterwards presented at the Royal Society. It gained him the Fellowship of the Society and at the same time marked him out as a careful and accurate observer. These letters unveil the secrets of his workshop. They show him as a man full of doubts, not sure of his results and so humble-minded that he was anxious to lay all his difficulties before a teacher whom it is clear that he held in veneration. Mr. Rudolf has published with the letters the reports made by the two referees, Sir James Paget and Prof. Goodsir, to whom the finished papers were submitted before they were printed by the Royal Society. The seventh letter deals with Lister's application for the chair of surgery at Glasgow; the eighth with medical education in Scotland, when Lister shows himself an opponent to clinical examinations. They are of minor importance compared with the first six which are a real find.

COARCTATION OF THE AORTA

A FORM of congenital "heart" disease, pure coarctation of the aorta is not associated with cyanosis, and may escape detection or be otherwise diagnosed, unless the significance of certain signs is understood. Dr. William Evans[2] of the London Hospital reports 28 cases, with the post-mortem findings of 26, the other 2 patients being still alive. He rejects the unsatisfactory Bonnet classification which divided the condition into infantile and adult types, and instead makes six groups, based on the site, nature, and extent of the coarctation, and on the associated or compensatory developmental lesions, especially the state of the ductus arteriosus. In some wish to buy quinine, whether they are governments or individuals, cannot afford to buy it in adequate amount at its present cost. It follows that even if a satisfactory synthetic substitute is ever found, it cannot benefit mankind to the full unless it can be sold far more cheaply that are the cinchona alkaloids at the present time.

A FUND FOR RESEARCH WORKERS

INFECTIVE endocarditis is one of the most hopeless diseases with which the physician can be confronted. No means at his disposal have any effect on the essential lesion in the heart, and even if the local disease is limited in its extent the patient suffers from chronic septicæmia to which eventually he succumbs. Our actual knowledge of the pathogenesis of the disease is limited, and although its manifestations are well recognised they illustrate fundamental pathological processes with which at present we are quite unable to cope. No other disease calls more urgently for organised investigation, and to this end Sir Lester Harmsworth and Mr. H. C. A. Harmsworth founded in 1924 a Research Fund in memory of Robert Lovell St. John Harmsworth, who died of infective endocarditis. The fund is administered by a board of trustees advised by a small scientific committee, consisting of Lord Horder, Dr. M. H. Gordon, and Prof. E. H. Kettle, and grants in aid of research work are made from time to time to duly accredited persons. The attention of clinical and scientific workers who are particularly interested in the problem of malignant endocarditis is drawn to the existence of this fund of which Dr. P. Seymour Price, 33, Sloane-gardens, S.W.1, is the secretary. Applications for grants should be made to Dr. Price who will give information about the conditions governing such grants, and the lines along which it is suggested that investigations might proceed.

THE ALPS FOR CHILDREN

NEARLY a year ago we announced[1] that the ancestral Buol château overlooking Davos-Dorf had been placed at the disposal of the Birmingham Children's Hospital for use as a place for convalescent treatment. The report of the hospital for the year 1932, which was presented on Monday last, contains an account of how this offer has been utilised, although the first twelve months' working is not yet complete. Groups were sent out in May, August, and December, amounting in all to 53 children, of whom 38 were still in Davos at the end of the year. Of the 15 who returned after a stay of 3 or 6 months all except one were regarded as fit for returning; the exception was a boy who was sent home for further operative treatment. Sixteen of the 53 lucky children were selected because they had not fully recovered from an attack of pneumonia, chronic bronchitis, or other chest condition; 14 were asthmatic; 5 had failed to become robust after prolonged illness; 18 were suffering from actual tuberculosis of bones, joints, glands, or skin. The children are under the care of the very competent head of the Pro-juventute Sanatorium at Davos-Platz, and Prof. L. G. Parsons or some other member of the honorary medical staff of the parent hospital visits the château at least once a quarter to discuss progress, and to determine which child should come home and which should stay longer. A staff of five nurses and a certified teacher are supplied from home. It is of course too soon to speak of anything but immediate results; the report states that the medical staff have been immensely impressed with the results and possibilities of this new department. The impression was formed by observation on the spot, in free consultation with other children's specialists for whom the château has become something of a meeting-place. The report also states that the condition of the children who have returned proves that the same benefits would not have been possible in the same period of time in England, and that in many of the cases now at Davos it is recognised that their only chance of a permanent cure will be in a prolonged stay at a high altitude. These are brave words, for which it might not be possible at the moment to give chapter and verse. But confirmatory evidence is available in the valley from the observation of children sent from Vienna for periods of a few months at a time to the rather less favourably situated hamlet of Wiesen-Filisur. Davos has a well-equipped institute for physiological research, making it specially suitable for an experiment which is being watched with sympathetic interest by all those interested in the prophylaxis of tuberculosis by the timely care of the susceptible and recently infected. While the time may be gone by when a short sojourn in the Alps was considered specific for recognised disease of the lungs, there may well be an opportunity for trying out to its logical conclusion some such scheme as the enterprise of Birmingham and the generosity of Mr. Christian Kunzle are making possible in the Davos valley.

THE LAW AND THE OFFENDER

THE vigorous movement for the scientific study of crime, though very necessary, has tended to disparage somewhat unfairly the present arrangements for dealing with offenders. This excess of zeal received a salutary correction from Mr. Claud Mullins in a lecture he gave on March 2nd to the Friends of the Institute of Medical Psychology. He admitted that the system contained several anomalies. For instance, if a man keeps a brothel or exposes his person indecently he has no right of trial by jury and cannot receive more than three months' imprisonment, but if he steals 6*d.*, sells an indecent book, or lends his motor licence to a friend, he has a right to trial by jury and is liable to a more severe sentence. If a woman who has been deserted by her husband for six years marries again, her crime must be dealt with in the same way as murder—namely, by judge and jury at assizes—but if she encourages the prostitution of her child under 16 she is dealt with at quarter sessions. On the other hand, the legal system of this country, he said, possesses two features which render it much more humane than that of most others; an offender is deemed innocent until he is proved guilty, and his past record is not admissible until he is proved guilty. It is frequently alleged that magistrates, in common with the criminal law, lay too much stress on a man's offence and too little on the man; that they make little attempt to probe into the offender's mind. Mr. Mullins would have an expert available in every prison and for special cases in the police-court, but his conviction of the paramount importance of presuming the innocence of the accused person compels him to object strongly to any kind of examination before the verdict in most cases. As he pointed out, modern psychology is better at diagnosis that at cure, and the treatment it offers is still in the experimental stage. Many people talk as if a psycho-therapeutic treatment could be poured into the patient like a dose of medicine;

---

MEDICINE AND THE LAW

Cancer Treatment by Unregistered Practitioner

An inquest was concluded at Wigan on Feb. 22nd on Mrs. Thorpe, aged 55, who, after 18 months in the Radium Institute at Liverpool, was treated by an unregistered practitioner for the last four months of her life. Dr. W. E. Cooke, pathologist at Wigan and Leigh infirmaries, said that his post-mortem examination showed signs of hypostatic pneumonia in the lungs and an extensive cancerous process in the abdomen. Death was caused by heart failure due to cancer. A son of the deceased gave evidence of his mother's treatment by Mr. C. C. Abbott, described as a physio-medical practitioner. At her first visit (for which a fee of five guineas was charged) she was examined for three hours with the aid of an electrical machine. She was charged 10*s.* 6*d.* for each subsequent visit and 2*s.* 6*d.* for each bottle of medicine and each box of paste. The coroner invited Dr. Cooke's views of Mr. Abbott's formulæ for his medicines and pastes. The witness said he could not read them; the amounts of the ingredients were not stated; he found no active principle in them for the cure of cancer. Lamps supplied by Mr. Abbott to reduce swelling were ultra-violet ray electric lamps which would have no effect upon swellings. Dr. Cooke, in reply to the coroner, said he could not go so far as to say that Mr. Abbott's treatment of Mrs. Thorpe accelerated her death in any way; he thought, however, that during her last month her life would have been easier if she had been under proper medical care.

Volunteering to give evidence, Mr. Abbott said he gave the patient herbal medicine and herbal treatment for a malignant abdominal growth. He used an electronic diagnostic machine registering the vibration of the body. Medicines were put into the machine: if the machine did not reject them, they were considered suitable for the cure of the patient; if rejected, the balance of the vibration would be upset. The coroner advised the jury that the evidence had not disclosed any criminal responsibility on the part of anyone. It could not be shown that Mr. Abbott did not honestly believe in his remedy. A verdict of death from natural causes was returned.

Electronic Vibration and Meningitis

Further explanation of Mr. Abbott's method of treatment was given at an inquest at Royton, Lancashire, on a boy who had died of meningitis. According to his father, the boy had suffered from fits since he was 2½ years old. These grew worse as he grew older. After treatment by four doctors and a specialist, the boy was taken to Mr. Abbott whom the father believed to be a medical practitioner. He had treatment from Mr. Abbott about a dozen times; the bills, according to the coroner, totalled £28 16*s.* 3*d.* In answer to Mr. Abbott the father said five guineas was charged for the first visit when the boy underwent an electrical test, and a guinea was charged for each visit afterwards. The father agreed that the boy seemed to be better after Christmas. At the electrical test the boy was placed on a chair in the corner and was connected by wires to Mrs. Abbott who was called "the subject." A man named Dr. Foster took a test and said that the boy had nine different varieties of worms, including some on the brain. The coroner informed the jury that he had himself visited the premises, Mr. Abbott giving him every facility. Mrs. Abbott, the young woman described as "the subject," wore a metal disc on her forehead. An assistant knelt on the floor in front of her and passed a glass roller up and down her body. The two of them were railed in by a wire fence. Mr. Abbott was standing by a large black box which looked like an enormous wireless set. Mr. Abbott put several bottles into the box and eventually said that the bottles contained the correct medicine. Earlier in the proceedings Mr. Abbott himself gave evidence. He said he had been practising as a physio-medical practitioner for 25 years; he had previously been connected with a colliery. The initials M.H. and F.P.C., which appeared on his papers, meant Medical Herbalist and Fellow of the Physiological College. He had for some years been working on research experiments with an improvement of the diagnostic machine called Abrams Box. He did not agree with the medical committee which reported in 1924 that the claims of electronic practice had no basis in fact. He had studied the Abrams method of diagnosis and the theory of vibrations.

Mr. Arnold Pickup, an analytical and consulting chemist practising in Rochdale, spoke of his analysis of the contents of two bottles said to have been supplied by Mr. Abbott. One contained 95 per cent. of water, the other 77 per cent. The remainder of the contents consisted chiefly of extract of liquorice, a little sweetening matter and flavouring agents. In reply to Mr. Abbott, he said he found no trace of ginseng, a Chinese drug. Dr. E. P. Maitland, police surgeon, who made the post-mortem examination, expressed the view that the dead boy had not had proper medical treatment. The jury found that the boy died of meningitis, that his death was hastened by Abbott's neglect, and that Abbott had unlawfully killed the boy. The coroner, observing that this was equivalent to a verdict of manslaughter, committed Abbott for trial.

Heart Disease and Workmen's Compensation

In addition to the other cases summarised in our columns (Feb. 25th, p. 421, and March 4th, p. 489) the following decisions were discussed by Mr. W. A. Robson in a lecture at the London School of Economics on Feb. 28th. In each case the workman's dependents had claimed compensation on the ground that his death at work from heart failure had been caused by an accident arising out of his employment.

In *Davies* v. *John Vipond & Co., Ltd.* (25 B.W.C.C., 47), a workman who, except for an attack of muscular rheumatism two years previously, appeared to have enjoyed excellent health, had reached over a truck to get at a piece of coal with his pick; in doing so he had collapsed and died at once. At autopsy a large rupture had been found in the left ventricle, together with serious changes in the wall. The judge had found the death was due to the disease and not at all to the work. The Court of Appeal had supported this finding on the ground that there had been evidence to support the judge in deciding that death had not been accelerated to any material extent.

In *Walker* v. *John Brown & Co.* (25 B.W.C.C., 166) a healthy coal-getter had been pulling down coal with an iron bar and had handed it to his mate at the latter's request. After a few minutes his mate had seen the deceased lying on the ground, and the man had soon afterwards given a groan and died. The post-mortem examination had shown death to be due to syncope caused by double pneumonia of one or two days' duration, and the medical evidence was that death was accelerated by the strain of the work on an overburdened heart. The judge had carotene; vitamin D—a solution of irradiated ergosterol in olive oil; vitamin B_1—a quantity of the dry absorption product from an extract of rice bran prepared by Dr. S. L. Brug, of Java, and stored at the National Institute for Medical Research at Hampstead.

VITAMIN D

In connexion with vitamin D it is noteworthy that though calciferol shows very intensely the specific anti-rickets activity of the natural vitamin D, it has been obtained in pure form only as a product of the artificial irradiation of ergosterol, and there is no chemical evidence identifying it with the natural vitamin. An attempt is accordingly being made by Mr. R. K. Callow, D.Phil., and Mr. T. A. Webster to isolate the natural vitamin D by methods which were successful in isolating calciferol from irradiation mixtures, using material prepared by the Glaxo laboratories, in which the vitamin has been concentrated from cod-liver oil.

The recognised poisonous action of very large doses of irradiated ergosterol—enormously in excess of normal vitamin requirements—has been attributed by some to a by-product of irradiation and by others to overdosage with the active principle of the parathyroid gland secondary to stimulation of the glands by excess of the vitamin. Both of these theories have been disproved. Dr. R. B. Bourdillon and his colleagues found that the pure substance in largely excessive doses had the same toxic effects on mice as the mixed irradiation product, and Mr. Webster that certain pure esters of calciferol produce toxic effects proportional to their anti-rickets action; while Sir Henry Dale and others found that absence of the parathyroid glands makes no difference to the effects produced by gross excess of calciferol. Prof. J. C. Drummond, working at University College with Dr. Muriel Bell on disturbances of nutrition caused by excessive dosage with cod-liver oil, has obtained results suggesting that the vitamin itself, even in large amounts, has no harmful effects.

Mr. Webster, studying the fate of calciferol in the body on material supplied by British Drug Houses, Ltd., finds that it does not pass out of the system, so that its disappearance is due to destruction rather than to excretion.

Dr. Callow and Miss H. M. Bruce have found some evidence that phytic acid, which represents most of the high phosphorus content of cereals, may be the substance in cereals which Prof. E. Mellanby has found to be antagonistic to the action of vitamin D.

Human Pathology. Diagnosis and Prognosis

In the department of clinical research at University College Hospital the scope of research has been deliberately widened. Not only investigations into cardiac and vascular diseases, but studies of the kidney function and of the sympathetic nervous system in man are now being pursued, as a natural development of previous work on hypertension and cardiac asthma and on the blood circulation. A study of kidney disease is leading to a general exploration of the symptom "headache," and histamine has been used to induce this experimentally in normal persons.

Investigations of pain in an active leg muscle deprived of its blood-supply have led to the conclusion that this pain is due to purely chemical or physico-chemical stimulus developed in the muscle, and this explanation is applicable also to the anginal pain due to disease of the coronary arteries. Studies of the onset of paralysis of the limb nerves following occlusion of the blood-supply have shown that loss of sensation begins at the extremities of the limb and passes gradually up, and that the motor apparatus is generally affected in a similar ascending order. Nerves in passing from their peripheral endings to the central nervous system become more and more susceptible to lack of oxygen. This characteristic onset of ischæmic paralysis gives warning that if nerve and muscle have been exposed equally to a toxic influence, and it is found that the muscle responds to direct stimulation but not to indirect stimulation through its nerve, a conclusion that the neuromuscular junction is at fault may be incorrect; the fault may still lie in the nerve itself, its nearer parts being more paralysed than its further parts.

These observations have obvious bearing upon peripheral neuritis as it occurs in man, since the process is strikingly similar in neuritis from toxic causes to that found in simple ischæmia, and there can be little doubt that a similar explanation applies to both.

The after-histories of 1000 patients suffering from structural heart disease have been completed, and the final report upon them is now in preparation.

At Guy's Hospital Dr. E. P. Poulton and Dr. W. W. Payne, in the course of biochemical studies on rheumatoid arthritis, have obtained results which indicate that a rise in the respiratory quotient does not necessarily mean, as had been believed, an increased consumption of carbohydrate in relation to fat. This inquiry, which may have an important bearing on the action of insulin in diabetes, is being extended. Dr. A. A. Osman and Dr. H. G. Close have been studying the morbid structure of the kidney with reference to the previous clinical history in a large series of cases. Special attention is being given to the incidence and extent of kidney disease in patients dying from other causes than nephritis. Further work has been done on the incidence and prevention of scarlatina and nephritis.

A statistical study is being made of the records of the diabetic clinic at King's College Hospital, where Dr. R. D. Lawrence is working for the Council. At Manchester Dr. J. C. Bramwell and his assistants, and at Edinburgh Prof. D. Murray Lyon and Dr. A. R. Gilchrist, have been making studies of the effects of pregnancy on patients with heart disease. At Manchester special attention has been given to the indications respectively for Cæsarean section and the induction of premature labour in cardiac cases. At Edinburgh Dr. G. H. Percival has been studying the classification and treatment of the different types of dermatitis and inquiring into dermatitis due to chemical irritants.

At St. Mark's Hospital, London, Mr. W. B. Gabriel and Dr. Cuthbert Dukes, studying the after-histories of patients with rectal cancer, found that 78 per cent. of the patients survive for three years or more after the operation of perineal excision of the rectum, provided that the regional lymph glands are not affected at the time of operation. At Edinburgh Mr. D. Band is investigating the excretions of the tubercle bacilli in the urine of patients with pulmonary tuberculosis who show no clinical signs of genito-urinary involvement; he is also making a microscopical study of tuberculous kidneys removed at operations, and relating the findings to the clinical symptoms and the evidence given by pyelography.

Research into different aspects of the anæmias, nutritional problems, dental disease, and malignant disease are being carried on at many centres, and, in fact, subjects covering the whole range of medicine, surgery, and obstetrics seem to be being attacked from new points of view. The researches quoted are only samples of the clinical investigations in progress. For an account of others and of more specialised laboratory studies the report itself should be consulted.

for two years showed no beneficial effects and appeared to have a slight detrimental effect upon reproductive activity. As regards the practical application of phosphorus feeding to stock under ranching conditions, work has been carried out to find a suitable water-soluble phosphate so that the daily ration of phosphate could be given in the drinking-water. Mono-sodium phosphate is shown to give excellent results under experimental conditions, but the method has not yet been subjected to the crucial test in the hands of the farmer.

Ectoparasites.—G. A. H. Bedford has published a synoptic check-list and host-list of the ectoparasites found on South African mammals, birds, and reptilia. This list is intended to correct the errors in the previous list published in 1927 and to include the new parasites and hosts since described. The list, including references to the literature, covers 300 pages.

Poisonous plants.—C. Rimington describes the isolation and identification of the toxic principle of *Dimorphotheca spectabilis* and *Dimorphotheca zeyheri*. It is a cyanogenetic glucoside identical with linamarin or phaseolunatin. It occurs in a hitherto unreported crystalline form; therefore the glucoside is dimorphous.

A SCHOOL OF CHILD WELFARE

THE President of the French Republic (Mr. Albert Lebrun) on March 5th attended the inauguration of the Ecole de Puériculture of the Paris Faculty of Medicine. He referred in his speech to Prof. Adolphe Pinard's life-work on behalf of mothers and children, which reaches its consummation in the new building, and at the close of the proceedings he bestowed on him the insignia of Grand Officer of the Legion of Honour. Prof. Pinard, who is now in his 90th year, is, with Prof. B. Weill-Hallé, director of the school.

The Ecole de Puériculture dates from 1919. It originated with a gift of a million francs from the American Red Cross, supplemented by 550,000 francs from the League of the Children of America (Junior Red Cross). So far the buildings have cost about 19 million francs, and the total will be about 25 millions. The object is to promote the welfare of children, and so make up the wastage caused by war and reduction of the birth-rate. Though this idea is an old one, it was not developed until sometime during the late war, when a department for the protection of mothers and children was created under the ægis of Prof. Pinard. Prof. A. B. J. Marfan has extended it and these two can claim the paternity of "puericulture."

The personnel falls into two categories: (1) doctors who take a special course in the subjects; and (2) nurses or nurse-visitors who spend one or two years in residence (or living outside). Those taking a full course sit for a diploma. The building is situated in the Boulevard Brune (Paris XIVe), and the architects are to be congratulated on the simplicity of the red-brick exterior and the excellence of their plans. There is a large amphitheatre for lectures—it was here that more than 400 persons were assembled for the inauguration ceremony—well arranged and lighted; there are administrative, consultative, and X ray departments, a good diet kitchen and laboratory both elaborately supplied and fitted, and a restaurant for the pupils. A pleasing feature of the school is the resident accommodation for no less than 150 resident pupils or nurses, each having her own bed-sitting room tastefully furnished and decorated, with washing accommodation partitioned off. In addition there is to be, when the building is completed, accommodation for 20 mothers and their infants, and for 20 older children (up to the age of puberty) suffering from nutritional disorders. There will also be out-patient clinics in all branches of child welfare.

THE ROYAL SOCIETY

THE candidates recommended by the Council for election to the Royal Society include three medical men and many others who are working on subjects the development of which is essential to medical progress. Clinical medicine is honoured in the selection of Dr. Gordon M. Holmes, who has managed to combine with consultant and hospital practice the tireless pursuit of research, and has made notable contributions to our knowledge of neurology and to the anatomy of the nervous system. Prof. J. W. McLeod, professor of bacteriology at Leeds, has done important work on the respiration and nutrition of bacteria, on the hæmolysins of streptococci, and on the different strains of diphtheria bacilli. Prof. J. B. Collip, professor of biochemistry at McGill, is known chiefly for his researches on the parathyroid hormone, and on the processes by which this hormone and also insulin could be prepared for clinical use.

Mr. A. S. Parkes, D.Sc., a Foulerton Student of the Society, has investigated the physiology of reproduction and sex, and has demonstrated the properties of the œstrus-producing and other hormones. Mr. W. R. Thompson, D.Sc., superintendent of Farnham House laboratory of the Imperial Institute of Entomology, has worked on the biology and anatomy of parasitic insects, and the inter-relationship between parasites and hosts. Mr. H. King, D.Sc., of the National Institute for Medical Research, Hampstead, is distinguished for his applications of the theory and practice of organic chemistry to substances of therapeutic importance. Prof. E. J. Salisbury, D.Sc., of University College, London, has published numerous original papers on plant anatomy and physiology, and is an authority on the ecology of woodlands and the chalk. Mr. John Hammond, D.Sc., senior assistant in the Animal Nutrition Institute at Cambridge, is distinguished for researches in the physiology of reproduction and growth.

Among those less closely associated with medicine, Mr. P. M. S. Blackett, university lecturer in physics at Cambridge, already well known for his contributions to physics, has recently made a further notable advance in our knowledge[1]; Mr. R. E. B. Crompton, now 88 years of age, was a pioneer in electrical engineering; Prof. H. M. Dawson holds the chair of physical chemistry at Leeds; Mr. A. T. Doodson is associate director of Liverpool Observatory and Tidal Institute; Mr. H. J. Gough, Ph.D., is a civil engineer working at the National Physical Laboratory; Prof. J. E. Lennard-Jones holds the Plummer chair of inorganic chemistry at Cambridge; Mr. Bernard Smith, Sc.D., is a district geologist of H.M. Geological Survey; Prof. A. M. Tyndall holds the Henry Overton Wills chair of physics at Bristol; and Prof. J. H. M. Wedderburn is professor of mathematics at Princeton, New York.

---

[1] See Nature, Feb. 25th, 1933, p. 286.

awarded for the employers on the ground that there had been no real evidence that any particular piece of work had caused the death. The Court of Appeal had ordered a new trial, partly to get a more explicit answer to Lord Loreburn's question, and partly because it suspected that the judge had misdirected himself by believing it necessary to connect the death with the work through a particular action or strain.

The essential difficulties of the courts, said Mr. Robson, and their conflicting decisions had been due to two causes. The first was that the law presumed an accuracy and precision in the analysis of causation which medical science was in fact unable to provide. The second was that for personal injury by accident within the meaning of the Act it was necessary that the death or injury must follow suddenly upon the event occasioning it. In *Ismay Imrie* v. *Williamson* (1908, A.C., 437) a trimmer in a liner, in an emaciated condition, had been killed by a heat-stroke in the act of raking out ashes; his dependents had been awarded compensation. On the other hand, in *Pyper* v. *Manchester Liners* (1916, 2, K.B., 691) a stoker had died of heat-stroke after complaining of the heat for four or five days, during which he had, although suffering, continued at work to relieve his mates. His injury had been held not to be by accident. When the workman had a predisposing condition, the dividing line between being gradually overcome by disease and suddenly succumbing to personal injury by accident was so fine that it was impossible to expect justice to be done in all the cases.

RESEARCH IN VETERINARY DISEASE

THE Institute of Comparative Pathology maintained by the Department of Agriculture of the Union of South Africa at Onderstepoort, Pretoria, has long been famous for the quality of the researches carried out there and for its contribution not only to veterinary education but to the solution of the practical economic problems with which farmers in South Africa are faced. In the routine department laboratory products are manufactured on a large scale for sale to farmers practically at cost price. The organisation developed by Sir Arnold Theiler is now carried on under the direction of Dr. P. J. du Toit, but in the eighteenth annual report just published[1] it is shown that his former colleagues still have the advantage of Sir Arnold Theiler's collaboration in certain researches. The report is issued in two large volumes, and contains accounts of investigations into many aspects of veterinary medicine and surgery, among which the following may be noted as of especial interest:—

Protozoal disease.—W. O. Neitz and P. J. du Toit describe a successful method of obtaining a pure infection of *Anaplasma marginale* and *centrale* free of *Theileria mutans* and *Piroplasma bigemminum* contamination for vaccine purposes. By passage of the mixed infection through the blesbok the theileria and piroplasma infections are eliminated as the blesbuck is not susceptible to these infections. The investigation has shown that buck are susceptible to anaplasmosis and this factor will influence future legislation for the stamping out of this disease.

Virus disease.—The same observers describe experiments on the use of formolised spleen virus in place of the virus-antiserum method of immunising mules against South African horse sickness. The use of formolised vaccine gives no better immunity than the older method but the cost of immunisation is reduced. The method is still in the experimental stage. With C. Jackson, Neitz is continuing investigations upon heart water. They have shown that by injecting saline-washed endothelial cells, scraped from the intima of the jugular vein of infected sheep, into normal sheep typical heart water can be set up in the recipient. Such endothelial cells contain rickettsiæ. This experiment is held to afford direct evidence that *Rickettsia ruminantium* and not some ultra-visible virus is the causal agent of heart water. With I. P. Marais, Neitz gives a summary of the history and distribution of rabies in South Africa. It is of interest that in South Africa the disease has been almost invariably transmitted by bites of members of the viveridæ family—e.g., mongoose, gennet cat—whilst dogs have very seldom been involved.

Helminthological section.—H. O. Mönnig reports further results of his investigation of the nematode parasites of wild buck and the significance of wild animals as possible reservoirs of infection of the parasites of domestic animals. One new genus of the metastrongylidæ and five new species amongst various genera are described. In the blesbuck amongst other parasites the following were found: *Cooperia pectinata* and *punctata*, *Œsophagostomum columbianum*, species of ostertagia and trichostrongylus, and *Trichuris ovis*. In the Sassaby *Hæmonchus contortus* was found. These parasites are all of considerable economic importance in domestic animals.

Mineral deficiency diseases.—A section of nearly 300 pages deals with mineral deficiency diseases published by du Toit, I. P. Malan, and numerous other workers. With the financial assistance of the Empire Marketing Board an extensive survey of the mineral deficiencies of South African pastures has been begun. The problem is being approached by soil analysis, by chemical analysis of the pasture plants, and by the estimation of the organic phosphorus content of the blood of stock grazing over the pastures in question. A preliminary survey has shown a reasonable correlation between the phosphorus content of the soil and of the pasture growing upon that soil. A considerably closer correlation has been shown to exist between the phosphorus content of the pasture and the inorganic phosphorus content of the blood of animals grazing upon it. Where discrepancies have occurred they have been easily explained. On account of the relative simplicity of the blood-phosphorus estimation this branch of the investigation is being extended widely. Blood is drawn and the protein material precipitated with trichloracetic acid. Analysis must be performed as soon as possible because of the hydrolysis organic phosphorus to inorganic during storage. Study of the mineral metabolism of sheep has shown that the effects of phosphorus deficiency follow the same general lines as deficiency in cattle as described by Sir Arnold Theiler, du Toit, and H. H. Green, in previous reports, except that in sheep fecundity appears to be unaffected. A study of wool production, on 20 sheep fed a sufficiency of phosphorus and 20 on an insufficient phosphorus diet, showed that the phosphorus-sufficiency group produced on the average 32 per cent. heavier fleeces with 16·6 per cent. greater length of staple and 13·5 per cent. greater thickness of fibre. The experiment lasted two years. The effect of feeding small doses of iodides to sheep

[1] Union of South Africa. Eighteenth Report of the Director of Veterinary Services and Animal Industry, Onderstepoort, Pretoria, 1932.

Several of these are bad subjects; they were born in the hard period closing the war, and as yet are not good physical specimens; they are trying patients, for just as they appear to be getting fit they often relapse. Great patience on our part and theirs may be called for. There are four minor accidents and two cases of jaundice. In the infectious block there are eight cases of chicken-pox; the rash is profuse and the spots are reported to be very irritable, but life is made more tolerable for them by night and morning soakings in fairly strong pot. permang. baths.

After my visit to the sanatorium, usually I call on the headmaster to report, and I am able to say that influenza is slacking off, but that chicken-pox may be coming. At present it is confined to two houses, and I am justified, I think, in saying that it does not seem likely to spread. The position of convalescents who do not get well promptly enough to enable them to re-enter school life is discussed, and I make suggestions for a few days' leave for these lads; the value of change in "school sickness," which I regard as an entity, is very great. Then follow visits to patients in the various houses, the summons having been received by telephone whilst I was having consultations. The invalids are those who were unfit to come to my house. The houses are visited in turn, and to-day this implied half a dozen visits. As a result three boys are sent to the sanatorium, the others, suffering from colds, are sent for walks, with instructions to the various matrons to report to me later. My routine school work should be over by 11.30, and from then until lunch my practice is attended to. The necessity for method, to which I have referred, becomes clear, because the calls of the practice have, with the coöperation of partners, to be fitted in with the school duties, and they must be undertaken in keeping with the school time chart. The motor makes this possible even when some of the visits to be made may mean visiting places far apart.

THE AFTERNOON

In the afternoons, especially at those seasons when games are being played that must entail risk of accidents, I am within call, if not actually on the ground, and two beds, with hot bottles in them, are always in readiness at the sanatorium. To-day boxing competitions are being decided; it is necessary that I should be present. Accidents may happen, or a boy may be having too much punishment. We do not want a fight to a finish which may leave lasting effects on his pluck. The fight should stop before a bad defeat is registered. It happens that I am interested particularly in one competitor. He came here in September, 1931, an Anglo-Indian war baby, and so poor a specimen physically that most of his time during his first and second terms was spent in the sanatorium. There was reason to hope for better things by the summer of 1932, but the unlucky boy got pneumonia about mid-term, made slow recovery, and was not in school for the rest of the term. It seemed hopeless to expect that the life in a public school, whatever the individual care expended, would suit him, and a provisional notice of removal was discussed. He came back in September, 1932, looking better in every way; had a good bill of health—for him—throughout the term, and when weighed in January, 1933, he had put on 12 lb. since September, 1932. One morning three weeks ago he turned up and asked my approval of his boxing. I was astonished, and told him he was not fit for such a trial of endurance. He replied: "I have been training and I'm all right." He fought and beat his man. This was a lame duck: safely across and he will go forward, for a boy who can win a boxing bout is made of the right stuff.

There remain letters to be written, mostly in reply to queries from parents as to progress (medical side) of the boys, and it is now that there occurs to me a suggestion that a change of air might be useful to a boy who comes under consideration. I am told that at many public schools this sort of leave is not allowed during term, unless in extreme cases, but our Head deals sympathetically with requests from parents, if I agree that benefit will follow.

The day ends with an after-dinner visit to the sanatorium, when there is anything special to talk over with the matron of the happenings of the day, or in formulating plans for the morrow.

THE DIFFICULTY OF EPIDEMICS

I have not dealt with the most trying part of the M.O.'s school work; this occurs in times of epidemics of the infectious diseases—i.e., scarlet fever, measles, German measles, diphtheria, mumps, and chicken-pox. My way of dealing with them is as follows. To begin with I look up in THE LANCET on Friday mornings the section on the incidence of infectious diseases, and see what is happening all over the country and therefore what may happen here. Early detection and isolation of a suspected case may and does limit epidemics. I have got the housemasters, and all those in charge of the boys, to see the value of detection as early as possible; they know that it is the first 24 hours that may make all the difference to the course of an epidemic by lessening the risk of the infected boy mixing with others. One result is that for several years scarlet fever and diphtheria have been confined to the original cases. In scarlet fever, the most difficult disease here, the rash calls for early attention and boys can be seen before much risk has occurred of their infecting others. Before the arrival of the Dick and Schultz-Charlton tests we were much handicapped, for though the rash and other symptoms pointed to scarlet fever, there were links wanting in the diagnostic chain. We dare not risk an epidemic; it was a case of "wait and see," and cases were isolated for weeks which I am now quite sure were not scarlet fever. The infected house was isolated, feelings of uncertainty kept the school authorities on tenterhooks, and parents generally, when they got to know the position, wanted their boys home. The M.O. was a sorely tried man. Now all that is changed. If there is reason to think that the inmates of a house are infected the house is isolated, all the inmates are Dick-tested within 12 or 18 hours, the non-immunes are given a dose of anti-scarlet serum, the immunes return to school, and not more than a couple of days' work are lost. The patient is treated with the serum which so modifies the course of the disease that instead of six or seven weeks, he is out of the sanatorium by the end of the fourth week. If the rash is doubtful the Schultz-Charlton test settles the question.

Diphtheria is more difficult, because of the carrier whom one has got to remember, but the Schick test spares much worry. A procedure similar to that with scarlet fever is followed—isolation and testing and serum prophylactic treatment, with a wholesale swabbing of the inmates of the infected house. Cases of measles and German measles and mumps are capable of spreading infection at a very early stage, and outbreaks are not so likely to be stopped promptly. Chicken-pox is troublesome because the first case may be so slight as to escape notice. Whooping-cough can be controlled in my opinion by early use of whooping-cough vaccine, and I have found Knyvett Gordon's diagnostic test of considerable value before the typical clinical symptoms appear.

There remain for mention two serious forms of disease for which we have always to be on the watch—the mastoid and appendix cases. It is a crime if a boy complains of earache and his complaint is not reported to the M.O., and here this is well understood by all concerned. And the temperatures are always taken in what are colloquially termed "bilious attacks" with pain, and if only a slight rise is registered the case must be reported at once. Appendicitis is thus seen early and here again the blood film is often the deciding factor.

SANITARY SUPERVISION

I am responsible for the sanitary supervision of school buildings, but here my duties are practically nil, unless some particular point is brought up. All

THE DOCTOR'S DAY

"Come, tell me how you live," I cried,
"And what it is you do!"

XVIII.—THE MEDICAL OFFICER TO A PUBLIC SCHOOL

MY day usually begins the evening before, when I go through my lists of what has to be done—memoranda suggested by the past day's work—and arrange the programme for to-morrow's work. This is necessary as my school work is not a whole-time job and private practice has got to be fitted in; thus method is essential.

THE MORNING

If any cases in the school sanatorium are causing anxiety, either from what I have seen or from reports made to me, the patients are seen before breakfast. To-day there is a case of pneumonia and a case where the symptoms may point to some appendix trouble. I find the former is going on satisfactorily, and with the latter the trouble yielded to an enema. Back to breakfast and letters at 7.45. All letters which permit of the delay wait; I read the *Times* whilst feeding, and by 8.30 I am ready to see the boys who come to my house sent by the housemasters. Consultations go on until nearly 10 A.M.—naturally some days are busier than others, but to fit in with the school organisation the boys ought to have finished with me by that hour. If I have not finished by that time exeats are given, and much appreciated by the patients, who in this way escape class, wholly or partly.

The boy patients fall generally into two divisions, those who believe their condition to be more serious than it is—these come from homes where health supervision is scrupulous if not fussy; and those who would not, or would not readily complain, and whose unfitness has to be detected for them. Of genuine malingering one sees practically nothing, though I do remember that on several successive Monday mornings a hefty youth turned up at the last minute to report sick. After two or three of his visits I got suspicious as the symptoms were subjective—headaches and pains generally, and nothing to be discovered as a cause. I found that recovery always took place in time for games, so I queried the symptoms and freely expressed my doubts, adding, "Come now, what is it? I won't give you away, but you must not pull my leg. To whom are you going this period?" "The headmaster for scripture, Sir," he replied. An exeat was required to exempt him.

There are ten patients this morning. No. 1: This is a recovery from a sharp attack of influenza. He is a senior boy, a good athlete, and expects to do well in sports if he can get fit in time. I tell him that he must go slowly, if not, he will crock up and not be able to compete; and I send a chit of what I think is well within his powers to his housemaster, containing the warning that there is a risk unless those instructions are kept to. I tell the boy to follow the advice and report to me in five days' time. No. 2: This pasty-looking boy is an albuminuric—albumin averages about two degrees Esbach. He is not allowed to take part in strenuous games, or house or school "runs," but trots in his own time, as opposed to timed runs for fit boys. He is on the modified "gyms" list. With exercise kept within due limits it is my experience that these cases clear up during school life; indeed I have only known one that did not, and he was accepted for insurance as a first-class life, with a policy slightly loaded, which he has long ago cleared. No. 3, another candidate for success in sports, very anxiously assures me that he is fit—he had been suffering from influenza. I agree with him, he goes away delighted. No. 4. an "under"—i.e., being under 16—he can compete in junior sports. He is big and well developed, and has a good chance of doing well in his games if he is allowed to compete, but influenza has intervened. He watches me keenly while I percuss him, for next year he will be an "over," when the competition will be very much stronger, and his chances of immediate distinction will be gone. I can tell him he is pretty well all right and to continue to report to me. No. 5: This boy, many would think, ought not to be here, but the family tradition is "public school," and we have a reputation for dealing kindly with our lame ducks. This very lame one has got a congenital heart writ all over him—livid face, ears, and hands, clubbed fingers. His exercise is limited to easy walks and is excused fagging. Would he be better off elsewhere? He is happy, and in a quiet, unobtrusive way the boys are kind—boys can be beasts, they can also be gentlemen. No. 6: This is a case of flat-foot. He reports every fortnight—massage, special exercises, and suitable boots are producing satisfactory results, as is nearly always the case if the disability is detected early. A few years ago one of the very worst cases of flat-foot that I have seen got a place eventually in the football "XV," but our masseuse is a genius. No. 7: This was a football casualty; I removed the big toenail. The other cases need no comment.

The notes indicate the work making up an average consultation morning. There are boys of undoubted delicacy, who are under recurrent inspection; there are cases where early diagnosis is of the first importance; and there are the accident cases. In all these the school doctor has to consider the question of fitness to join in organised games, but I am not digressing into theories as to the place of games in an educational curriculum. The games are here and it is my job as a school doctor to see that the boys get the proper benefit from them and that those who participate in them run no risks.

With regard to such a case as No. 5 noted above, the question may be raised as to what, if any, standard of physical fitness is laid down before the boy is accepted as a member of the school. We have no cut-and-dried system for dealing with new boys on their arrival, finding that the safer way is not to have a medical entrance examination, which so easily becomes perfunctory. We have a paragraph on a "Medical Sheet" which is sent to parents and guardians of our entrants, asking for information about any diseases that have already been incurred and any special illness or weakness to which the boy is subject, and the special cases are dealt with. These boys are examined and a report of their condition is sent to their housemasters with instructions and advice as to the limitations under which the boy should be placed in regard to games and athletics generally. I find this plan to work satisfactorily, and under it unfitness is not suggested to the fit—a very important point. The answers to the Medical Sheet are, of course, valuable information, as we get the home doctor's evidence and advice, but the letter from the home doctor, inspired by the parental views rather than the observed facts, saying that the boy "is not equal to games," may create a difficulty when he is found to be obviously fit upon examination.

When the consultations are over I turn to my letters, and the number of these will be accidental. I receive the medical reasons why a boy has returned late from the holidays; get permission for the performance of a late circumcision, and learn details of the boy's health as observed when he was recently at home. And there are, of course, inquiries about the progress of any boy known to be ill.

Now, at 10 o'clock, a routine visit is paid to the sanatorium, our three hospital blocks of about 70 beds being grouped under that common title. There are this morning 21 boys under treatment, including the already mentioned cases of pneumonia and of suspected appendix trouble. I find them both doing well. A good proportion of the other cases are suffering from the results of influenza.

CORRESPONDENCE

EARLY DETECTION OF MALIGNANT DISEASE

To the Editor of THE LANCET

SIR,—The interesting correspondence on this subject which has been appearing in your columns centres about the possibility of the early diagnosis of cancer, and about the psychological effects of periodic special examination. I am, of course, incompetent to define the precise stage at which malignant disease can be detected, but I should have thought it obvious (*a*) that the earlier it can be detected the better for the patient, and (*b*) that periodic examinations are more likely to do this than chance or irregular examinations.

In the psychological part of this discussion naturally I feel more at home. There can be no doubt that one effective method of treating patients who suffer from dread of cancer is the definite assurance afforded by periodic examination that these fears are without foundation. But surely it would be more scientific to refer such cases to the psycho-pathological expert so that he may discover the mental cause of their fears and endeavour by treating the cause to abolish its consequence?

Your correspondents however have argued that whatever good periodic examination may do to those suffering from carcinophobia, it will do at least equal harm by suggesting such a phobia to those hitherto free from it. That seems to me bad psychology. There are great numbers of people who pay regular visits to their dentist for periodic examination and (so my wife assures me) there are among them many women who dread caries, pyorrhœa, consequent extraction, and loss of personal beauty. Can anyone suppose that this dread is seriously extended among those in whom it has not hitherto existed, by periodic dental examinations? So too the fear of death is not uncommon among certain individuals. Will it be argued that a periodic general medical examination is likely to increase the number of persons suffering from this fear?

No. At most a periodic examination will only direct fears and anxieties from an older channel towards a new one. It is their *causation* which requires treatment, not their particular *expression*. In other words, malignant (and other) disease needs to be combated by periodic surgical (and medical) examination; while at the same time the dread of any disease needs to be combated by suitable psycho-therapeutic measures.

I am, Sir, yours faithfully,
CHARLES S. MYERS.
Montagu-mansions, W., March 6th, 1933.

DICHOTOMY

To the Editor of THE LANCET

SIR,—Your anonymous correspondent, the "unwilling accomplice," has clearly demonstrated that he lacks the guts and imagination to deal with his own problems. Do the pitiful meanderings of his conscience deserve the sympathy of the still dignified profession upon which he casts an unwarrantable slur? His remedy is perfectly simple. If he would only show the door to his shady associates, he might in time acquire a decent clientele. Let me assure him that a very large majority of the general practitioners of this country would promptly show *him* the door if he dared to suggest dichotomy to them. On the other hand, better men than he have starved for causes far less worthy than the honour of the medical profession. Has he not yet learnt that it is practically impossible for a straight player to beat a four-flusher at his own game? If he really wants to observe the strict rules, let him sit tight. His turn will come, *if he can play well enough* to seize his legitimate opportunities.

His statements imply that his reputation as a dichotomist, willing or unwilling, has been noised abroad. Personally I have come into contact with a fairly extensive variety of general practitioners since the war. Amongst the many who have failed to appreciate my professional qualities after one or two consultations, there may have been some who have resented my lack of commercial enterprise! But on two occasions only, throughout the whole of this period, have I been asked, directly or indirectly, to split a fee. In each case the amount concerned was trivial; and in each case the doctor was obviously a man of straw.

By all means let us have an association of consultants; but do let us black-ball at its foundation the whole tribe of dichotomists, whether they are practising or reformed—i.e., potential. They can form their own union, stiffen each other's spines, or pick each other's pockets, and the appendices of the public, as they please. One may hope that any genuine association of consultants in process of formation will consist of those who are consultants *in the strict sense of the term*; and that it will exclude the chameleon consultant or facultative G.P., as well as those whole-time mountebanks who are pleased to adopt the title. All these versatile performers, distinguished or otherwise, have quite sufficiently fomented internecine strife during the last 15 years—to the great disadvantage of the profession and the public. We certainly cannot afford to follow *their* example: although their transient success has possibly created envy in the heart of the "unwilling accomplice." *Ne sutor supra crepidam.*—I am, Sir, yours faithfully,

Harley-street, W., March 3rd, 1933. FRANK COOK.

To the Editor of THE LANCET

SIR,—Some years ago, when you were publishing a weekly article on "The Battle of the Clubs," a friend of mine bought a practice in a town where the club system was rife. One of his patients developed intestinal obstruction and a surgeon was called in. He decided to operate, and at the consultation my friend, not without some show of reason, advanced the view that as the surgeon was taking 50 guineas from the club-patient for about an hour's work, while he himself would have to attend him for a month and find all dressings for about a penny a week, it would be a gracious act if he handed over a part of the fee. How the argument would have ended I cannot say, as the nurse broke up the consultation with the news that the patient's bowels had acted freely.

I am, Sir, yours faithfully,
Bath, March 4th, 1933. R. L. WASON.

LEITH MURRAY MEMORIAL FUND

To the Editor of THE LANCET

SIR,—A committee has been formed with the object of raising a memorial to the late Prof. H. Leith Murray.

The members of the committee—Prof. A. Leyland Robinson (Chairman), Surgeon-Commander L. S. Ashcroft, V.D., Mr. Duncan A. Campbell, Prof. W. J. Dilling, Mr. A. A. Gemmell, Mrs. Tom Temple, the buildings are thoroughly up to date, and most have been modernised or even built since the war. During the summer holidays all the drains are inspected and tested by an expert, detailed reports of each school building and house are sent to me, when any suggestions for cleaning or repairs are dealt with before beginning of term. I regularly inspect the milk-supply. Samples are taken from time to time and warnings are sent where necessary—they have seldom been necessary.

A PLEASANT LIFE

To me school work is full of interest. The boys are "decent," and one knows what a boy means when he allows that a thing is "pretty decent." They will be boys, and he who forgets this and tries to make them or regard them as anything else asks for trouble, so I don't try. If you play fair with them and follow their reasoning they respond. I have said that my job is not a whole-time one, and herein lies the saving from possible "narrowing" with its necessary sequence of limited outlook. My general work helps to strike a balance, and one is brought into contact with educated people, not a one-sided folk at a school. The general school life with its lectures, concerts, and functions affords interest and it is always possible to get a "four" when one feels like a game of bridge. My favourite amusement is shooting over dogs trained by myself. There is just enough game on my small shoot here to get a brace or two of birds in the hours I can spare on quiet afternoons.

PANEL AND CONTRACT PRACTICE

Temporary Residents

JUDGING by the figures supplied by the Ministry of Health to the distribution committee the position with regard to temporary residents has not improved in the last year. Certain industrial areas naturally send their convalescent cases into other areas to recuperate after illness, and as they will not be likely to have as many cases sent into their area for this purpose the balance on these cases is negative, so that money has to be deducted to pay for temporary residents treated outside. Working on a percentage basis it may be said that for every 10,000 insured persons on their lists certain committees pay out for the following numbers of temporary residents placed against them in the three years:

	1930.	1931.	1932.
London	54	55	56·9
Birmingham	33	31	33
Newcastle	18	41	16
Manchester	33	36	36
Liverpool	19	19	18
Average deductions for England	—	20·8	20·7

London again shows a tendency to increase its indebtedness to outside committees, although its panel strength in percentage of the whole panel is going down, being only 12·8026 in 1932, while it was 12·9748 in 1931, and 13·0797 in 1930. (The total number of insured persons is, however, slightly up, being 1·917,000 against 1·904,000 in 1931.) The deduction for London is in fact well over double that of the average for all deduction for England. With the idea of trying to obtain a more equitable position it was decided by the distribution committee to cut down the fees allowed for treatment of temporary residents in institutions and convalescent homes from 2*s.* to 1*s.* It will be generally agreed that it was quite time something was done about the position of convalescents in these homes. Patients who often do not see the doctor to the home, and are certainly not in need of medical attendance, have their cards taken from them by the appointed collector (the matron of the home, it may be), and claims for temporary resident treatment are made for each case in the home. It is not surprising therefore, on examining the temporary resident figures for places where these convalescent homes abound, to find a large addition per 10,000 of the panel. Instances of this are:

	1930.	1931.	1932.
Southport	440	447	484
Blackpool	593	501	592
Hastings	384	348	359
Isle of Wight ..	178	176	185
Average additions for England	—	18·4	19·1

It will be interesting to see what effect the reduction in payment for convalescent home cases will have on next year's deduction and addition figures for temporary residents.

Road Accidents and the Police

A decision of the Middlesex Insurance Committee on a case in which the police called an insurance practitioner in to attend one of his own patients, who had met with an accident, would seem to be entirely contrary to the agreement recently arrived at. These emergency police cases had been giving rise to difficulty. What usually happened in the past was that some well-meaning onlooker of an accident would rush off to his own doctor, who would turn out and probably do what was necessary as first-aid, only to be told by the police that they had not sent for him and would not be responsible for his fee. So far, strictly speaking, the police were correct, but a new complication arose when the police themselves called a doctor to render aid to a patient who was an insured person. They were then in the position to say to any insurance doctor who responded that he was bound, under the regulations, to attend gratuitously. The necessity for calling in a doctor for a street accident is left by the police authorities to the constable on duty, who is not encouraged to incur medical expense unless urgent treatment seems to him to be required before removal by ambulance—e.g., severe hæmorrhage or shock. The position now is that the police will pay on an agreed scale of fees if the patient cannot afford to do so. In the Middlesex case it is not stated in the report whether the injured man was in a position to pay his own doctor an emergency fee on the police scale, but it would seem clear from the agreement between the Ministry of Health and the Insurance Acts Committee that when the police call any doctor—insurance or not—to a street emergency they are responsible for the fees. Had this agreement been known to the Middlesex insurance committee they could hardly have censured a practitioner for receiving a fee in respect of a police emergency call to one of his patients.

KING EDWARD'S HOSPITAL FUND FOR LONDON.—Hospitals within 11 miles of St. Paul's desiring to participate in the grants made by this Fund for the year 1933 must make application before March 31st to the hon. secretaries of the Fund at 7, Walbrook, London, E.C.4. Applications will also be considered from convalescent homes which are situated within the above area or which, being situated outside, take a large proportion of patients from London.

hospitals—epidemic gastro-enteritis with bacteriologically negative stools—are conveyed by nurses who, under the present system, combine the duties of feeding the children and attending to them after defæcation. We maintain that no nurse who is responsible for the feeding of any patient should handle stools, whether they are considered infectious or not. The ever persistent danger of carriers amongst nurses of anything from simple coryza to virulent Klebs-Löffler bacilli spreading their infections to their charges should be excluded by *regular* and efficient examination of nurses, by routine gargling, wearing of masks when attending young infants, and by less strenuous working hours.

We are, Sir, yours faithfully,

DAVID NABARRO,
A. GORDON SIGNY.

London, W.C., March 4th, 1933.

BLOOD PRESSURE AND CANCER

To the Editor of THE LANCET

SIR,—I should be grateful for help from any readers of THE LANCET who may be in a position to supply me with definite information as to the range of blood pressure in patients suffering from cancer—more especially in the earlier stages of the disease. Recently it was suggested to me that in cancer the blood pressure may, on occasion, be found to be raised considerably above what can be regarded as normal for the age of the patient. But thus far I have not come across a reference to any statistical evidence on the subject; and I am informed that no information is at present available at the Cancer Hospital.

I am, Sir, yours faithfully,

S. MONCKTON COPEMAN.

Prince Arthur-road, N.W., March 5th, 1933.

CHLOROFORM CAPSULES

To the Editor of THE LANCET

SIR,—Some misunderstanding seems to have arisen in connexion with my remarks on the use of chloroform capsules at the meeting of the National Birthday Trust Fund noticed in THE LANCET last week.

So many users reported the difficulty of one single attendant administering the capsules and conducting the labour, that I thought it wiser at this stage to state that two people should be present, and I carefully did not state "two midwives." A second nurse attendant, or a pupil midwife, or even an intelligent relative acting under the direction of a qualified midwife, should in my opinion fill the requirements.—I am, Sir, yours faithfully,

LOUIS CARNAC RIVETT.

Harley-street, W., March 6th, 1933.

THE ADMISSION OF WOMEN TO THE G.M.C.

To the Editor of THE LANCET

SIR,—I find to my dismay that an article with photograph has appeared in the lay press, dealing with the question of my possible nomination as a candidate for the General Medical Council. I need hardly say that this was inserted without my knowledge or consent. If I should have the honour to be selected by the British Medical Association as one of their candidates for the G.M.C. election for direct representation, it would be as a member of that Association and on my record of work in it that I should stand, and if so fortunate as to be elected would serve as a representative of the whole profession and not of medical women only.

I am, Sir, yours faithfully,

CHRISTINE M. MURRELL.

Porchester-terrace, W., March 6th, 1933.

OBITUARY

EDMUND HOBHOUSE, M.D., F.R.C.P. Lond.

WE regret to record the death of Dr. Edmund Hobhouse, which occurred at Grosvenor Hill, Wimbledon, on March 2nd, in his 73rd year.

Edmund Hobhouse was born in 1860, the eldest son of the Right Rev. Bishop Edmund Hobhouse, Bishop of Nelson, N.Z., by his first wife, Mary Elizabeth, daughter of General the Hon. J. Brodrick. He was educated at Eton and New College, Oxford. At Oxford he took classical honours in 1883, and later, deciding on the medical profession, he graduated M.B., B.Ch. in 1887, his clinical work being done at St. Thomas's Hospital, and supplemented later by post-graduate courses in Berlin and Vienna. At St. Thomas's Hospital he became both assistant house surgeon and house physician, and later was for a time attached as a resident physician at the Bethlem Royal Hospital. Further postgraduate work on the continent was interrupted by a breakdown in health, and he was advised not to attempt to practise in England. For the next five or six years accordingly he practised in Colorado and on the Riviera, but in 1895 he returned to England and settled in Brighton. Here he acquired a large practice. He had taken the diploma of M.R.C.P. Lond., and was appointed physician to the Sussex County Hospital and the Alexandra Children's Hospital.

DR. EDMUND HOBHOUSE

[*Photograph by Vandyk*

At the outbreak of the European war Hobhouse, with the rank of Lieut.-Colonel R.A.M.C., T.F., was in command of the Second Southern General Hospital at Brighton, and at the end of hostilities he remained there for a further six years in consulting practice, being elected F.R.C.P. Lond. in 1901. In 1924 he retired from the Brighton practice, and served for a period as a member of the Travelling Medical Board of the Ministry of Pensions.

On the termination of these duties he retired from the profession, living first in Kensington, and finally in Wimbledon. Latterly his health began to give way, and for some time he suffered severely from attacks of obscure pain. The disability did not prevent him from taking a deep interest in the antiquarian side of medicine and cultivating his literary proclivities. He had already edited "Health Abroad," a large portion of which he wrote himself, and he contributed much useful reading to THE LANCET, especially in regard to continental literature, where his familiarity with three languages made up a valuable asset.

Dr. Hobhouse married, in 1896, Beatrice Hutton, daughter of Mr. H. E. Hutton, housemaster at Harrow, and is survived by his widow, a son, and a daughter.

Mr. R. H. Thornton, and Mr. George Leather, F.C.A.—represent the various activities with which he was associated, and they consider that the most appropriate form of memorial would be the foundation of an annual Leith Murray Prize or Scholarship in obstetrics and gynæcology at the University of Liverpool. Donations towards this object, both large and small, will be gratefully acknowledged, and contributions should be sent to Mr. George Leather, 24, North John-street, Liverpool.

I am, Sir, yours faithfully,

Liverpool, March 2nd, 1933. A. LEYLAND ROBINSON.

CHRONIC INFECTION OF THE SACRO-ILIAC JOINTS CAUSING SPONDYLITIS

To the Editor of THE LANCET

SIR,—The clinical classification of spondylitis in current use is dependent to a large extent on the changes noted in the spine in radiograms. On this basis spinal arthritis can be divided into two distinct types.

(*a*) *Spondylitis adolescens.*—Considered to be an infective or inflammatory arthritis of the spine, which attacks the young adult. A pathological condition of the sacro-iliac joints is always present, usually noted radiographically as bony ankylosis. The sedimentation-rate in these cases supports the view that infection is a cause. This group includes the Marie Strümpell, Bechterew, and ankylopoietica types, and also "poker back" and "bamboo spine."

(*b*) *Spondylosis.*—A degenerative arthritis that attacks the older patient, better known as spondylitis osteo-arthritica or "labourers' spine." The sacro-iliac joints never show any changes radiographically, and there is no abnormality of the sedimentation-rate. Unfortunately, in many cases, the changes seen in radiograms represent only the end-results of a long-standing arthritis, and are as variable as those met with in pulmonary tuberculosis.

Once the disease has become established, therapy in any form may be considered useless, although spontaneous arrest at various stages of the disease has been known to occur. Recent work at the British Red Cross clinic, however, has brought to light the following interesting facts :—

(1) All cases of spondylitis adolescens so far examined radiographically have shown in one or, more often, both sacro-iliac joints, signs of chronic infection, such as bony ankylosis.

(2) This sacro-iliac joint infection begins several years before there are any symptoms referable to the back.

(3) The onset of the infection is indicated by a definite prespondylitic syndrome consisting of attacks of wandering pains across the shoulders, down the arms and round the ribs, and finally down the legs to the knees and up to the hips. At this stage these cases are clinically diagnosed as muscular rheumatism.

(4) No spinal symptoms, such as rigidity and pain, are complained of until ankylosis of the sacro-iliac joints has begun, and often not until it is complete.

(5) The radiographic examination of the sacro-iliac joints during this prespondylitic period has revealed the early stages of infection—the stages that precede ankylosis—which, up to now, have not been detected.

These findings appear to be of considerable importance, for not only do they go to prove that the primary cause of spondylitis adolescens is an infection of the sacro-iliac joints, but also account, in many instances, for the attacks of so-called muscular rheumatism which occur in the young adult. In cases of "muscular rheumatism" which persist over a number of years without any local signs in any of the joints, a radiographic examination of the sacro-iliac synchondrosis should be made, for prognosis must necessarily be more hopeful if infection is detected at an early stage.

With regard to treatment, trephining and curetting of the sacro-iliac joints is a procedure that might be expected to do good. An alternative, less drastic form of treatment has been tried in a few cases, with encouraging results. This method consists in irradiating the whole spine, including the sacro-iliac joints, by X rays of medium wave-length.

We are, Sir, yours faithfully,

S. GILBERT SCOTT, M.R.C.S. Eng., D.M.R.E.,
Hon. Radiologist to the British Red Cross Clinic for Treatment of Rheumatism, Peto-place ;
F. C. GOLDING, M.R.C.P. Lond., M.B., Ch.M. Sydney,
Clinical Assistant to the X Ray Department of the Clinic.

CONTROL OF INFECTIONS IN CHILDREN'S WARDS

To the Editor of THE LANCET

SIR,—We are in entire agreement with practically every point raised by Dr. Spence in his letter of Feb. 25th. A great deal of work has been done on the control of the usual infections of childhood, so that we can now face with equanimity the occurrence of cases of diphtheria, scarlet fever, and measles in a children's ward. At the Children's Hospital in Great Ormond-street, after preventive inoculation, children are operated upon in surgical wards on the nasopharynx, even if a case of scarlet fever has been notified 24 hours previously. With regard to nasopharyngeal infections, a great deal of work has been done recently, particularly in connexion with hæmolytic streptococcal throats, and it is of interest to note that Dr. Bernard Schlesinger has observed a marked diminution in the spread of these infections in his Heart Home at West Wickham, by the simple expedient of alternating children in adjacent beds—placing them from head to foot. This doubtless acts by reducing the effects of droplet infection. In the suggested plans for the rebuilding of the Great Ormond-street Hospital, the arrangements are such that no ward unit will contain more than eight cots, and these will be separated by a partition into two groups of four each. The cots will be placed parallel to the windows, resulting in a similar head to foot arrangement to that at West Wickham.

Dr. Spence instances pyloric stenosis, where the prognosis between the private and hospital cases differs so considerably. We can bear this out from our own experiences. In addition we can recall cases which have been admitted for a simple surgical operation, such as radical cure for hernia or the treatment of a nævus, which have become infected in hospital before any operation has been done; the sequence of events being perhaps tonsillitis, otitis media, double mastoid, and septicæmia. These unfortunate complications, which are by no means isolated cases or confined to one or two institutions, are inherent in the present system—which obviously needs to be changed.

We are in entire agreement with Dr. Spence on the question of the nursing staff, and believe that once the difficulty of the housing of nurses can be overcome, and adequate nurses be available, no nurse should be responsible for more than one or two children. We firmly believe that dysentery in children, and therefore most probably that bugbear of all children's neonatorum, 69. No case of cholera, plague, or typhus fever was notified during the week.

The notifications of acute pneumonia (primary or influenzal) were below the expected number (based on the median value of the corresponding weeks of 1924–32) by 31 per cent. in England and Wales, and by 33 per cent. in the County of London.

The number of cases in the Infectious Hospitals of the London County Council on Feb. 28th–March 1st was as follows:—Small-pox, 56 under treatment, 1 under observation (last week 64 and 3 respectively); scarlet fever, 1556; diphtheria 1570; enteric fever, 6; measles, 286; whooping-cough, 668; puerperal fever, 22 (plus 10 babies); encephalitis lethargica, 232; poliomyelitis, 1; "other diseases," 338. At St. Margaret's Hospital there were 20 babies (plus 15 mothers) with ophthalmia neonatorum.

Deaths.—In 118 great towns, including London, there was no death from small-pox, 1 (1) from enteric fever, 31 (2) from measles, 1 (1) from scarlet fever, 50 (17) from whooping-cough, 29 (4) from diphtheria, 46 (7) from diarrhœa and enteritis under 2 years, and 344 (74) from influenza. The figures in parentheses are those for London itself.

No great town reported as many as 20 deaths from influenza, and only Birmingham (19) and Manchester (11) reported more than 10. Measles accounted for 4 deaths each at Hull, Liverpool, and Birmingham; whooping-cough for 3 deaths each at Liverpool, Middlesbrough, and St. Helens. Four deaths from diphtheria occurred at Acton, 3 at Manchester.

The number of stillbirths notified during the week was 256 (corresponding to a rate of 45 per 1000 total births), including 27 in London.

PARLIAMENTARY INTELLIGENCE

NOTES ON CURRENT TOPICS

Housing and Slum Clearance

ON March 6th in the House of Commons the Housing (Financial Provisions) Bill was considered on Report.

Sir P. HARRIS moved an amendment providing that the houses, to be built under the guarantees, except where otherwise approved by the Minister on the recommendation of the local authority, should be provided with a fixed bath.

Mr. SHAKESPEARE (Parliamentary Secretary to the Ministry of Health) agreed that a bath was an absolute essential to a house, but said that the amendment was unnecessary. The matter could safely be left to the discretion of the Minister.

In the course of the subsequent debate Sir FRANCIS FREMANTLE and several Members urged the Minister to reconsider the matter.

Sir E. HILTON YOUNG (Minister of Health) accepted the amendment, which was agreed to.

A further amendment, moved by Mr. GREENWOOD, to provide bathrooms as well as baths was rejected.

The Report stage of the Bill was concluded.

A New Epoch in Housing

Sir E. HILTON YOUNG, in moving the third reading of the Bill, said that the Government had seized the opportunity of the fall in building costs, in the price of capital for investment of this sort, to look forward to a more fertile and more productive epoch in housing—one in which those larger forces might be brought into play which had been so long checked by the insuperable obstacles of subsidised competition. They had a second line behind private enterprise, the line of the local authorities, and their liability and duty would be still to tend the housing needs of their locality. With the present level of money, it was within the capacity of local authorities to provide houses at rents which were within a few pence of the rents fixed as ideal under the subsidy. Then there was also the building society scheme. That had never been put forward by the Government as an essential part of their housing plan, but it had been put forward as a valuable aid in the promotion of that free play of the forces of private enterprise which was, in itself, an essential part of the scheme. It was a little practical step which might have great results. They could do no finer service for housing than to secure the services of the millions available in the hands of the building societies. It would be impossible to obtain from any other source so free a supply of capital at so low a rate. It was not true to say that only three societies were prepared to work the scheme. He had been in touch with nine societies, including the biggest, with total capital assets of £150,000,000, who were prepared to operate the scheme. Referring to the committee he had appointed to carry out a review of new conditions, he said that there would be no question of replacing the direct subsidy by the indirect subsidy, which would have an even more powerful effect in discouraging private enterprise.

Dealing with the plan of campaign by which the Government were going to wage war on the slums, the right hon. gentleman said that since the second reading of this Bill they had seen a remarkable demonstration of public opinion all over the country on this subject, and it left no doubt that the resolution of the country was to press the warfare against the slums in a determined and effective manner. (Cheers.) There was a clear demand for action. It was 60 years since the first provision was made by Statute for slum clearance, and in all that period the average annual rate of persons affected by a demolition of slums had been fewer than 3000 a year. It was 14 years since a subsidy was devoted to slum clearance, and in those 14 years the total number of houses affected was no more than 15,000; some few more than 1000 a year. There had been no progress adequate to the evil. Subsidies had only succeeded in scraping the surface of the evil. The basis of the programme he was now announcing was that there could be no more delay or trifling with the problem. He proposed to call on every local authority which was a housing authority to prepare a survey of its area from the point of view of slums and to follow that survey with a programme for the abolition of the slums so revealed. A distinction would be made between those areas which could be dealt with by reconditioning and those which required the more radical remedy of clearance. It would be suggested that the programme should state the periods during which each of the areas would be dealt with. The programme would also provide that a reconditioning area, when all the effects of reconditioning were exhausted, should become a clearance area. In consequence of the provision of a time limit for the programmes, they would secure that every dweller in the slums would have the assurance that within a limited time he would obtain deliverance from the conditions in which he dwelt. There were in existence five area programmes under the Act of 1930, but they were not sufficient for the present purpose, because they were not drawn up with the special object which the Government now had in view—namely, concentration on an effort to end the slums. They were drawn up with a view to the provision of a programme for the provision of houses in general, and must therefore be replaced by a special programme such as he had referred to. The part of the Government in this campaign would be no less direct than that of the local authorities. Its first action would be the provision of the essential finance. They would set no limit to the number of houses that might be thus dealt with. Every house that was unfit for human habitation should be dealt with as quickly as possible—the quicker the better. (Cheers.) The Government would stimulate and assist the local authorities in the preparation of their surveys and programmes. That was in general the

ALARIC CHARLES BALLANCE, M.B. Oxf.

The death occurred on Feb. 20th, at his house in Hatfield, of Dr. Alaric Ballance. This untimely termination to a useful career has been a source of deep regret to many friends and patients, and indeed to all the neighbourhood, where he was well known.

Dr. Alaric Ballance was born in 1888, the only son of Sir Charles and the late Lady Ballance. He was educated at Eton, Oxford, and St. Thomas's Hospital. At Oxford he took honours in chemistry and graduated in medicine in 1914, in which year he also obtained the English double diploma. At the hospital he acted as gynæcological house surgeon and assistant in the children's surgical department, and was resident accoucheur at the outbreak of the war. He joined the navy immediately as a temporary surgeon, and served in the navy for five years with the most varied experience, in critical circumstances. Commencing with the Antwerp episode, he served at Gallipoli with the grand fleet, and his personal work during the evacuation of Cape Helles was made the subject of public and admiring comment. His experiences at this seat of the war were terrible, on one occasion every officer senior to himself in one particular unit was killed. Later he went through the Battle of Jutland, after which he volunteered to serve in the Suvla expedition, while towards the end of the war he saw further severe service at Archangel.

At the close of the war he settled at Hatfield and obtained an extensive practice, finding time also to do valuable professional public work. He was M.O.H. for the Hatfield rural district, staff surgeon to the Herts Constabulary, and vice-chairman of the East Herts Division of the B.M.A. His professional skill and work, no less than his personal character, were appreciated by a large circle, among whom his death has caused a real gap. He was one more victim to the over-strenuousness of the doctor's life in times of wide-ranging sickness. He was tired out.

Dr. Ballance married a daughter of Sir Walter Tryon, and leaves a widow and four children, the two sons being at present at Eton.

PUBLIC HEALTH SERVICES

Consultants and Specialists at L.C.C. Hospitals

Up to now consultants have in the main been engaged for individual hospitals and institutions of the London municipal service, some being paid annual salaries, others a fixed charge a visit for a minimum number of visits each year, and others a fixed charge for visits as required. On Tuesday last the London County Council approved a scheme for putting the consultant and specialist service as far as possible on a regional basis. The general hospitals have been divided into seven geographical groups with affiliated special hospitals and residential schools; and the specialists are to be available for head office purposes in connexion with the school medical and tuberculosis services, the work of medical examination of candidates, and so forth. In the future consultants will be appointed to the service and utilised as required for a group or groups of hospitals. At every hospital the services are to be available of physician, surgeon, gynæcologist, ophthalmic surgeon, ear, nose, and throat surgeon, orthopædic surgeon, dermatologist, pædiatrist, urologist, radiologist (except at Lambeth hospital), obstetrician (where there is a maternity ward), and tuberculosis officer (under appropriate circumstances). In each group the total estimated number of weekly sessions required is as follows:—

Physicians	27	Ear, nose, and throat surgeons	25
Surgeons	34	Dermatologists ..	15½
Obstetricians and gynæcologists	16½	Pædiatrists	15
Ophthalmologists ..	20	Urologists	9½
Radiologists	51	Orthopædists	11

The time required by anæsthetists and neurologists being difficult to estimate, the suggestion is that panels should be formed, and their services utilised as required, and paid for at sessional rates: anæsthetists 34*s.* and neurologists 52*s.* 6*d.* for a session of 2½ hours. Other consultants will be engaged on a basis of yearly salaries; they would work at different hospitals to each of which they would be definitely attached for a fixed number of sessions a week, undertaking in addition any emergency work. The salaries proposed are held to cover operations. The minimum period for which each consultant or specialist is appointed is normally to be two sessions a week of approximately 2½ hours each. Salaries of the part-time staff are to be fixed on the following basis:—

1 session a week	£125 a year.
2 sessions ,, ...	£200 ,,
3 ,, ,, ...	£275 ,,
4 ,, ,, ...	£350 ,,
5 ,, ,, ...	£425 ,,
6 ,, ,, ...	£500 ,,

In the event of being required to divide one session's work between two or more hospitals, the time spent in travelling from one hospital to another is to be regarded as part of the session.

With a view to the possibility in the future of full-time consultant positions in the service, certain officers at present on the hospital medical staff are to be detailed for part-time consultant work, additional staff being employed to ensure that the work at these hospitals does not suffer. The salary of a full-time consulting physician or surgeon is fixed at £1250–£50–£1500 a year (no emoluments), that of a full-time radiologist at £900–£50–£1100 a year.

The appointment of part-time consultants and specialists is to be subject to annual review. In the case of a woman, marriage shall terminate her contract of service. In view of the linking up of special hospitals with general hospitals, a number of the existing positions of consultant at the special hospitals will be discontinued; a list is given in the agenda paper of the officers whose position at present is to be retained. The new scheme is to come into force on July 1st, 1933. Notice of termination of engagement on June 30th is to be given to consultants and specialists now in the hospital service, who will be informed that the question of their re-engagement after that date will depend upon the arrangement made for the provision of a consultant service.

INFECTIOUS DISEASE

IN ENGLAND AND WALES DURING THE WEEK ENDED FEB. 25TH, 1933

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 22 (last week 18); scarlet fever, 1564; diphtheria, 768; enteric fever, 15; *acute pneumonia* (primary or influenzal), 1436 (last three weeks 5151, 4106, 2228); puerperal fever, 33; puerperal pyrexia, 104; cerebro-spinal fever, 55; acute poliomyelitis, 6; encephalitis lethargica, 12; dysentery, 4; ophthalmia

New York had done much to check transport noise in that city; and if he would have a similar body appointed here.—Mr. Oliver Stanley replied: I have no information as to the steps taken by this committee, but I am making inquiries and will then consider whether there is any further action which could usefully be taken.

Mr. Lovat-Fraser asked the Minister of Transport how many cases of enforcement had taken place during 1932 under the regulations forbidding the use of motor-cycles which were not fitted with silencers.—Sir J. Gilmour (Home Secretary) replied: I regret that I cannot give the information asked for, as the returns made by the police for purposes of the annual return of motoring offences do not distinguish between motor-cycles and other motor vehicles in respect of noise offences.

Mr. Lovat-Fraser asked the Home Secretary if he was aware that, on the adjournment of the Committee on Traffic Noises *sine die* about three years ago, Sir Henry Maybury, the chairman, promised that the Ministry would refer the question of evolving a standard motor horn, which should be at once effective and less injurious to the health and nerves of the community, to the committee of research; and whether anything had been done with regard to this.—Mr. Oliver Stanley replied: Inquiries were made from the National Physical Laboratory, and the conclusion was reached that further expenditure on experiments directed towards the production of a standard type of motor horn was not likely to be useful in results.

Hours of Labour

Mr. Lindsay asked the Prime Minister whether the question of the reduction of hours of labour would be considered by the World Economic Conference.—Mr. MacDonald replied: As my hon. friend is probably aware, this subject has been under consideration by the International Labour Organisation, and I cannot say at present whether or in what form it may come before the World Economic Conference. It is not included in the Draft Agenda prepared by the Preparatory Committee of Exports.

Powers of Coroners

Lieut.-Colonel Moore asked the Home Secretary whether he intended introducing legislation with a view to revising the powers of coroners.—Mr. Hacking (Under Secretary for Home Affairs) replied: My right hon. friend does not contemplate any such legislation.

THURSDAY, MARCH 2ND

Census Returns

Mr. McGovern asked the Minister of Health when the completed Returns of the Census taken in 1931 would become available; and what were the reasons for the delay in the publication of the figures.—Sir E. Hilton Young replied: It is expected that publication of the County Report series for the census of England and Wales will be completed in June next. A series of subject and summary volumes will follow, the issue of which should be completed early next year. As regards the latter part of the question, I am not aware of any delay, since both the estimated rate of progress and that already realised compare favourably with the experience of previous censuses and, I am advised, of other countries.

Certified Milk

Captain McEwen asked the Minister of Health whether he was now in a position to alter the requirement of the Ministry whereby it was laid down that the date of production must be stated on the caps of all bottles of certified milk.—Sir E. Hilton Young replied: This matter has not been lost sight of, but pending decisions on certain wider questions of policy I cannot at present undertake to consider altering the relevant requirements of the Milk (Special Designations) Order, 1923.

Maternity and Child Welfare

Mr. Price asked the Minister of Health whether his attention had been drawn to the decision of the Cornwall public health committee to reduce the number of health visitors from 11 to 9, combining their work with that of inspectors of midwives; and whether, in view of the fact that he had on more than one occasion pointed out to this authority that the medical and clerical staff employed by it on the public health work of the county was insufficient and did not provide proper maternity and child welfare services, he would state what steps he intended to take.—Sir E. Hilton Young replied: I do not find that my attention has been previously drawn to this matter, but I am causing inquiries to be made of the Cornwall county council in regard to it.

Disease among Milch Cattle

Sir Gifford Fox asked the Prime Minister by what approximate date the committee which was examining the question of disease among milch cattle would issue its report.—Mr. MacDonald replied: The committee are still engaged in taking oral evidence, and in view of the large number of difficult questions embraced in their terms of reference and the important interests likely to be affected by their recommendations, I do not anticipate that they will be in a position to submit their report for some time.

Hours of Work Convention

Captain Peter Macdonald asked the Minister of Labour how many nations had now ratified the hours-of-work convention put forward by the International Labour Office.—Sir H. Betterton replied: The Washington Convention on hours of work in industrial undertakings has been ratified by 11 countries; four other countries have undertaken to ratify when others do so. The following is the list:—Washington Hours Convention ratified by: Belgium, Bulgaria, Chile, Czechoslovakia, Greece, India,[1] Lithuania, Luxemburg, Portugal, Rumania, and Spain. Ratification with conditional or delayed application: Austria, France, Italy, and Latvia.

MONDAY, MARCH 6TH

Reconditioning of Slums

Captain Cazalet asked the Minister of Health whether he was able to announce the terms of reference and composition of the departmental committee to be set up with regard to the reconditioning of slums and other matters.—Sir E. Hilton Young (Minister of Health) replied: The terms of reference to the committee will be as follows: To consider and report (*a*) what, if any, further steps are necessary or desirable to secure the maintenance of a proper standard of fitness for human habitation in working-class houses which are neither situate in an area suitable for clearance under Part I. of the Housing Act, 1930, nor suitable for demolition under Section 19 of that Act; and (*b*) what, if any, further steps are necessary or desirable to promote the supply of houses for the working classes without public charge, through the agency of public utility societies or other bodies subject to similar limitations operating in particular areas or otherwise. Lord Moyne has consented to act as chairman of the committee, and the other members will be Sir Francis Dyke Acland, M.P., Major J. W. Hills, M.P., Sir Charles Barrie, M.P., Sir Geoffrey Ellis, M.P., Sir V. Henderson, M.P., Miss F. Horsbrugh, M.P., Mr. N. K. Lindsay, M.P., Major G. Lloyd George, M.P., and Dr. J. V. Worthington, M.P.

Use of Pensions Hospitals

Mr. Donner asked the Minister of Pensions what was the policy of the Ministry with regard to utilising hospitals under their control or, alternatively, transferring patients to civil hospitals as a measure of economy.—Major Tryon replied: It is the policy of the Ministry to utilise civil hospitals in preference to duplicating existing facilities so far, but only so far, as this practice is consistent with the interests of ex-Service patients for whom the Ministry is responsible. Ministry hospitals are provided for various special types of case for which either civil institutions do not provide, or which can be more suitably dealt with in Ministry institutions. With the decline in demand for treatment some of the Ministry hospitals have necessarily had to be dispensed with, but my hon. friend may rest assured that special accommodation will continue to be provided so long as it is needed.

Mr. Donner asked the Minister of Pensions the intentions of the Ministry with regard to Maghull Hospital, near Liverpool; and whether any patients were to be transferred to any other hospitals.—Major Tryon replied: The accommodation provided at Maghull, near Liverpool, which is Crown property and has been used for the treatment of severe cases of epilepsy, has become increasingly in excess of the requirements of my Department, and the institution is required by the Board of Control who are in a position to use it more advantageously for their own cases. I have accordingly arranged for the transfer of the patients now at Maghull, along with the medical nursing staff, to Chepstow, another Ministry hospital of more suitable size where equivalent accommodation will be provided.

Mr. Donner asked if it was the case that there was no truth in the suggestions that the Minister of Pensions was trying to get all these patients out of Ministry of Pensions hospitals.

Major Tryon replied in the negative. He said that those patients were being transferred from one Ministry of Pensions hospital to another Ministry of Pensions hospital.

Mr. Hall-Cain asked the Minister of Pensions how many patients for whom he was responsible were at present being treated for war disabilities in civil hospitals in Liverpool; and what amount of accommodation existed in Mossley function of the general inspectors of the Ministry, but there was a certain weight of inertia to lift, and, therefore, he proposed to assist the local authorities in the preparation of their surveys and programmes by a flying squad of special experts from the Ministry of Health, whose function would be to stimulate initiative where such stimulation was needed and to give technical assistance and advice in the preparation of the programmes.

---

[1] 60 hours not 48, applicable only to certain categories of workers.

There were ample powers under the Act of 1930 to enable the Minister to carry out this programme in consequence of the passage of this Bill, and in case of need there would be no hesitation to put those powers into force.'

Mr. **Greenwood** said that the only idea of the Bill was a return to private enterprise. The Bill contained no single constructive proposal and no word dealing directly or indirectly with slums.

The Bill was read the third time by 233 votes to 66.

Compensation for Road Accidents

In the House of Lords on Tuesday, March 7th, Lord **Danesfort** moved the second reading of the Road Traffic (Compensation for Accidents) Bill. He said that their Lordships were all agreed that there must be some remedy devised for the present intolerable state of things on the roads. Instead of the numbers of deaths and injuries being decreased they had actually increased. The difficulties in the way of the pedestrian getting compensation were very great under the existing law. Under the present Bill there was a right given to the pedestrian to claim compensation without proof of negligence on the part of the motorist, but there were two important exceptions—namely (1), where the injury was solely caused by the negligence of the person injured; and (2) where the injury was caused by the negligence of the person injured coupled with the negligence of a third person. The proviso limited the operation of the Bill to pedestrians and pedal cyclists, the claims of motorists *inter se* being met by the existing law. Clause 2 gave the right to a motorist in a case where he had to pay under the Bill, because his car had actually caused the damage, to obtain an indemnity from a third person by whose negligence the accident was really caused. Owing to the accidents on the roads the hospitals throughout the country were to-day put to enormous expense, of which they could recover under the existing law only a small part. If this Bill went into Committee he would gladly welcome any amendment that was brought forward by the hospital authorities to put the hospitals on a more favourable position than they now were. (Cheers.)

Lord **Moynihan**, in support of the Bill, suggested that the yearly toll from motor casualties now equalled the total mortality and injuries of two and a half years of the South African war. He described the unfair situation in which the medical profession was placed by this frequent occurrence of serious road accidents, and suggested that there should be a central pool established by the insurance companies, that the pool or fund thus created should be vested in a competent body, and that payments from that fund should relate only to first-aid treatment. A registered medical practitioner who rendered first-aid treatment should be paid a fee from the pool unless he was otherwise remunerated for his services. Such payment should not be regarded, as at present, as an admission of liability by the insurance company; and the medical report should be available free to the coöperating insurance company and on payment of a fee to any other insurance company. He thought that such a plan would do a great deal to remedy the disadvantages from which medical practitioners were now suffering.

The effect on the hospitals of the Road Traffic Act, Section 32 Subsection (2) was intended to be beneficial, but in actual practice it had proved to be nothing of the kind. During the year 1931 he was informed by the British Hospitals Association, on the board of which he sat, that there were 25,000 motor accidents taken to the voluntary hospitals as in-patients; that the cost to the hospitals was £225,000; that the claims received were £35,000; that was to say, that 16 per cent. of the cost of the treatment of the patients was paid after claims had been made to the insurance companies. The cost borne by the various hospitals varied from 45 per cent. at the Westminster Hospital to 81 per cent. at Guy's. Unhappily, the burden which was borne by the hospitals was chiefly borne by the smaller hospitals. In those hospitals which had over 50 beds, 37 per 100 beds per annum were taken up by motor accident cases, whereas in those hospitals which had less than 50 beds, 77 motor accident patients per 100 beds per annum were admitted. The intended benefit to hospitals under the Road Traffic Act resulted in only one-sixth of the cost being borne by any one authority outside the hospitals, and nothing whatever was done in respect of out-patient treatment which might be in itself very costly. Motor accidents caused a disturbance to the routine work of the hospitals which he thought was most objectionable. The routine of a hospital was not only concerned with the treatment of patients from the immediate neighbourhood and from very far abroad, but quiet clinical research was going on which was so important and this had to be compulsorily set aside. Further, these accidents added to the hospitals' waiting-lists. He thought there ought to be a rather different point of view in any legislation of the future on this matter. (Cheers.)

The Earl of **Halsbury** opposed the Bill, the principle of which, he said, was quite wrong.

Viscount **Buckmaster** supported the Bill.

Earl **Howe** said that he did not quite like Lord Moynihan's suggestion of a central pool, but if some sort of legislation could be introduced on the lines indicated by the noble lord, he would welcome it so as to enable the medical profession and the voluntary hospitals to get payment.

The **Lord Chancellor**, speaking personally and not as the Lord Chancellor, supported the principle of the Bill.

After further debate,

The Earl of **Plymouth**, replying for the Government, said that while there was a considerable amount of precedent for altering the principle of the law in regard to the onus of proof of negligence, in the opinion of the Government Lord, Danesfort's Bill went a great deal too far. He suggested that if the Bill was given a second reading, Lord Danesfort might be willing to move that the Bill be sent to a Select Committee, so that the whole matter might be fully examined.

Lord **Danesfort** agreed to this course, and the Bill was read a second time by 31 votes to 2.

The Bill was then referred to a Select Committee.

HOUSE OF COMMONS

WEDNESDAY, MARCH 1ST

Physical Fitness and Motor-driving Licences

Mr. **Ross Taylor** asked the Minister of Transport if, in view of the number of accidents on the roads, some of which were due to physical disability and, in particular, defective vision on the part of drivers, he would institute a system for testing the declarations in regard to physical fitness made by applicants for motor-driving licences.—Mr. **Oliver Stanley** *replied:* Under the Road Traffic Act, 1930, every applicant for a licence to drive a motor vehicle is required to make a declaration in a prescribed form as to his physical fitness, including eyesight. Any person who knowingly makes a false statement is liable to severe penalties under the Act. I have no evidence to show that false declarations are frequent and, in any case, I think it would be well to gain some rather longer experience of the operation of the provisions of the Act before coming to any conclusion as to the need for imposing further requirements in regard to physical fitness.

Abatement of Noise

Mr. **Lovat-Fraser** asked the Minister of Transport if he was aware that the noise abatement committee of

MEDICAL NEWS

University of Oxford

Mr. R. L. Vollum, D.Phil., has been reappointed demonstrator in pathology; Dr. C. G. Douglas, F.R.S., demonstrator in general metabolism; and Dr. R. S. Creed, demonstrator in physiology. All these reappointments are for four years from Oct. 1st, 1933.

An election of two members of the board of the faculty of medicine, in place of Mr. E. L. Pearce Gould and Dr. J. J. Conybeare, who have served for three successive periods and are ineligible for re-election, will be held on June 2nd. The electorate consists of all Oxford graduates who are members of convocation. Nominations must be received before May 12th.

Society of Apothecaries of London

At recent examinations the following candidates were successful:—

Surgery.—J. Burden-Cooper, Univ. Coll. Hosp.; R. P. Huggins, Westminster Hosp.; W. W. B. Kelly Wiseham, Middlesex Hosp.; and A. W. Turner, St. Mary's Hosp.

Medicine.—M. Belo-Zercovsky, London Hosp.; J. A. Bull, Univ. of Toronto; J. Burden-Cooper, Univ. Coll. Hosp.; T. R. Hornby, Univ. of Manchester; V. L. Kahan, Univ. of Cambridge and London Hosp.; W. B. Mattar, St. Mary's Hosp.; T. E. Mitchell, Guy's Hosp.; J. T. Moohalaparackel, Queens Univ., Belfast; and L. Wailer, Guy's Hosp.

Forensic Medicine.—E. H. Antoniades, Royal Colleges, Edinburgh; J. G. Q. Brown, Guy's Hosp.; J. A. Bull, Univ. of Toronto; J. Burden-Cooper, Univ. Coll. Hosp.; L. A. Freeman, London Hosp.; T. R. Hornby, Univ. of Manchester; D. Kyle, Univ. of Cambridge and St. Mary's Hosp.; E. O'C. Parsons, Univ. of Sheffield and St. Bart.'s Hosp.; and F. H. Williams, Univ. of Sheffield.

Midwifery.—J. A. Bull, Univ. of Toronto; J. B. Frumin, Guy's Hosp.; E. C. Rowlands, St. George's Hosp.; J. A. van Rooyen, St. Bart.'s Hosp.; and C. E. Wetherall, Royal Free Hospital.

The following candidates, having completed the final examination, are granted the diploma of the society entitling them to practise medicine, surgery, and midwifery: J. A. Bull, D. Kyle, W. B. Mattar, and L. Wailer.

Royal Institute of Public Health

The annual Whitsuntide conference of the institute will be held this year at Eastbourne. The inaugural meeting will take place on Tuesday, May 30th, when Lord Leverhulme will deliver a presidential address on Public Health in Relation to Industry, and the next day the sections will meet to hear the addresses of their presidents. The section of state medicine and industrial hygiene are discussing the pure milk problem (opened by Dr. E. G. Annis), the principles and practice of health education (Dr. Arthur Massey). There will also be numbers of papers, including one by Sir Thomas Oliver on industrial welfare under existing conditions. Sir Josiah Stamp is to give a special address on the economic test of the limits of public health expenditure, and Prof. S. D. Adshead will open a discussion on the housing problem. In the section of women and children Dame Louise McIlroy, the president, will speak on a maternity service for patients of moderate means, and Sir Ewan Maclean will introduce a discussion on the rôle of the midwife in a national maternity service. A group of papers on the various aspects of the study and care of exceptional children forms part of the programme of this section, and Prof. Winifred Cullis is opening a discussion on biology as a basis for teaching sex hygiene to children. In the tuberculosis section Sir Pendrill Varrier-Jones will ask the question why tuberculosis is still a problem? There will also be discussions on the rehabilitation of the tuberculous cripple (Dame Agnes Hunt), on open-air hospital schools (Sir Henry Gauvain), and a third on radiology in pulmonary tuberculosis (Dr. W. Paton Philip). Dr. Ernst Brieger, Dr. R. H. Hazemann, and Mr. T. W. te Nuyl will describe the after-care work that is being done for the tuberculous in Germany, France, and Holland. The section of pathology will be addressed by Prof. Alexander Fleming, the president, on the trend of modern research in bacteriology, and its proceedings will include discussions on the centralisation of pathological laboratory service (opened by Dr. G. W. Goodhart) and on blood transfusion (Mr. Geoffrey Keynes). The section of hydrology and climatology will hold one discussion on Sir Gilbert Walker's presidential address on the importance of airs, waters, and places, and another on the relation of soil and climate to rheumatic disease. The usual receptions and ceremonies will be held in connexion with the congress. Apart from visits of instruction to places in the locality there will be pleasant opportunities of seeing some of the beauties of the coast. Anyone who is interested is invited to join the congress. The address of the institute is 23, Queen-square, London, W.C.

Royal Faculty of Physicians and Surgeons of Glasgow

At a meeting on March 7th Dr. Andrew James Hutton and Dr. John Dunbar were admitted Fellows of Faculty.

Royal College of Surgeons of England

A series of demonstrations of specimens in the museum of the College has begun and will be continued for the next fortnight. On Monday, March 13th, and Wednesday, the 15th, Mr. E. K. Martin will demonstrate Inflammatory Diseases of the Stomach and Duodenum, and on Friday, March 17th, Inflammatory Disease of the Cæcum and Appendix. On Monday, March 20th, Mr. C. E. Shattock will show specimens illustrating diseases of the kidneys, and on Friday, March 24th, specimens illustrating diseases of the testicle. The demonstrations will be at 5 P.M., and are open to all medical practitioners.

University of London

On Monday, Tuesday, and Wednesday, March 20th–22nd, at 4.30 P.M., Sir Arnold Theiler, formerly director of veterinary education and research in the Union of South Africa, will lecture at the Royal Veterinary College, Great College-street, Camden Town, London, N.W., on the Osteodystrophic Diseases of Domesticated Animals.

Royal Microscopical Society

A meeting of this society will be held in the Hastings Hall of B.M.A. House, Tavistock-square, London, W.C., on Wednesday, March 15th, at 5 for 5.30 P.M., when Dr. R. G. Canti will give a cinematograph demonstration of living tissue cells cultivated in vitro.

Irish Medical Schools and Graduates Association

The St. Patrick's day dinner of this association will be held at the Dorchester Hotel, Park-lane, on Friday, March 17th, at 7.30 P.M. The president, Dr. T. G. Moorhead, will be in the chair.

French Congress of Therapeutics

The first Congrès français de Thérapeutique will be held in Paris from Oct. 23rd to 25th, under the presidency of Dr. Loeper, professor of therapeutics in the Faculté de Médecine of Paris. Papers will be read on parenteral treatment of gastric ulcer; the association of remedies; the treatment of colibacillosis; the adrenalines; short waves in therapeutics; and the treatment of radiodermatitis. Inquiries should be addressed to the treasurer, Dr. G. Doin, 8, place de l'Odéon, Paris VI.

Dinner to Dr. Edward F. Stephenson

On the occasion of his retirement from office as chief medical officer of the Department of Local Government and Public Health of the Irish Free State, Dr. Edward F. Stephenson was recently entertained to dinner by the members of the Society of Medical Officers of Health of Ireland, who also presented him with an illuminated address. Dr. J. A. Harbison presided, and proposed the toast of Dr. Stephenson's health. He drew attention to the part Dr. Stephenson had taken in the development of a public health service in Ireland, and his courage and modern outlook in public health problems, as well as his encouragement of the medical officers of health. In addition to the members of the Society, among others present were the Lord Mayor of Dublin, the chairman of the General Council of County Councils, and Mr. E. P. McCarron, secretary of the Department of Local Government and Public Health.

New Nurses' Homes

The Princess Royal recently opened an extension of the district nurses' home at Holbeck, Leeds, to which several new rooms and many amenities have been added.—A nurses' home has been added to the Birmingham Children's Hospital, containing a separate bedroom for each of the 120 nurses. Each of the three floors of bedrooms has its distinctive colour. One floor is chiefly for the use of the night nurses, who have their own lounge and a small tea-kitchen. A concert and dance room is provided and there are one or two sitting-rooms into which a nurse can invite her friends of either sex; they can be reserved for any required time by making previous application. The nurses raised the cost.—Greatly improved accommodation for nurses at Whiston Sanatorium, Lancashire, has just been opened. Hitherto the nurses have been badly housed. Some of the rooms were dark and ill-ventilated, there was no recreation room, four maids shared a bedroom 10 ft. by 13 ft., and there was only one bathroom. There are now three bathrooms, eight new bedrooms have been provided, nurses and maids have separate sitting-rooms, and electric light has replaced gas.

Hill Hospital.—Major TRYON replied: No patients for whom the Ministry is responsible are at present being treated in any Liverpool civil hospital for their accepted war disabilities. Patients requiring institutional treatment in Liverpool are ordinarily sent to the Ministry hospital at Mossley Hill, which has accommodation of 300 beds, of which at present 255 are occupied.

Mr. BROCKLEBANK asked the Minister of Pensions what was the present policy of the Ministry with regard to the treatment in Liverpool of men whose minds were injured by war service; and whether in any cases such men had been transferred to lunatic asylums.—Major TRYON replied: There has been no change in the policy of the Ministry with regard to the treatment in Liverpool or anywhere else "of men whose minds were injured by war service." I have no authority to detain or treat in a Ministry institution a certified case of mental unsoundness, but my own policy and that of my predecessors has been to provide suitable treatment in special institutions for all cases of mental affection for which the Ministry is responsible, so long as they are not certifiable. As a matter of fact, during the past 12 months only one case had to be transferred in the Liverpool area to a mental hospital, and that was eight months ago. Any statement, such as I believe has recently been publicly made in Liverpool to the effect that the policy of the Ministry was, in the interests of economy, to transfer men from Ministry institutions to lunatic asylums is wholly untrue and can only cause needless anxiety.

Indian Medical Council Bill

Mr. RHYS DAVIES asked the Secretary of State for India what action the Government of India proposed to take in response to the representations from the Indian Medical Association with regard to the exclusion of Indian medical licentiates from the provisions of the Medical Council Bill.—Sir S. HOARE replied: I have not heard what action the Government of India propose to take. As the hon. Member is no doubt aware, the Indian Medical Council Bill has been referred to a Select Committee of the Legislative Assembly.

TUESDAY, MARCH 7TH

Medical Opinion and Disablement Pensions

Mr. HUTCHISON asked the Minister of Pensions whether his department would adopt the principle, in cases of difference of medical opinion over attributability of a disease to the Great War, of appointing an independent medical arbitrator to be agreed on by both sides in order to allay much existing bitterness.—Major TRYON replied: I could not, I fear, adopt my hon. friend's suggestion with due regard to my responsibility to Parliament. I would, however, remind my hon. friend of the present arrangements under which medical specialists of eminence, nominated by the Presidents of the Royal Colleges of Physicians and Surgeons, are invited by me to give their independent advice upon the merits of cases of late claim for disablement which present serious doubt or difficulty on the evidence.

Cost of Assistance to Ex-Service Men

Mr. LOUIS SMITH asked the Minister of Pensions what was the present total annual expenditure on assistance to those who served in the late war and to their dependants; what amount this represented per head of those who were killed and wounded; and how such amounts compared with similar expenditure in the United States of America.—Major TRYON replied: It is not possible to obtain comparable figures for the United Kingdom and the United States of America as to the expenditure on ex-Service men of the late war. In the United States of America all public expenditure on monetary benefits and on medical and other services for all classes of ex-Service men and their dependants, whether disabled by war service or otherwise, is administered through a single Department of State—the War Veterans' Bureau. In this country, on the other hand, in addition to the benefits administered by the Ministry of Pensions and the Service Departments, ex-Service men draw benefit, frequently on specially favourable terms, under the Health and Unemployment Insurance schemes, the Contributory and other Old Age Pensions Acts, and through other agencies, but the portion of the expenditure under these heads which is attributable to ex-Service men and their dependants cannot be distinguished.

THE SERVICES

DIRECTOR-GENERAL, ARMY MEDICAL SERVICES

THE War Office announces that the appointment of Lieutenant-General Sir Harold B. Fawcus, K.C.B., C.M.G., D.S.O., D.C.L., K.H.P., Director-General, Army Medical Services, has been extended for a period of one year from Sept. 16th, 1933.

ROYAL NAVAL MEDICAL SERVICE

Surg. Lts. J. B. Patrick and J. Johnston to be Surg. Lt.-Comdrs.

Surg. Lt. W. J. M. Sadler is transferred to the Permanent List.

C. J. Mullen and P. N. Walker-Taylor to be Surg. Lts.

The following appts. are notified: Surg. Comdr. E. L. Markham to *President*, for R.N. and R.M. Recruiting Headquarters. Surg. Lt.-Comdr. C. B. Fox to *Danae*. Surg. Lts. F. W. Chippindale to *Vindictive*; G. H. Sellars to *Renown* and to *Malaya*; H. O. O'Connor and E. A. Gerrard to *Victory*, for Haslar Hospital; S. J. Savage to *Pembroke*, for R.N.B., Chatham; and A. J. A. Gray to *Victory*, for R.N.B., Portsmouth.

ROYAL ARMY MEDICAL CORPS

Maj. W. H. Cornelius, half-pay list, is restd. to the estabt.

Lt. J. Taylor relinquishes his temp. commn.

G. L. McLeod to be Lt. (on prob.).

ARMY DENTAL CORPS

Lt.-Col. D. Blair, having attained the age for compulsory retirement, is placed on retd. pay.

Maj. A. R. Inglis to be Lt.-Col.

TERRITORIAL ARMY

Capt. W. W. MacNaught to be Maj.

Lt.-Col. W. H. Fisher, having attained the age limit, retires and retains his rank, with permission to wear the prescribed uniform.

Capt. G. W. Elkington resigns his commn.

INDIAN MEDICAL SERVICE

The undermentioned appts. are made: Capt. C. V. D. Rose, from R.A.M.C., to be Capt. B. A. Porritt, M. S. Purvis, F. W. Whiteman (and remains secd.), and M. E. Kirwan to be Lts. (on prob.).

ROYAL AIR FORCE

Flight Lt. M. T. O'Reilly is granted a permanent commission in this rank.

Wing Commander P. M. Keane is placed on the retired list.

COLONIAL MEDICAL SERVICE

Dr. A. W. H. Donaldson has been appointed Medical Officer in charge of the Medical Department, Somaliland; Dr. J. M. Gray, Health Officer, Hong-Kong; and Dr. H. North has been promoted to Senior Medical Officer, Nigeria.

INCOME OF PATIENTS AT GUY'S HOSPITAL.—At the end of 1931 the court of committees at Guy's Hospital authorised an inquiry into the means of in-patients, and their assessment on the main lines of the assessment in force in the local London County Council hospitals. Patients were to be informed that if they had been admitted to an L.C.C. hospital they would have been charged the amount of their assessment, and it was suggested that they might, if they wished, contribute an amount not less than they might have had to pay in an L.C.C. hospital. The analysis shows that the income of 95 per cent. of the 8232 patients interviewed in the wards was within the Hospital Savings Association limits—viz., £4 per week for a single person, £5 for a married couple without children, and £6 per week for a married couple with children—and of these 28½ per cent. had incomes up to £2 per week. These figures are held to refute the suggestion sometimes made that the poor have to go to L.C.C. hospitals because the voluntary hospitals are being utilised to a much greater extent for the lower *middle classes. As a result* of the assessment the actual contributions from patients in the wards have increased very little, but the contributions by the Hospital Savings Association have risen by over £2300. The more careful investigation into the means of in-patients has also produced contributions from provincial contributory schemes and public authorities, which show an increase of £1360 over 1931. The small additional charges made to out-patients since last April have resulted in an increase of £2350 over the amount received from out-patients in 1931. One effect of these charges has been to stimulate the production of vouchers from the Hospital Savings Association. Another effect is a 10 per cent. decrease in dispensary attendances. This is attributed to the fact that patients suffering from trivial complaints are now tending to avail themselves either of the services of their panel doctors, or are doing trifling dressings and treatment at home. The total receipts from in-patients and out-patients for 1932 amount to £39,887, and show an increase of £6700 over the total receipts of 1931.

Medical Diary

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

SOCIETIES

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

TUESDAY, March 14th.—5 P.M., THERAPEUTICS AND PHARMACOLOGY. Short communications will be read by Dr. R. D. Lawrence and Dr. W. W. Payne. 8.30 P.M., PSYCHIATRY. Papers. Dr. E. A. Bennet and Dr. J. A. Hadfield: The Psychopathology of Sexual Perversions.

THURSDAY.—5 P.M., DERMATOLOGY. (Cases at 4 P.M.) Case. Dr. A. Cambell: 1. Unusual Case of Arsenical Dermatitis. Dr. Barber: 2. Case for Diagnosis. Dr. Sibley: 3. Pustular Psoriasis. Other cases will be shown. 8.30 P.M., NEUROLOGY AND PHYSICAL MEDICINE. Special Discussion. The Causation and Treatment of Interstitial Neuritis. Openers: Dr. Wilfred Harris and Dr. J. Purdon Martin, Neurology; Dr. M. B. Ray and Dr. J. Barnes Burt, Physical Medicine. Other speakers will take part.

FRIDAY.—8.15 P.M., OBSTETRICS AND GYNÆCOLOGY. Short communication. Mr. G. F. Gibberd: A Case of Concealed Accidental Hæmorrhage Associated with Spontaneous Complete Rupture of the Uterus. Papers. Mr. L. Carnac Rivett: Puerperal Sepsis—Reports of Cases at Queen Charlotte's Hospital. Mr. Carlton Oldfield and Mr. L. N. Pyrah: Some Observations on the Pathology, Diagnosis, and Treatment of Puerperal Peritonitis. 8.30 P.M., RADIOLOGY. Paper. Dr. R. E. Roberts and Mr. R. Watson Jones: Calcification and Ossification. Mr. Duncan Fitzwilliams and others will take part in the subsequent discussion. Members of the Section of Orthopædics are specially invited to attend the Meeting.

MEDICAL SOCIETY OF LONDON, 11, Chandos-street, Cavendish-square, W.

MONDAY, March 13th.—8.30 P.M., Discussion on Chronic Pancreatitis to be introduced by Mr. A. J. Walton, Sir W. H. Willcox. and Prof. E. C. Dodds.

ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE.

THURSDAY, March 16th.—8.15 P.M. (at the Royal Army Medical College, Grosvenor-road, Millbank). The following amongst others will give Demonstrations:—Dr. Mary Andrews, Dr. G. M. Findlay, Drs. E. Hindle and Bruce White, Mr. B. Jobling, Dr. P. D. Johnson, Colonel Clayton Lane, Dr. G. Carmichael Low, Dr. R. D. Mackenzie, Colonel H. Marrian Perry, and Major H. J. Benstead, Mr. J. S. Steward, Prof. J. Gordon Thomson, and Prof. Warrington Yorke.

PADDINGTON MEDICAL SOCIETY.

TUESDAY, March 14th.—9 P.M. (at the Great Western Royal Hotel, Paddington), Mr. Leonard Phillips: The Place of the General Practitioner in the Practice of Midwifery.

NORTH LONDON MEDICAL AND CHIRURGICAL SOCIETY.

TUESDAY, March 14th.—9 P.M. (at St. Mary Islington Hospital), Dr. H. S. Burnell-Jones, Dr. Buckley Sharp, and Dr. Malcolm Manson: General, Special, and Public Practice.

BIOCHEMICAL SOCIETY.

FRIDAY, March 17th.—2.30 P.M. (at University College, Gower-street, London), Annual General Meeting. Communications.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

ROYAL COLLEGE OF PHYSICIANS, Pall Mall East, S.W.

TUESDAY, March 14th.—5 P.M., Dr. Charles Newman: The Physiology of the Gall-bladder and its Functional Abnormalities. (Last Goulstonian lecture.)

THURSDAY.—5 P.M., Dr. Charles R. Box: On Complications of Specific Fevers. (First Lumleian lecture.)

ROYAL COLLEGE OF SURGEONS, Lincoln's Inn-fields, W.C.

MONDAY, March 13th, and following WEDNESDAY and FRIDAY.—5 P.M., Mr. E. K. Martin: Museum demonstrations of Inflammatory Conditions of Stomach, Duodenum, Cæcum, and Appendix.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, W.

MONDAY, March 13th, to SATURDAY, March 18th.—MEDICAL SOCIETY OF LONDON, 11, Chandos-street, Cavendish-square. Tues., 4 P.M., Practical Problems in Medicine and Surgery. Lecture by Dr. Philip Ellman, on Recent Advances in Diagnosis and Treatment of Chronic Diseases of the Chest. (Free to Members and Associates of the Fellowship of Medicine.)—NATIONAL
TEMPERANCE HOSPITAL, [illegible] N.W.

Monk's Orchard, Eden Park, Beckenham, Kent. Course in Psychological Medicine. Tues. and Fri., at 11 A.M.—WEST END HOSPITAL FOR NERVOUS DISEASES, 73, Welbeck-street, W. Post-graduate Course in Neurology. Daily at 5 P.M.

WEST LONDON HOSPITAL POST-GRADUATE COLLEGE, Hammersmith-road, W.

MONDAY, March 13th.—10 A.M., Medical Wards, Skin Clinic. 11 A.M., Surgical Wards. 2 P.M., Surgical Wards, Gynæcological and Eye Clinics. 4 P.M., Lecture: Dr. Burnford: Febrile States.

TUESDAY.—10 A.M., Medical Wards. 11 A.M., Surgical Demonstration. 2 P.M., Throat Clinic. 4.15 P.M., Lecture: Mr. Roche: Growths of the Testicle.

WEDNESDAY.—10 A.M., Medical Wards, Children's Clinic. 2 P.M., Eye Clinic. 3.45 P.M., Venereal Diseases.

THURSDAY.—10 A.M., Neurological Clinic. 11.30 A.M., Fracture Demonstration. 2 P.M., Eye and Genito-urinary Clinics. 4.15 P.M., Lecture: Mr. Sinclair: Swellings in the Breast.

FRIDAY.—10 A.M., Skin Clinic. 12 noon, Lecture on Treatment. 2 P.M., Throat Clinic. 4.15 P.M., Lecture: Dr. Ironside: Diseases of the Nervous System.

SATURDAY.—10 A.M., Medical Wards, Children's Clinic. Surgical Wards. The lectures at 4.15 P.M. are open to all Medical Practitioners without fee.

DAILY.—2 P.M., Operations, Medical and Surgical Out-patients.

CENTRAL LONDON THROAT, NOSE, AND EAR HOSPITAL, Gray's Inn-road, W.C.

FRIDAY, March 17th.—4 P.M., Mr. C. Gill-Carey: Diagnosis of Sinusitis.

ST. PETER'S HOSPITAL FOR STONE, Henrietta-street, W.C.

WEDNESDAY, March 15th.—3 P.M., Mr. J. A. Andrews: Carcinoma of Prostate.

ST. MARK'S HOSPITAL, City-road, E.C.

THURSDAY, March 16th.—4 P.M., Mr. A. Baldwin: Some Painful Conditions About the Anus.

NATIONAL HOSPITAL, Queen-square, W.C.

MONDAY, March 13th.—2 P.M., Dr. Riddoch: Out-patient Clinic. 3.30 P.M., Dr. Hinds Howell: Vascular Diseases of the Nervous System.

TUESDAY.—2 P.M., Dr. Walshe: Out-patient Clinic. 3.30 P.M., Dr. Martin: Meningitis.

WEDNESDAY.—2 P.M., Dr. Martin: Out-patient Clinic. 3.30 P.M., Dr. James Collier: Clinical Demonstration.

THURSDAY.—2 P.M., Dr. Kinnier Wilson: Out-patient Clinic. 3.30 P.M., Dr. Riddoch: Heredo-familial Nervous Diseases.

FRIDAY.—2 P.M., Dr. Adie: Out-patient Clinic. 3.30 P.M., Dr. James Collier: Diseases due to Neurotoxins.

PRINCESS ELIZABETH OF YORK HOSPITAL FOR CHILDREN, Shadwell, E.

WEDNESDAY, March 15th.—3.30 P.M., Prof. Leonard Findlay and Mr. K. J. Acton Davis will give a demonstration on Medical and Surgical Aspects of Rickets.

LONDON JEWISH HOSPITAL, Stepney Green, E.

THURSDAY, March 16th.—4 P.M., Dr. Harold Avery: Diet and Treatment of Gastric Disorders.

NATIONAL COUNCIL FOR MENTAL HYGIENE.

WEDNESDAY, March 15th.—5.30 P.M. (at 11, Chandos-street, Cavendish-square, W.), Dr. G. Somerville: Superstition.

ROYAL NORTHERN GROUP OF HOSPITALS.

WEDNESDAY, March 15th.—3.15 P.M. (at the Royal Chest Hospital, City-road), Dr. H. E. Symes-Thompson: Demonstration of Cases in the Wards.

KING'S COLLEGE HOSPITAL MEDICAL SCHOOL, Denmark-hill, S.E.

THURSDAY, March 16th.—9 P.M., Dr. M. S. Thomson: Common Skin Diseases Often Missed.

LONDON SCHOOL OF DERMATOLOGY, St. John's Hospital, 49, Leicester-square, W.C.

TUESDAY, March 14th.—5 P.M., Dr. H. MacCormac: Malignant Growths of the Skin.

THURSDAY.—3 P.M., Dr. I. Muende: Pathology Demonstration.

UNIVERSITY COLLEGE HOSPITAL MEDICAL SCHOOL.

TUESDAY, March 14th.—5.30 P.M., Dr. C. Bruce Perry: Paper prepared by the late Dr. Carey Coombs on Thirty Years of Progress in the Study of Rheumatic Heart Disease.

SOUTH-WEST LONDON POST-GRADUATE ASSOCIATION, St. James's Hospital, Ousley-road, Balham, S.W.

WEDNESDAY, March 15th.—4 P.M., Mr. E. T. C. Milligan: Hæmorrhoids.

ANCOATS HOSPITAL, Manchester.

THURSDAY, March 16th.—4.15 P.M., Mr. H. Platt: Common Disabilities of the Foot.

MANCHESTER ROYAL INFIRMARY.

TUESDAY, March 14th.—4.15 P.M., Mr. Geoffrey Jefferson: The Explanation and the Clinical Application of the Early Symptoms of Increased Intracranial Pressure.

FRIDAY.—4.15 P.M., Mr. C. Roberts: Demonstration of Surgical Cases.

ST. MARY'S HOSPITALS, Manchester.

FRIDAY, March 17th.—4.15 P.M. (at the Whitworth-street West Hospital), Post-graduate Lecture. Mr. Arnold Jones: Nasal Obstruction in Sucklings.

GLASGOW POST-GRADUATE LECTURES.

WEDNESDAY, March 15th.—4.15 P.M. (at the Ophthalmic Institution), Dr. H. W. Thomson: Eye Cases.

POST-GRADUATE COURSE ON VENEREAL DISEASES.—A course in modern methods in the diagnosis and treatment of venereal disease is being held at the municipal clinic, 155, Regent-road, Salford, at 2 P.M., on Fridays from March 10th. Particulars may be had from Lieut.-Colonel E. Tytler Burke, M.B., venereal diseases officer to the city of Salford.

BRITISH HEALTH RESORTS

CONFERENCE AT BATH

At Bath last week-end Mr. Douglas Hacking, M.P. (Under-Secretary for Home Affairs), presided over a conference including representatives of the British Health Resorts Association, the British Spas Federation, the Travel and Industrial Development Association of Great Britain and Ireland, the Conference of Health and Pleasure Resorts, the spa practitioners' group of the British Medical Association, and many of the coastal health resorts and spas. The Mayor of Bath (Councillor Rhodes Cook) welcomed the delegates, and addresses were delivered on behalf of the various groups. A lively discussion followed, and the following resolution was unanimously passed :—

> That this conference, convinced of the necessity for the coördination of effort on behalf of the British health resorts, strongly urges that the various organisations interested therein should, through their chairman or other representative, and their secretary, confer at an early date with a view to defining their respective functions and suggesting lines of coöperation.

In the course of the discussion Lord Meston (chairman of the British Health Resorts Association) described the association's immediate objects as: (1) To obtain the most complete and scientific data of the curative and restorative values of the British health resorts—whether on the coast or moorland or spas; this entailed the coöperation of the local authorities and medical experts and the establishment of local branches. (2) To coördinate and examine this information. (3) To issue it as an annual handbook for the benefit of all medical practitioners. Lieut.-Colonel R. H. Elliot, M.D. (chairman of the executive of the Association), spoke of the great undeveloped resources in the British health resorts. Medical men must of course send their patients where they could get most good, whether at home or abroad, but many people were unaware of the great advantages of our own country in this respect. Mr. L. A. de L. Meredith, on behalf of the Travel and Industrial Development Association, gave some details of the work which was being done by them in making this country known overseas, through the press, by means of films (such as the one shown overnight at the reception), by broadcast talks, and in many other ways. By their constitution they were precluded from using their funds for advertising in this country. They were anxious to include in their overseas propaganda the medical case for the British health resorts, and for that they must have the help of the profession. Alderman Kelynge England (chairman of the British Spas Federation) described the objects of the Federation, established in 1917, and the new programme for bringing spa treatment within the reach of members of friendly societies and others who would otherwise be unable to afford it. The scheme provided for medical advice from a spa specialist, a complete course of spa treatment and accommodation, with board, in an approved hostel. Dr. C. W. Buckley, speaking for the spa practitioners' group and the physical medicine group of the British Medical Association, emphasised the great field for preventive treatment at the health resort. Small places were often of great advantage, and it was in the interest of the State that facilities for treatment should be brought within the reach of all classes. Belgium, Holland, and the Scandinavian countries were practically without spas and visitors from these countries should be welcomed at our health resorts by those who spoke their own language.

The morning session was marked by the unanimous desire of the speakers that a united movement should be pressed forward without delay, to which expression was given in the above resolution.

In the afternoon session the medical case for a comprehensive development of the health resorts as a national whole was set forth. Sir Humphry Rolleston, speaking on the Service of the Health Resorts to the Public, contrasted the subsidised spas of Europe with the British or individualised method, and stated that it was "obviously desirable to combine British initiative and individuality with more practical support and active encouragement from the Government, in order to develop in every direction the various resources and potentialities of our spas and health resorts, which so far had been somewhat neglected as a national asset." Sufficient attention had perhaps hardly been paid to the value of spas in the prevention of diseases, especially those prone to occur in or after middle life as the result of strain and worry. The cure should be open to the poor as well as to the rich. Dr. Fortescue Fox said that, with the growth of science and the increasing needs of crowded urban populations, new avenues of usefulness were opening for the health resorts. These calls could only be met by coördinated development. War-time experience had shown what a little organisation could do. On the continent large funds were available to keep the spas abreast of modern requirement and also—more important—State organisation and scientific guidance, special teaching, and official publicity. There was nothing so valuable to a health resort as the prestige of a national service. The health resorts, inland and on the coast, were the natural centres of physical medicine, which was now coming into its own. The mere care of the children on the coast was of national importance, and should be given much closer study. To meet the new demands on the health resorts and on those responsible for them three things were needed: a clear medical policy, organisation, and public support.

Mr. R. C. Vaughan bore witness to the many improvements effected in the British hotels, but they lay under serious difficulties, he said, because the hotel industry had no pity either from the Government or the local councils. A foreign hotel-keeper modernising his establishment applied for a rebate of taxation or even a government grant, as it was realised that his enterprise brought money into the country. In England improvements were heavily taxed and rated. The best hoteliers were most anxious to work with the doctors in providing necessary diets and conditions. Mr. K. W. C. Grand referred to the pioneer work of the Great Western Railway in coöperating with the health resorts on their line in the matter of publicity, and the efforts of the British railways to perfect their service in speed and comfort.

Dr. Alfred Cox, secretary of the British Health Resorts Association, spoke warmly in support of the new movement, and Lieut.-Colonel W. Byam, chairman of the advisory medical committee, in winding up the discussion, pointed out that up to date the expenses of the Association had been privately met, and appealed to the localities concerned for their generous support.

Mr. Leslie Paton has been elected an honorary member of the Hungarian Ophthalmological Society. He is already an honorary member of the French, Spanish-American, and Japanese Ophthalmological Societies.

necessary for absorbing each man into the industries. The number of cases suitable for admission to the settlement at Preston Hall greatly exceeds the number of vacancies which we have to offer owing to present financial and industrial limitations. But at present there are no fewer than 30 cases from one county council area in the village settlement at Preston Hall; it is estimated that the capital expenditure involved in settling these men in houses and workshops is about £17,000, and so far no contribution of any kind has been asked for from this particular county council in connexion with the establishment of these men in the village.

Contribution of Local Authorities

It is further the view of the council of management of Preston Hall that one of the best methods of adding to the number of settlers in the village would be for local authorities who are not in a position to undertake the direct provision of such accommodation to make use of established village settlements which have passed beyond the experimental stage. With this end in view it is suggested that the local authority shall pay no part of the capital for housing or for the establishment of men in the industries, but that the authority shall pay the sum of £78 per annum in respect of married men with their wives and families and the sum of £52 per annum in respect of single men admitted to the settlement.

The amounts just mentioned are suggested as those which appear, on the information available, to be appropriate and it is submitted that these amounts compare favourably with the cost of maintaining tuberculous individuals from public assistance and other funds, and that they are considerably less than providing public assistance together with treatment for tuberculous adult males and for the tuberculous members of their families. The council of management of Preston Hall propose that this sum shall be allocated to a capital and general fund which, at their discretion, would provide for the extension of the industries and be available for the growth and welfare of the village generally.

The council of management would agree, in return for this contribution to the general fund, to let a house at a low rent (average rent is 8s. per week) to each man admitted and to supervise the man medically throughout the entire course of his stay as a settler at Preston Hall: they would also provide facilities for the medical supervision of his wife and children at no additional cost to the authority. Settlers who break down in health are either pensioners for tuberculosis or are non-pensioners. In cases of the former the local authority and the Ministry of Pensions would, as at present, be advised of the admission of pensioners to the sanatorium, and treatment charges for such cases are, of course, recoverable from the Ministry of Pensions in full. Non-pensioners would be admitted for treatment without extra charge to the local authority.

It is understood, of course, that men selected for settlement would be given work at Preston Hall at a reasonable wage.

Selection of Suitable Cases

Cases suitable for settlement would be selected by the medical director at Preston Hall from amongst the patients sent there for treatment by the officers on the tuberculosis staff of the local authority. So far as ex-Service men are concerned it is clear that most of the patients would be ex-Service men without pensions. Cases selected for admission to the village settlement would be subject to review from time to time by the tuberculosis officer of the local authority, in consultation with the medical director at Preston Hall. The authority could limit the length of stay in the settlement in any individual case.

It is of interest to know that where a death has occurred in the village settlement there has not, as a rule, been any difficulty in arranging for the widow and family to return to the district in which they originally resided, but the council of management of Preston Hall feels strongly that, in the event of a death occurring, the contribution to the general fund by the local authority should be reduced by 50 per cent. until such times as alternative arrangements are made for the widow and family to remove to the district from which the family originally came.

The proportion of cases likely to be admitted to the settlement and the probable duration of their stay in the settlement is a matter which is, under the scheme proposed, as much in the hands of local authorities as with the settlement itself. If, for example, very ill men are sent for treatment as potential colonists it follows that none would be admitted to the settlement, but if the type of case which is likely to respond to treatment is admitted then the settlement can absorb just as many men as there is capital availabe for expansion of the scheme as a whole. Under this scheme local authorities would have the privilege of having two, six, ten, or more settlers in the village, as they desire.

As has been said, the probable duration of settlement would rest with local authorities acting in consultation with the medical director of the settlement, each case being reviewed from year to year. In this way, an authority could calculate its commitment from the very beginning and be at liberty to expand or retract as time went on.

It is realised, of course, that during the present financial stringency any active steps by local authorities in the direction indicated are quite out of the question, but even medical men, especially those in administrative posts, must budget ahead and prepare for the future. It will not be until each existing village settlement is freed from the handicap of restricted capital expenditure that the true function of the village settlement will be appreciated. Then, and then only, shall we be in a position to determine with any degree of certainty its true rôle in the anti-tuberculosis campaign.

ANTIMONY POISONING FROM ENAMELLED VESSELS

SEVERAL outbreaks of antimony poisoning in this country of late years have been traced to the use of enamelled vessels of inferior quality for the preparation of acid drinks such as lemonade. Antimony oxide is widely used, in place of tin oxide, as an opacifying agent in the enamelling of hardware, and it is readily attacked and disintegrated by acid, with the result that the antimony goes into solution. A leaflet[1] just issued by the Ministry of Health describes three such outbreaks, all of them due to the preparation of lemonade in enamelled jugs or buckets. At Newcastle-upon-Tyne, in 1928, 70 employees of a large firm became ill, complaining of a burning sensation in the stomach, colic, nausea, vomiting, and collapse; the drink was made with lemonade crystals containing 18 per cent. of tartaric acid, and a tumblerful of the fluid contained grs. 1½ of antimony calculated as tartar emetic, the emetic dose being gr. ½–1. At Folkestone, in 1929, 25 people were poisoned by lemonade made with fresh lemons in jugs whose enamel contained 9 per cent. of antimony oxide, and it is noteworthy that the jugs, when sold, bore labels saying "we guarantee all articles having this brand to be perfectly safe in use and free from any injurious substances." In the third outbreak, in a large London hospital last December, there were 65 cases of poisoning, and in some of them there was serious collapse. Here again the lemonade was made from fresh fruit. "It is the cheap low-grade enamels," the memorandum says, "that are the danger. These enamels are made from a mixture relatively low in silica content and are fired at a comparatively low temperature. They are not acid-proof and appear to be readily dissolved by citric, tartaric, acetic, and other acids present

NOTES, COMMENTS, AND ABSTRACTS

LOCAL AUTHORITIES AND VILLAGE SETTLEMENTS

By J. B. McDougall, M.D. Glasg., F.R.C.P., F.R.S. Edin.

MEDICAL DIRECTOR, BRITISH LEGION VILLAGE, PRESTON HALL, AYLESFORD, KENT

It is some fourteen years since the village settlement at Papworth was founded. During the period which has elapsed two further important additions have been made to the total strength of the village settlement movement in this country—one at Barrowmore Hall, in Cheshire, and the other at the British Legion village, Preston Hall, in Kent. Sir Pendrill Varrier-Jones, the creator of Papworth, was also the creator of Preston Hall in Kent; but in any account, however brief, of the early history of village settlement work the name of the late Dr. Stanley Tinker, the first director of Barrowmore Hall, can never be forgotten. I feel sure that his early death did much to retard the progress of the village settlement movement in this country.

The work of Sir Pendrill Varrier-Jones is well known throughout the world, and whatever criticisms may be levelled against village settlements there is unanimity in the view that the "Papworth experiment" has been a model of its kind and must always form the foundations upon which similar work must be built.

It may, however, be pertinent to ask: Why, in view of the declared success of Papworth, are there not more village settlements in Great Britain? I have been at a difficulty in answering this question when foreign visitors have come to Preston Hall, for a complete reply to the question must necessarily take into account the psychology of public health committees, the mechanism of local authority finance, and local industrial resources—points which are rarely appreciated to the full by visitors from other countries.

Difficulties of the Present System

At conferences and during private discussions with colleagues in the tuberculosis service in this country I have encountered the following criticisms:—

1. The difficulties in establishing new industries de novo, to be manned by sub-standard labour, are too numerous, especially in areas where the majority of the male population normally follow one particular industry —e.g., coal-mining in South Wales and Yorkshire.
2. Local authorities are no doubt prepared, subject to the approval of the Ministry of Health, to undertake the necessary capital expenditure, but it is the fear of possibly having to meet a large and recurrent annual loss on trading that is the most serious obstacle in the path of local authorities.
3. If the settlement is a success on the commercial side it could be so only by successful trading in competition with ratepayers, the majority of whom are resident within the administrative area of the authority; if a loss had to be met the subsidy would, under existing conditions, have to be paid—in part at least—from the rates.
4. The relative success of Papworth and Preston Hall has obscured the fact that there have been a number of schemes in different parts of the country which have not made the progress anticipated.
5. Substantial alterations in the present "block grant" system of budgeting would be necessary to enable local authorities to regard the sanatorium, industries, and estate as one account for the purposes of audit.
6. The total number of settlers at Papworth, Preston Hall, and Barrowmore Hall, the three largest settlements in the country, number approximately 325. Papworth has been in existence for some 14 years, Preston Hall for 7 years under the British Legion, and Barrowmore Hall for nearly 10 years. The total contribution of the village settlement to the anti-tuberculosis campaign is therefore almost negligible.
7. Unity of control is desirable in a village settlement, and there are few men trained in the complicated administration of a village settlement.

In reply to such criticisms as these I would say at once that I am in entire agreement with the view that local authorities are at a distinct disadvantage in embarking upon settlement work. And in the absence of greater experience than that which is available at Papworth, Preston Hall, and Barrowmore Hall it would, to say the least, be a risky proceeding for a local authority to begin with a preconceived idea of establishing a large village settlement. It is not, however, quite fair criticism to say that the contribution of the village settlement to the anti-tuberculosis campaign is insignificant merely because the combined contribution of the three existing village settlements is small, for there are several important factors involved over which the present village settlements have no control. The first of these is capital. All three organisations—the Cambridgeshire Tuberculosis Colony at Papworth, the British Legion at Preston Hall, and the East Lancashire Red Cross Society at Barrowmore Hall in Cheshire—are voluntary organisations, dependent to a large extent upon the generosity of the public for the capital at their disposal.

At Papworth and at Barrowmore Hall the financial resources are very limited, but at Preston Hall—the British Legion village, controlled by one of the largest voluntary organisations in the country—the position is different. There is not the slightest doubt that Preston Hall could expand by building more houses in the estate section for additional settlers and by increasing the scope of the existing workshops. As it is, growth has been multiplied by five in seven years, thanks to the soundness of the principles laid down by Sir Pendrill Varrier-Jones in 1925 when he first undertook the difficult task of reconstruction. And as a result of close contact with the work at Preston Hall from day to day during nearly six years I have no hesitation in saying that it would be practicable to add 12 to 15 settlers per annum to the British Legion village, whilst at the same time increasing the scope of the industries pari passu with the extension of the housing accommodation. What the ultimate size of the village would be no one can say. It might be better to have two villages, as at Papworth and Enham, each being steered on a similar course under a unified administration. But, so far as Preston Hall is concerned, I take the view that, the fundamentals having been established, the experimental stage having been passed, the industrial position having been made relatively stable, the British Legion must now ask for further assistance to come from local authorities and the Ministry of Health. The work of the British Legion for tuberculous ex-Service men at Preston Hall is merely one, and quite a small part, of the main functions of the British Legion; to expand Preston Hall indefinitely out of Poppy-day funds for the benefit of one class of disabled ex-Service men would not be in keeping with the professed ideals of the British Legion which has a much wider field to explore.

Suggested Scheme of Coöperation with Local Authorities

In a memorandum which I recently submitted to the council of management of Preston Hall, it was pointed out that at the present moment no fewer than 152 ex-patients are in residence in the British Legion village; 124 of these are living in houses in the village with their wives and families. The majority of these men, but for the scheme, would have returned to their local authorities and would have been reintroduced into the vicious cycle which we know only too well. The council of management of Preston Hall are of the opinion that at least one of the ways in which local authorities may become identified with settlement work is by coöperating on the medical side with existing settlements. I am advised that it would be impossible for local authorities to build houses with their own capital at Preston Hall, and to furnish a proportion of the capital

PNEUMOCOCCAL INFECTIONS *

By Robert Cruickshank, M.D. Aberd., D.P.H.

LECTURER IN BACTERIOLOGY, THE UNIVERSITY AND ROYAL INFIRMARY, GLASGOW; BACTERIOLOGIST TO GLASGOW ROYAL INFIRMARY

I.—LOBAR PNEUMONIA IN THE INDIVIDUAL †

The apologia for my subject is twofold. The continued prevalence of bacterial diseases disseminated by spray or droplet infection from the respiratory tract is in itself sufficient justification for bringing to your notice the group of respiratory infections—lobar pneumonia, broncho-pneumonia, and bronchitis—the most common cause of which is the pneumococcus. The need for a re-orientation in our methods of dealing with respiratory tract infections as well as a concentration of attack on this formidable group which includes measles, whooping-cough, scarlet fever, and diphtheria, is becoming generally realised by medical officers of health. In pneumonia even a cursory consideration reveals a complicated problem. Although "acute primary pneumonia" is a notifiable disease, there is no provision under the Act for a clinical separation of lobar from broncho-pneumonia, all pneumonias are not caused by the same organism, and even among pneumococcal pneumonias there are numerous different infecting types. It follows that the established facts about pneumococcal lobar pneumonia as a specific infection are still scanty and we cannot hope to diminish its incidence without an accurate knowledge of its behaviour.

The second reason is a corollary of the first but is more intimate. Three years ago an investigation into the value of the serum treatment of pneumonia was commenced in the Glasgow Royal Infirmary, with the financial assistance of the Scottish Branch of the British Red Cross Society, and has now developed into a large scale research into the clinical, bacteriological, and epidemiological aspects of the disease, in several hospitals, through the kindly coöperation of the medical officer of health, Dr. A. S. M. Macgregor. It cannot be too strongly emphasised that the investigation is the work of a team; indeed, work of this kind can only hope to be fruitful through the active coöperation of clinician, bacteriologist, and epidemiologist. Although the data so far collected are largely corroborative of results obtained elsewhere, there are not, so far as we are aware, comparable findings in our country, so that our data may be useful as a standard for comparison when similar investigations are instituted, as we hope they will be, in various centres in Britain. In these lectures I shall utilise material, including 1215 serologically typed cases of lobar pneumonia, collected between February, 1930, and September, 1932, and shall discuss in turn Lobar Pneumonia in the Individual, Lobar Pneumonia in the Community, and Broncho-pneumonia and other Pneumococcal Infections. It is obviously impossible in the compass of three lectures to review the enormous literature on pneumococcal infections. While, therefore, a certain orderly arrangement and sequence of facts will be attempted, greater prominence will be given to those aspects of the problem with which our own investigations have been concerned.

In considering any specific bacterial infection in the individual there are certain questions to which we expect answers. Of the bacteriologist we ask "What is the organism?" and "How does it affect the individual?"; of the physician we ask, "What is the patient's response to infection?"; of the immunologist, "How is the infection overcome?"; and of the therapeutist, "Is there a specific antidote?" When these questions are applied to lobar pneumonia, it will be seen how inadequate are some of the answers.

What is the Organism?

The pneumococcus is related to the large family of streptococcus. Its distinguishing characters are the possession of a capsule, ready autolysis best exemplified by its solubility in bile, and its very high pathogenicity for the mouse. Of these three tests of identity, bile-solubility is the only absolute one and should never be omitted. The high pathogenicity for mice is most useful in isolating the pneumococcus from sputum or other sources where there is a mixture of organisms. But the most important biological character of the pneumococcus is its possession of a capsule. Neufeld and Händel (1909) first discovered that pneumococcal strains are not all serologically identical. In 1913 Dochez and Gillespie, of the Rockefeller Institute, and F. S. Lister, of the South African Institute of Medical Research, independently, and by quite different methods, showed that there was a number of strictly specific pneumococcal strains responsible for lobar pneumonia. The Americans labelled their most common infecting Types I., II., III., and recognised in addition a heterogeneous Group IV., while Lister named his most frequent types A, B, C, &c. It was subsequently shown that C, B, and E corresponded respectively with the American Types I., II., and III., whereas A, the most common type in South Africa, was not identified with any of the American strains. The next step was the demonstration by Dochez and Avery (1917) that the pneumococcus parted, during the active stage of growth in vitro and during infection in vivo, with a soluble substance which was specific for each type and which was apparently associated with the capsule of the organism. Heidelberger and Avery (1923) in a chemical analysis found the specific soluble substance (S.S.S.) to be of carbohydrate nature and—a discovery of greater import—the chemical constitution of the S.S.S. from the three serological Types I., II., and III. was distinctive for each type. Griffith (1923) showed that the pneumococcus may by various methods be wholly deprived of its capsule and become a rough or R strain; it then no longer belongs to a specific type and all R strains are antigenically identical

---

* *Acknowledgments.*—My first debt is to clinical and public health colleagues: in the Royal Infirmary, Drs. John Cowan, A. W. Harrington, and J. Fleming; at Woodilee Hospital, Dr. J. McLeod; at Ruchill Hospital, Dr. T. Anderson; at Knightswood Hospital, Dr. I. M. Christie; at the Royal Hospital for Sick Children, Prof. G. B. Fleming and Dr. J. W. S. Blacklock; and in the Sanitary Chambers, Dr. A. S. M. Macgregor, medical officer of health, and his statistical staff. The bulk of the cases of lobar pneumonia analysed in these lectures have been admitted to Belvidere Hospital, largely under the care of Dr. J. Montgomery, with whom I have collaborated during the past three years. To him especially I am indebted for his most careful clinical examination of the cases, without which such work as this would be valueless. Much of the technical work in the laboratory has been done by my laboratory assistant, Mr. D. B. Colquhoun. I have to thank Prof. C. H. Browning, Dr. Cowan, and Dr. Macgregor for revision of the text and for much valuable advice and criticism. The Medical Research Council have given me financial assistance and also encouragement throughout the investigation.

† The first Milroy lecture for 1933 delivered before the Royal College of Physicians of London on Feb. 23rd.

in foods. The antimony oxides disseminated throughout the enamel are thus exposed to the action of these acids and any trioxide present goes into solution."

ANGER IN CHILDREN

A COMPREHENSIVE study of the outstanding response in behaviour of both normal and abnormal children which reaches us from America[1] may be of little practical value to those in daily contact with difficult children. But Prof. Goodenough's inquiry provides useful data on the type of child-reaction which may become a problem in certain circumstances. The study was so arranged that the qualifications of the observers could be established and the conditions of observation rigidly adhered to. It was necessary at the outset to define the types of emotional response in children in order that the specific anger response could be defined and its field of operation determined. Age- and sex-incidence is considered as well as frequency, duration, and occasion. No moment in the life of the child was left unconsidered in relation to anger —i.e., sleep, enuresis, physical conditions, and everyday hygiene and habits. Thus all basic occasions for outbursts were studied in order that family and group factors could be given their proper weight. Pædiatricians and child psychiatrists will find the chapter on methods of control of some assistance. It is here, however, that the complexity and variability of the reaction is driven home to us. For however behaviourism may clarify our understanding of emotional response by simple statement of problems in terms of stimulus and response, the parent-child relationship in which, and through which, anger is most frequently expressed, is more complicated than the laboratory method makes it appear. Anger is an end-result and even then is a part of a tangled skein of emotions, the causes of which lie in the mixed feelings of the child towards its parents. The examples are more simple and convincing than most of those we meet with in practice.

Appointments

BLIGH, J. M., M.D., Ch.B. Liverp., has been appointed Medical Referee under the Workmen's Compensation Act for Liverpool County Court District.

COPEMAN, W. S. C., M.B., M.R.C.P. Lond., Assistant Physician (with charge of children), West London Hospital.

ELLIS, GWYNETH N., House Surgeon, Royal Hospital for Children, Bradford.

HARRIS, K. E., M.D., M.R.C.P. Lond., Physician to Out-patients, Royal Chest Hospital, City-road.

Putney Hospital: CROOK, E. A., M.Ch.Oxf., F.R.C.S. Eng., and MASSIE, G., M.S. Lond., F.R.C.S. Eng., Surgeons.

Vacancies

For further information refer to the advertisement columns

Aberdeen University.—Lecturer in Medicine. £400.

Aylesbury, Buckinghamshire County Council.—Asst. County M.O.H. and M.O.H. £800.

Barnstaple, North Devon Infirmary.—Res. M.O. At rate of £150.

Brighton, Royal Sussex County Hospital.—Cas. H.S. £120.

Burden Mental Research Trust, B.M.A. House, Tavistock-square, W.C.—Principal Investigator. £750.

Burnley Municipal Hospital.—Jun. Res. M.O. £150.

Bury Infirmary.—H.S. to Special Depts. At rate of £175.

Durham County Hospital.—H.S. £150.

East Ham Memorial Hospital, Shrewsbury-road, E.—H.P. At rate of £150. Also H.S. and Cas. O. At rate of £120.

Edinburgh City, Public Health Dept.—Sen. Asst. M.O. £600.

Evelina Hospital for Sick Children, Southwark, S.E.—Hon. Physician to the Skin Dept. Also H.S. At rate of £120.

Greenwich, Dreadnought Hospital.—H.P. and H.S. Each at rate of £110.

Hampstead General and N.W. London Hospital, Haverstock-hill, N.W.—Cas. Surg. O. for Out-patient Dept., Bayham-street. At rate of £100.

Harrogate, Royal Bath Hospital.—Res. M.O. At rate of £156.

Hospital of St. John and St. Elizabeth, 60, Grove End-road, N.W. Res. H.S. At rate of £75.

Hospital for Tropical Diseases, Endsleigh-gardens, W.C.—H.P. At rate of £120.

Hove Hospital, Sussex.—Res. M.O. £200.

Ilford, King George Hospital.—Hon. Surgeon.

Ipswich, East Suffolk and Ipswich Hospital.—H.S. £120.

Leeds, Herzl Moser Hospital, Leopold-street.—R.M.O. £200.

Leicester Royal Infirmary.—Two Cas. H.S.'s. Each £125.

Liverpool, Mill-road Infirmary.—Med. Supt. £1000.

Liverpool, Royal Southern Hospital.—Orthopædic H.S. Also M.O. to Special Depts. and Res. Anæsthetist. Each at rate of £60.

L.C.[illegible]

Lon[illegible] Dept. £400. Hon. Asst. Surgeon. [illegible] Reg. to Ear, Nose and Throat Dept. £150.

London Lock Hospital, 283, Harrow-road, W.—Res. M.O. At rate of £175. Also Surg. Reg. £100.

London Lock Hospital, 91, Dean-street, W.—Res. M.O. At rate of £175.

Manchester, Ancoats Hospital.—Res. Surg. O. £200. Also Orthopædic H.S. At rate of £100.

Manchester Ear Hospital, Grosvenor-square, All Saints.—Res. H.S. £120.

Manchester Hospital for Consumption, &c.—Asst. M.O. for Crossley Sanatorium. £200.

Manchester, St. Mary's Hospitals.—Res. Surg. O. for High-street Hospital. £175. Also Two H.S.'s for Whitworth-street West Hospital. Each at rate of £50.

Manchester, Victoria Memorial Jewish Hospital.—Res. Surg. O. £200. Also Jun. H.S. and Res. M.O. Each at rate of £125.

Manchester, Withington Hospital.—Asst. M.O. £300.

Miller General Hospital, Greenwich-road, S.E.—H.P. £100.

Ministry of Health, Whitehall, S.W.—Vacancy on Medical Staff. £833.

Mitcham U.D.C.—Part-time M.O. At rate of £300.

Newcastle-upon-Tyne, Hospital for Sick Children.—H.P. Also Sen. and Jun. H.S. Each at rate of £100.

Newcastle-upon-Tyne, Royal Victoria Infirmary.—Hon. Physician.

Northwood, Mount Vernon Hospital.—Res. M.O. £250. Also Asst. for Radio-therapeutic Dept.

[illegible] *Hospital.*—H.P. At rate of £150.

[illegible] *ary.*—H.S. At rate of £175.

[illegible] *Harrow-road, W.*—M.O. £325.

Princess Beatrice Hospital, Richmond-road, Earl's Court, S.W.—Res. M.O. At rate of £110.

Princess Elizabeth of York Hospital for Children, Shadwell, E.—H.P. and Cas. O. Each £125.

Princess Louise Kensington Hospital for Children, St. Quintin-avenue, N. Kensington, W.—H.S. At rate of £75. Also Hon. Anæsthetist.

Queen Charlotte's Maternity Hospital, Marylebone-road, N.W. Asst. to Pædiatrician and M.O. to Infant Consultation Centre. 1½ gns. per Clinic.

Royal National Orthopædic Hospital, 234, Great Portland-street, W.—H.S. At rate of £150.

St. Leonards-on-Sea, Buchanan Hospital.—Sen. and Jun. H.S. At rate of £175 and £125 respectively.

St. Mary's Hospital, W.—Cas. H.S. At rate of £100.

St. Paul's Hospital for Diseases of the Genito-Urinary Organs and Skin, Endell-street, Holborn, W.C.—H.S. At rate of £150.

[illegible] *Bloemfontein.*—Radiologist. £900.

[illegible] *pital.*—Second H.S. £100.

[illegible] *Vomen, Clapham-common, S.W.*—H.P. and H.S. Each at rate of £100.

South Shields, Ingham Infirmary.—Jun. H.S. £150.

Stoke-on-Trent, North Staffordshire Royal Infirmary, Hartshill.—Asst. Hon. Surgeon.

Swansea General and Eye Hospital.—H.P. At rate of £140.

Wakefield, West Riding Mental Hospital.—Asst. M.O. £350.

Watford, Herts, Peace Memorial Hospital.—Two Res. Officers. Each at rate of £150.

West Bromwich and District General Hospital.—H.P. and Two Cas. H.S.'s. Each at rate of £200.

West London Hospital, Hammersmith-road, W.—H.P. Two H.S.'s to Spec. Depts. Also Res. Anæsthetist. Each at rate of £100.

Willesden General Hospital, N.W.—Res. Cas. O. At rate of £100.

Winchester, Royal Hampshire County Hospital.—H.P. At rate of £125.

Windsor, King Edward VII Hospital.—H.S. At rate of £100.

The Chief Inspector of [illegible] appointments for Certifyin[illegible] ixworth, Northampton; and

The Secretary of State fo[illegible]s notice that he is considering [illegible] Referee or Referees under th[illegible] Act for [illegible] Court Districts: West London [illegible]on and Wood Green, Romford [illegible], Bow (Circuit No. 40), Willesden [illegible] Abbey (Circuit No. 56). Appli[illegible] Private Secretary, Home Office, not later than March 29th.

Vacancies are also announced at Halifax County Court District at Fort William Sheriff Court District (Argyll, &c.); and at Lochmaddy and Portree Sheriff Court Districts (Inverness, &c.).

Births, Marriages, and Deaths

BIRTHS

BEARE.—On Feb. 27th, at Deepdene Park-road, Dorking, the wife of C. E. Beare, M.B., F.R.C.S., of a daughter.

ADDRESSES AND ORIGINAL ARTICLES

PNEUMOCOCCAL INFECTIONS[*]

By Robert Cruickshank, M.D. Aberd., D.P.H.

LECTURER IN BACTERIOLOGY, THE UNIVERSITY AND ROYAL INFIRMARY, GLASGOW; BACTERIOLOGIST TO GLASGOW ROYAL INFIRMARY

I.—LOBAR PNEUMONIA IN THE INDIVIDUAL[†]

The apologia for my subject is twofold. The continued prevalence of bacterial diseases disseminated by spray or droplet infection from the respiratory tract is in itself sufficient justification for bringing to your notice the group of respiratory infections—lobar pneumonia, broncho-pneumonia, and bronchitis—the most common cause of which is the pneumococcus. The need for a re-orientation in our methods of dealing with respiratory tract infections as well as a concentration of attack on this formidable group which includes measles, whooping-cough, scarlet fever, and diphtheria, is becoming generally realised by medical officers of health. In pneumonia even a cursory consideration reveals a complicated problem. Although "acute primary pneumonia" is a notifiable disease, there is no provision under the Act for a clinical separation of lobar from broncho-pneumonia, all pneumonias are not caused by the same organism, and even among pneumococcal pneumonias there are numerous different infecting types. It follows that the established facts about pneumococcal lobar pneumonia as a specific infection are still scanty and we cannot hope to diminish its incidence without an accurate knowledge of its behaviour.

The second reason is a corollary of the first but is more intimate. Three years ago an investigation into the value of the serum treatment of pneumonia was commenced in the Glasgow Royal Infirmary, with the financial assistance of the Scottish Branch of the British Red Cross Society, and has now developed into a large scale research into the clinical, bacteriological, and epidemiological aspects of the disease, in several hospitals, through the kindly coöperation of the medical officer of health, Dr. A. S. M. Macgregor. It cannot be too strongly emphasised that the investigation is the work of a team; indeed, work of this kind can only hope to be fruitful through the active coöperation of clinician, bacteriologist, and epidemiologist. Although the data so far collected are largely corroborative of results obtained elsewhere, there are not, so far as we are aware, comparable findings in our country, so that our data may be useful as a standard for comparison when similar investigations are instituted, as we hope they will be, in various centres in Britain. In these lectures I shall utilise material, including 1215 serologically typed cases of lobar pneumonia, collected between February, 1930, and September, 1932, and shall discuss in turn Lobar Pneumonia in the Individual, Lobar Pneumonia in the Community, and Broncho-pneumonia and other Pneumococcal Infections. It is obviously impossible in the compass of three lectures to review the enormous literature on pneumococcal infections. While, therefore, a certain orderly arrangement and sequence of facts will be attempted, greater prominence will be given to those aspects of the problem with which our own investigations have been concerned.

In considering any specific bacterial infection in the individual there are certain questions to which we expect answers. Of the bacteriologist we ask "What is the organism?" and "How does it affect the individual?"; of the physician we ask, "What is the patient's response to infection?"; of the immunologist, "How is the infection overcome?"; and of the therapeutist, "Is there a specific antidote?" When these questions are applied to lobar pneumonia, it will be seen how inadequate are some of the answers.

What is the Organism?

The pneumococcus is related to the large family of streptococcus. Its distinguishing characters are the possession of a capsule, ready autolysis best exemplified by its solubility in bile, and its very high pathogenicity for the mouse. Of these three tests of identity, bile-solubility is the only absolute one and should never be omitted. The high pathogenicity for mice is most useful in isolating the pneumococcus from sputum or other sources where there is a mixture of organisms. But the most important biological character of the pneumococcus is its possession of a capsule. Neufeld and Händel (1909) first discovered that pneumococcal strains are not all serologically identical. In 1913 Dochez and Gillespie, of the Rockefeller Institute, and F. S. Lister, of the South African Institute of Medical Research, independently, and by quite different methods, showed that there was a number of strictly specific pneumococcal strains responsible for lobar pneumonia. The Americans labelled their most common infecting Types I., II., III., and recognised in addition a heterogeneous Group IV., while Lister named his most frequent types A, B, C, &c. It was subsequently shown that C, B, and E corresponded respectively with the American Types I., II., and III., whereas A, the most common type in South Africa, was not identified with any of the American strains. The next step was the demonstration by Dochez and Avery (1917) that the pneumococcus parted, during the active stage of growth in vitro and during infection in vivo, with a soluble substance which was specific for each type and which was apparently associated with the capsule of the organism. Heidelberger and Avery (1923) in a chemical analysis found the specific soluble substance (S.S.S.) to be of carbohydrate nature and—a discovery of greater import—the chemical constitution of the S.S.S. from the three serological Types I., II., and III. was distinctive for each type. Griffith (1923) showed that the pneumococcus may by various methods be wholly deprived of its capsule and become a rough or R strain; it then no longer belongs to a specific type and all R strains are antigenically identical in foods. The antimony oxides disseminated throughout the enamel are thus exposed to the action of these acids and any trioxide present goes into solution."

---

[*] *Acknowledgments.*—My first debt is to clinical and public health colleagues: in the Royal Infirmary, Drs. John Cowan, A. W. Harrington, and J. Fleming; at Woodilee Hospital, Dr. J. McLeod; at Ruchill Hospital, Dr. T. Anderson; at Knightswood Hospital, Dr. I. M. Christie; at the Royal Hospital for Sick Children, Prof. G. B. Fleming and Dr. J. W. S. Blacklock; and in the Sanitary Chambers, Dr. A. S. M. Macgregor, medical officer of health, and his statistical staff. The bulk of the cases of lobar pneumonia analysed in these lectures have been admitted to Belvidere Hospital, largely under the care of Dr. J. Montgomery, with whom I have collaborated during the past three years. To him especially I am indebted for his most careful clinical examination of the cases, without which such work as this would be valueless. Much of the technical work in the laboratory has been done by my laboratory assistant, Mr. D. B. Colquhoun. I have to thank Prof. C. H. Browning, Dr. Cowan, and Dr. Macgregor for revision of the text and for much valuable advice and criticism. The Medical Research Council have given me financial assistance and also encouragement throughout the investigation.

[†] The first Milroy lecture for 1933 delivered before the Royal College of Physicians of London on Feb. 23rd.

ANGER IN CHILDREN

A COMPREHENSIVE study of the outstanding response in behaviour of both normal and abnormal children which reaches us from America [1] may be of little practical value to those in daily contact with difficult children. But Prof. Goodenough's inquiry provides useful data on the type of child-reaction which may become a problem in certain circumstances. The study was so arranged that the qualifications of the observers could be established and the conditions of observation rigidly adhered to. It was necessary at the outset to define the types of emotional response in children in order that the specific anger response could be defined and its field of operation determined. Age- and sex-incidence is considered as well as frequency, duration, and occasion. No moment in the life of the child was left unconsidered in relation to anger—i.e., sleep, enuresis, physical conditions, and everyday hygiene and habits. Thus all basic occasions for outbursts were studied in order that family and group factors could be given their proper weight. Pædiatricians and child psychiatrists will find the chapter on methods of control of some assistance. It is here, however, that the complexity and variability of the reaction is driven home to us. For however behaviourism may clarify our understanding of emotional response by simple statement of problems in terms of stimulus and response, the parent-child relationship in which, and through which, anger is most frequently expressed. is more complicated than the laboratory method makes it appear. Anger is an end-result and even then is a part of a tangled skein of emotions, the causes of which lie in the mixed feelings of the child towards its parents. The examples are more simple and convincing than most of those we meet with in practice.

The Chief Inspector of Factories announces vacant appointments for Certifying Factory Surgeons at Brixworth, Northampton; and Heckington, Lincoln.

The Secretary of State for the Home Department gives notice that he is considering th [illegible] l Referee [illegible] Act for [illegible] London [illegible] Romford [illegible] Willesden [illegible] Appli- [illegible] vate Secretary, Home Office, Whitehall, London, S.W., not later than March 29th.

Vacancies are also announced at Halifax County Court District at Fort William Sheriff Court District (Argyll, &c.); and at Lochmaddy and Portree Sheriff Court Districts (Inverness, &c.).

Births, Marriages, and Deaths

BIRTHS

BEARE.—On Feb. 27th, at Deepdene Park-road, Dorking, the wife of C. E. Beare, M.B., F.R.C.S., of a daughter.

ROBERTSON.—On March 3rd, at Southgate-street, Winchester, the wife of Dr. Robertson, of a son.

DEATHS

HOBHOUSE.—On March 2nd, at Grosvenor-hill, S.W., Edmund Hobhouse, M.D., F.R.C.P., aged 72.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths there has not yet been demonstrated any specific exo- or endo-toxin of the pneumococcus. How then is the obvious intoxication to be explained? If we examine first the experimental evidence, one thing is certain: the pneumococcus is only virulent for laboratory animals when it has a well-developed capsule around it. If the capsule is removed, or if the organism is allowed to disintegrate, virulence disappears. It would seem therefore as if the poison resided in the capsular substance or S.S.S. Toxins as we ordinarily know them are of protein constitution, can produce their lethal effect though separated from the parent organism, and their toxicity is destroyed by heat. S.S.S. is a carbohydrate substance unaffected by heat and injected by itself is absolutely harmless to the mouse or rabbit, animals highly susceptible to the pneumococcus. However, although it is not antigenic, it has the property of combining specifically with pneumococcus antibodies. In an experimental inqury Robertson and Sia (1927) have shown that animals, such as cat, dog, horse, which are resistant to pneumococcal infection, are so in virtue of natural opsonin. Further, if S.S.S. be added to a mixture of fresh unheated animal serum, plus the homologous avirulent pneumococcus, the latter will be enabled to multiply (Sia, 1926)—i.e., S.S.S. has the power of neutralising opsonin, a natural protector against infection. Incidentally, it must not be thought that the pneumococcus is unique in not having any demonstrable toxin. An example of the same phenomenon among capsulated organisms is afforded by the anthrax bacillus, and it is now known that numerous non-capsulated organisms are also endowed with specific soluble substances—for example, meningococcus, Shiga dysentery bacillus, streptococcus, leptospiræ.

---

[1] Anger Responses in Young Children. By Florence L. Goodenough, professor in the Institute of Child Welfare, University of Minnesota. University of Minnesota Press Monograph. No. IX. Minneapolis. 1932. Pp. 278. 14*s.* 6*d.*

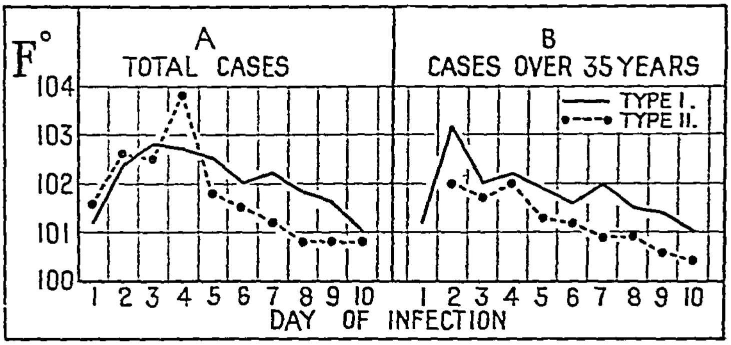

FIG. 3.—Composite temperature charts of Type I. and Type II. infections (each 100 cases).

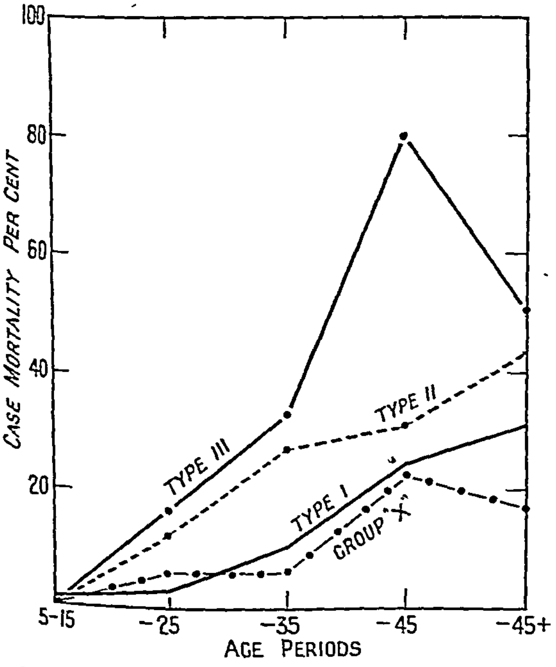

FIG. 2.—Mortality of types of pneumococcal infection in various age-groups.

Regarding the clinical evidence, it is worth while recording first the findings of the earlier workers. Eyre (1909), in an examination of the opsonic index in cases of lobar pneumonia, found that after an initial low period there was a gradual rise during the fifth, sixth, and seventh days in the cases that recovered reaching a maximum at or soon after crisis; the rise was closely paralleled by a rise in the leucocyte count. Lister based his initial observations regarding the specificity of pneumococcal types on the development of specific opsonins in the infected individual, immediately prior to the critical fall of temperature. There was no evidence of opsonin in the blood of fatal cases. Sia et al. (1928) have recently attacked the problem from a similar aspect and have demonstrated the importance of opsonin as well as agglutinin and pneumococcocidal power in the process of recovery. It will be remembered that in their animal experiments opsonin was neutralised by S.S.S. It is true of course that opsonin is only one of the elements in the complex substance known as antibody, but it is also true that it is directly responsible for sensitising the organism for attack by the leucocytes and the leucocytes play an important part in the fight against pneumococcal infection. S.S.S., therefore, may or may not be directly toxic to the cells of the host, but at least it is a powerful antiphagocytic agent and must play a large part in pneumococcal infection. Dochez and Avery have recovered it in the blood and urine of infected persons. Among 88 cases of lobar pneumonia it was present in the urine of 55, of whom 20 died (36·4 per cent.), while it was absent from the urine of 33, of whom 2 died (6 per cent.).

What is the Patient's Response?

The severity of infection in an individual suffering from pneumococcal lobar pneumonia depends largely on the age of the individual and the type of infecting pneumococcus. I shall consider only the influence of the pneumococcal type at this point. My clinical colleagues were early impressed by certain differences in the response of patients suffering from Types I. and II. pneumococcal pneumonia, and in 1931 we communicated some of our observations (Cruickshank, Fleming, and Montgomery). The death-rate from Types I., II., and III. pneumococcal pneumonia in our series of 1118 non-serum-treated cases was respectively 10·8, 21·5, and 40·9 per cent., and the same difference in mortality from the three types is evident when similar age-groups are contrasted (Fig. 2). An analysis was therefore made of certain clinical and laboratory findings in Types I., II., and III. pneumonia in an attempt to find how far these phenomena would help to explain the differences in the severity and mortality of these infections. There

(Reimann, 1925). The present conception then of the pneumococcus is of an organism with a protein nucleus common to the species surrounded by a carbohydrate envelope which, because of the differences in its chemical constitution, confers specificity upon the pneumococcus and divides the strains into a number of distinct serological types. So far, 32 such types have been separated by serological tests.

Besides a *qualitative* difference there is also a *quantitative* difference in the capsular substance of the three most common Types, I., II., and III. This difference is readily appreciable with Type III. pneumococcus which has a voluminous capsule and a spreading mucoid colony. The distinction between Types I. and II. is less evident. Avery et al. (1917) state that "in Type II. pneumococci the capsules are generally somewhat larger and denser than in Type I." We have stained many preparations by different methods of capsular staining, but have found it difficult to differentiate between Types I. and II. pneumococci in this way. We have been impressed, however, by differences in the size and appearance of the colonies of Types I., II., and III. pneumococci growing on artificial culture media. Examination under the microscope of young growing colonies (four to eight hours) has shown a definite difference in the colonial "texture" of each type, that of Type I. being most compact, of Type II. less close, and of Type III. a still looser texture, indicating, I think, a difference in the amount of capsular substance round each organism, so that the bigger the capsule the looser the texture of the colony (Fig. 1). There are other methods of demonstrating this quantitative difference if we accept the view that the capsule is intimately associated with the production of S.S.S. Dochez and Avery (1917), for example, found that in young broth cultures, S.S.S. was first demonstrable for Type III. pneumococcus, then for Type II., and lastly, for Type I., while Blake (1917) by inoculating separate mice with equal amounts of culture of Types I., II., and III. pneumococci showed that precipitinogen, presumably S.S.S., was demonstrable in the peritoneal exudate of Type III. mouse in five hours, of Type II. mouse in six hours, and of Type I. mouse in seven hours. Sufficient multiplication of the organisms to demonstrate agglutination did not occur in any case until eight hours after inoculation. I stress this quantitative difference in the S.S.S. as later I hope to show its relation to the intoxication and mortality in pneumonia.

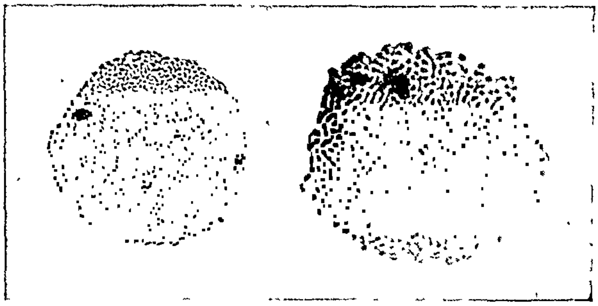

FIG. 1.—Six-hour colonies of pneumococci on serum agar showing closer texture of Type I. (on left) compared with Type II.

How Does the Organism Affect the Individual?

The mechanism of *infection*—how and where the organism penetrates the body's first line of defences, and how it is carried to its elective organ and tissue has not received from pathologists the attention it deserves. In pneumonia there are three obvious routes by which the pneumococcus may reach the lung—the air-passages, the peritracheal and peribronchial lymphatics, or the blood stream. The spread of infection along the bronchial mucous membrane does not, I think, occur in lobar pneumonia. The idea of a primary septicæmia or bacteriæmia with subsequent localisation in the lung appeals particularly to the clinician (see Kidd, 1912) who is impressed by the sudden onset of the infection frequently with rigor and profound toxæmia, and the finding of the pneumococcus in the blood within the first 24 hours of infection. In our own series the pneumococcus was recovered in two of six patients on whom blood culture was done within one day of the clinical onset of infection. In another patient blood culture happened to be done twice on the day before infection and again within 12 hours of the onset of fever, each time with negative result. On the fifth of the pneumonia Type II. pneumococcus was recovered from the blood.† A lymphogenous infection receives most support from the experimental production of pneumonia in monkeys (Blake and Cecil, 1920). These workers produced lobar pneumonia in 32 out of 37 freshly imported monkeys (*Macacus syrichtus* and *Cebus capucinus*) by intratracheal inoculation of highly virulent Types I., II., and III. pneumococci, whereas subcutaneous or intravenous inoculation resulted in a generalised infection without localisation in the lung. Inoculation into the nose or throat failed to produce any infection. In an examination of the pathology of the experimentally produced pneumonias, Blake and Cecil (1920) found that the pneumococcus first penetrated the walls of the larger bronchi at or near the hilum and that spread of the organism in the pulmonary tissue occurred primarily by way of the perivascular, peribronchial, and septal interstitial tissue and lymphatics, quickly reaching the pleura. Hepatisation began centrally and spread towards the periphery. It must in fairness be stated that other workers (e.g., McLeod and Gordon, see McLeod, 1929) have failed with monkeys to produce experimental lobar pneumonia by intratracheal inoculation.

The most probable explanation of the mechanism of infection then is of an early penetration of the tracheal or bronchial mucosa by the pneumococcus, a lymphatic spread to the lung root and a rapid lobar invasion of the susceptible lung tissue. "Spilling over" of the organisms into the blood stream may occur at any time during the first four to five days of infection, disappearing in patients that recover, but often becoming a true septicæmia in the fatal cases. In 330 patients in our series on whom blood culture was done only on the day of admission, there were 33 per cent. (two out of six) positive on the first day, 28 per cent. on the second day, 42 per cent. on the third day, 22 per cent. on the fourth day, and 15 per cent. on the fifth day; in 24 post-mortem examinations the pneumococcus was recovered from the spleen as well as from the lung in all but one case.

The consolidation of part of the lung leads to respiratory embarrassment, cyanosis, and anoxæmia, and while the mechanism of their production may be complex and still imperfectly understood, these phenomena are at least explicable on physiological grounds. There is, in addition, a varying degree of toxæmia or intoxication and the prognosis of the case depends as much on the severity of the toxæmia as on the degree of cyanosis or anoxæmia. But in spite of many attempts and occasional claims,

---

† I am indebted to Dr. D. M. Hart, Glasgow Royal Maternity Hospital, for the record of this case.

Our experience of Type III. pneumonia is small. Blake (1931) has recently stated that Type III. pneumococcus is a less virulent organism than is generally supposed, the high mortality being due to its attack on older and debilitated individuals—e.g., over 50 per cent. of his 116 cases as compared with 20 and 30 per cent. for Types I. and II. infections were over the age of 40. Our figures in a smaller series of 41 cases agree with his findings, 56 per cent. of Type III. and only 28 and 36 per cent. of Types I. and II. pneumonias being over the age of 35. But while Type III. pneumococcus is less invasive, it is not in our experience less virulent, as at all age-groups the mortality-rate was higher than that of any other Type (see Fig. 2).

In explanation, therefore, of the difference in the severity and mortality of Types I., II., and III. pneumonia it is suggested that the important factor is the amount of S.S.S. elaborated. Type I. pneumococcus, although highly invasive, produces the least amount of S.S.S. and the patient responds briskly to the infection, by high temperature usually falling by crisis, high leucocytosis, and a moderate or mild degree of toxæmia—in fact the classical picture of lobar pneumonia. Type II. pneumococcus, elaborating more S.S.S., produces, particularly in patients over 35 years of age, a much more severe infection; the patient is more toxic and less reactive. Type III. pneumococcus, although it produces most S.S.S., has little invasive power, and is therefore a rare cause of lobar pneumonia, but infection when it occurs is usually very severe and often fatal.

An analysis of 60 cases of Group "X" pneumonia shows that the infection occurs more in the young than in the old, the pneumonia is quite a typical one with temperature maintained around 102° to 103° F., the infection is often mild and terminates frequently by lysis (63 per cent. in the series).

How is the Infection Overcome?

The varying duration of the fever in different infections has never been satisfactorily explained. Why should typhoid fever continue for 3 to 4 weeks, typhus for 12 days, erysipelas 7 to 8 days, and undulant fever for months perhaps? In this respect primary pneumococcal pneumonia is a specific infection which differs in some degree from streptococcal or staphylococcal or influenzal pneumonia (Cole, 1928). The mechanism of the critical fall of temperature in lobar pneumonia has been variously explained. McLeod (1929) who has recently discussed the matter is inclined to attribute considerable importance to the local processes in the lung in causing the death of the pneumococcus. We have repeated many observations of English and American workers, and have usually found that antibodies develop in the blood of the patient at or near crisis in those who recover and are absent in fatal cases. There have been exceptions—e.g., the finding of protective antibody in the presence of septicæmia and its absence until after the clinical crisis. In spite of these anomalies, the termination of the infection is probably due primarily to a general humoral antibody response. An analysis of the duration of infection supports this opinion. In 100 cases each of Types I. and II. pneumonia, and in 60 cases of Group "X" pneumonia, the duration of pyrexia was respectively 7·6, 7·7, and 7·5 days. When the duration of fever in cases under the age of 35 was compared with that of those over 35 it was found to be 7·4, 7·4, and 7·0, as against 8·4, 8·1, and 8·4 days. It seems obvious that the antibody mechanism responds more briskly and more quickly overcomes the infection in the young than in the old.

Another aspect of pneumococcal pneumonia which has been used as argument by those who do not believe that the general antibody reaction is responsible for arresting the infection is the tendency to repeated attacks. We have records of five instances of second attacks of pneumococcal lobar pneumonia at an interval of six months or more after the previous infection. In each case the second attack was due to a different serological type of pneumococcus from that of the first. In a sixth case a Group "X" pneumococcus was recovered both times and was not further differentiated. A seventh case seemed to be the exception to the rule. This patient was readmitted a year after an attack of Type II. pneumonia and again Type II. pneumococcus was recovered from his spit. Luckily for us, unluckily for the patient for he died, he developed an empyema from which a hæmolytic streptococcus was recovered. We had the further consolation of having proved this man to be a chronic carrier of Type II. pneumococcus during the period between his first and second attacks, and, of course, he was still harbouring the organism when he was readmitted. These second and third attacks serve, I think, to show the specificity of the pneumococcal infection and indicate not a lack of immunity to the infecting pneumococcus but a susceptibility to pneumonia. It may be remembered that Hedley Wright (1929) found a rabbit still resistant to Type I. pneumococcus ten months after a single injection of the same organism.

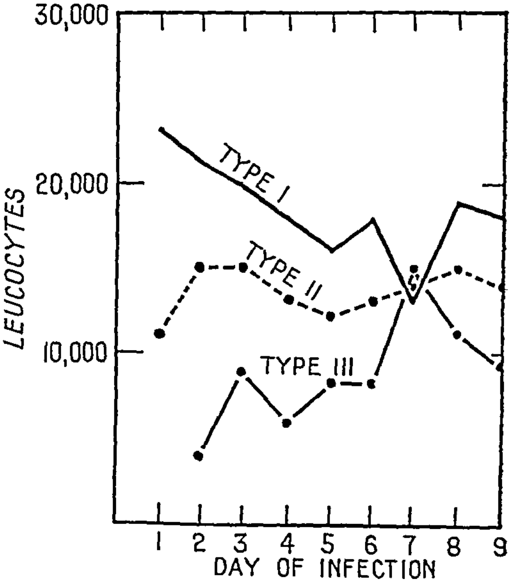

FIG. 4.—Leucocyte count in infection of the three types at various stages of the illness.

Is there a Specific Antidote?

The treatment of lobar pneumonia with antipneumococcal serum is no new development, and we owe much to American workers for their persistent efforts to make the treatment of pneumonia with specific antisera a practical possibility. Progress in recent years has been mainly concerned with the production of a refined and concentrated antiserum of high potency. The present obstacles to its wider use are its specificity which requires a bacteriological typing of the pneumonia, its expense and the need for intravenous medication, its doubtful value in pneumonia other than Type I. infection, and the difficulty of getting cases early for treatment when the serum is likely to be most effective. Let us deal were too few cases of Type III. pneumonia for it to be included in the full analysis.

(*a*) *Temperature.*—The highest recorded temperature on a four-hourly chart on each day of infection until temperature became normal was noted in each of 100 cases aged 15–70 of Types I. and II. pneumonia. The average temperature on each day for the 100 cases in each group and for the cases over and under 35 was calculated as was the number of pneumonias in each group terminating by crisis and by lysis (Fig. 3). A comparison of the composite charts shows that in Type I. pneumonia the temperature is maintained throughout the infection at a high level, usually above 102° F., whereas, in Type II. pneumonia, after an initial high temperature, evidence of a severe infection, the temperature gradually falls to a much lower level. The difference is accentuated if comparison is made between the groups over the age of 35 (Fig. 3). Although analysis of the pulse-rate was not made, it was noticed that in patients with Type II. pneumonia the pulse-rate did not so closely follow the fall in temperature as it did in Type I. infection. Critical fall in temperature occurred in 71 of the 100 Type I. pneumonias and in 52 of the Type II. cases.

(*b*) *Leucocyte count.*—The prognostic value of the leucocyte count in lobar pneumonia has long been recognised (Table I.). There is both in the natural infection and in the experimental pneumonia of monkeys a sharp initial rise in the numbers of leucocytes followed by a period of low count and a gradual increase towards crisis in the cases that recover. The only correlation of the leucocyte count with the infecting pneumococcal type which I can discover in the literature is that of Clough (1917) who, in 19 cases of Type I. pneumonia, found an average count of 24,000 and in 8 cases of Type III. pneumonia a count of 11,800. She had only 3 Type II. cases. In the present investigation Fleming has carried out daily leucocyte counts in practically all the cases of pneumonia coming into the Glasgow Royal Infirmary for serum treatment (Fig. 4). The effect of the serum, particularly in Type I. cases, is to bring the curve down more quickly, but the chart shows an appreciable difference in the average leucocyte counts of 45 cases of Type I., 32 cases of Type II., and 8 cases of Type III. pneumonia. There is obviously an antileucocytic substance acting most powerfully in Type III. pneumonia, less so in Type II. and least in Type I. infection.

TABLE I

Relation of Leucocytes to Mortality in Pneumonia
(Hospital of the Rockefeller Institute)

Leucocytes.	No. of cases.	Mortality per cent.
Under 10,000	29	65·5
10–20,000	163	23·7
20–30,000	177	18·0
30–40,000	76	14·0

(*c*) *Bacteriæmia.*—A positive blood culture in lobar pneumonia is generally interpreted as prejudicing the patient's chances of recovery—e.g., at the Hospital of the Rockefeller Institute, in 136 cases with positive blood culture, the mortality was 55·8 per cent., and in 312 cases with negative blood culture only 8·3 per cent., and in our own series of non-serum-treated cases 54 patients had positive blood culture with a death-rate of 44 per cent., whereas 184 cases with negative blood culture had a death-rate of 7·6 per cent. However, the prognostic significance of bacteriæmia varies considerably with the different types. Comparing first the proportion of positive blood cultures in lobar pneumonia due to Types I., II., and III. pneumococci (Table II.), we find that the bacteriæmia is actually most frequent in Type I., then in Type II. pneumonia, and least in Type III. pneumonia. Blake's (1931) figures in a recent paper on Type III. pneumonia were 21 positive blood cultures in 116 cases (= 16 per cent.). If we compare these figure with the death-rate ‡ of the different types in lobar pneumonia (Table II., col. 5) mortality would seem to vary inversely with bacteriæmia. Thus Type I. pneumococcus has a greater *invasiveness* and less toxigenicity than Types II. or III. pneumococci.

TABLE II

Relation of Bacteriæmia to Pneumococcal Type and to Mortality in Lobar Pneumonia

Institute.	Type.	No. of cases.	Positive.	Percentage positive.	Percentage mortality of +ve bl. culture.	General death-rate.
G.R.I. and Belvidere Hospital	I.	114	37	32·4	15·0	10·8
	II.	136	34	25·0	52·3	21·5
	III.	8	4	—	100·0	40·9
	Gr. X	71	9	12·6	66·6	8·6
Hospital of Rockefeller Institute.	I.	145	50	34·5	26·0	11·6*
	II.	148	49	33·1	73·4	28·5
	III.	55	16	29·0	100·0	43·0
	Gr. X	100	21	21·0	52·3	12·8

G.R.I. = Glasgow Royal Infirmary. Gr. = group.
* Mostly serum-treated.

If now the death-rate in the different pneumococcal types among those with positive blood culture is examined (Table II., col. 4) it is evident that whereas bacteriæmia is of little prognostic value in Type I. pneumonia, it has a grave significance in Types II., III., and Group "X" pneumonia. However, the absence of bacteriæmia when only one blood culture is done need not necessarily be of favourable import—e.g., of 12 deaths from Type I. pneumonia, 5 had a sterile culture, while 5 out of 17 deaths of Type II. pneumonia had no bacteriæmia. The value of blood culture is increased if daily counts are done (Avery et al. (1917), Sutton and Sevier (1917), Koch (1932)), although the number of organisms per c.cm. of blood which is to be regarded as the danger line is variously given from 5 to 20 by these authors. Blood culture is an essential procedure if only as a check, when positive, on serological typing from the sputum. But as a factor in prognosis, I feel it should not take precedence over the leucocyte count which has the additional asset of being a side-room test.

(*d*) *Toxæmia.*—The measurement of toxæmia must be left largely to the physician. My colleague, Dr. Montgomery, has made a clinical evaluation of toxæmia based on such phenomena as delirium, prostration, headache, incontinence, and pulse pressure. He found that there was no positive correlation between toxæmia and the amount of lung involved, or the degree of dyspnœa and cyanosis. There was some correlation with positive blood culture, with advancing age, and with a history of alcoholism or a positive Wassermann reaction. When correlated with the infecting type, the toxæmia was usually more severe in Type II. infections, the difference from Type I. being particularly noticeable in patients under the age of 35. Using S.S.S. as an indicator of toxæmia, Dochez and Avery found the specific substance present in the urine in 57, 71, and 70 per cent. respectively of cases of Types I., II., and III. pneumonia; of the positive cases, 10 per cent.§ of Type I., 50 per cent. of Type II., and 58 per cent. of Type III. pneumonias died.

---

‡ In this lecture, mortality-rate or death-rate means the case-mortality rate. § Mostly serum-treated.

EPIDEMIOLOGY APPLIED TO SCHOOL LIFE *

By J. A. H. Brincker, M.B., D.P.H. Camb.
PRINCIPAL MEDICAL OFFICER, PUBLIC HEALTH DEPARTMENT, LONDON COUNTY COUNCIL

Medicine has advanced considerably during our lifetime along certain lines—e.g., medical and surgical treatment—but progress has been slow and erratic in the prevention of infectious disease. We are using to-day practically the same methods of control as when bacteriology and the study of immunity were in their infancy ; the same procedure of notification, isolation, and disinfection as that to which our grandfathers pinned their faith. Yet there is no excuse. for epidemiology, whether statistical, experimental, or field study, has made great advances and we know to-day much more than we did of how infectious diseases are bred, how they behave, the conditions which help or hinder their spread, and how they can be prevented. As members of this association, we are responsible for the health and physical welfare of a number of young people, living a community life and therefore exposed to the forces which govern epidemics. On our study of the laws of epidemiology we have to base our rules for the control of infection in the schools.

Quarantine

Quarantine is the source of all our preventive methods against the spread of infectious diseases. It took its origin from the sea, and the application of its principles was mainly to shipping and the movements of pilgrims and troops from one country to another. The dominating principle in modern as opposed to the older quarantine is that it must be a sieve and not a dam. Its art consists in regulating the openings so as to hold back certain infections, but to permit all else to pass through. In practice, quarantine has failed in the case of droplet-borne diseases, such as influenza, and in diseases such as poliomyelitis where subinfections and carriers are numerous. Diseases, such as small-pox and cholera, against which a solid immunity can be effected ; those, such as pneumonia and plague, in which the disease can be easily identified ; and those transmitted by rats, lice, or mosquitoes are capable of complete control.

Four Interacting Factors

Every epidemic is influenced by the interaction of four variable factors. These are :

1. The reservoir factor,
2. The transmission factor,
3. The infecting factor,
4. The immunity factor,

and the character and progress of the epidemic depend on the dominant factor. This is the basis of C. A. Gill's quantum theory of infectious disease.

Karl Pearson taught (1911) that an epidemic could best be studied by the use of curves, and he introduced the term "*epidemic wave*" in relation to frequency distribution curves. He showed that the number of cases affected in an epidemic rises, more or less rapidly, to a maximum or peak, and then falls with a roughly proportionate rapidity, to the normal or endemic level. J. Brownlee (1905–09), in studying epidemics of small-pox and measles, showed that these waves varied considerably according as to whether the immunity peak was prominent or not. When this was insignificant an epidemic—e.g., variola major—would exhaust itself only after the whole community had been affected ; where the immunity factor was dominant the outbreak either did not occur or came to an end long before the susceptible population had become exhausted. The first phenomenon he describes by a loss of susceptibility curve and the second by a loss of infectivity curve. These phenomena are of particular importance in diseases such as diphtheria and scarlet fever, where the immunity in city populations is very high. It has also been demonstrated that the immunisation of a comparatively small proportion of the population is a powerful preventive in outbreaks of variola major, scarlet fever, and diphtheria.

The dominant factor is that which saves us from epidemics of such diseases as poliomyelitis and cerebro-spinal fever. There are, in an urban community, so many carriers in the population that they keep the immunity potential so high that the virus either does not produce infection or, if it does, only in a very mild and so unrecognised form. This salting of a community continues, provided a certain number of carriers exist in that community. It can be clearly demonstrated in such diseases as scarlet fever and diphtheria, where it can be tested by the Dick and Schick tests. Individuals may be immunised artificially to withstand attacks of these diseases. P. Stocks has shown this immunity to exist in such high velocity diseases as measles and whooping-cough.

Again, S. F. Dudley has shown that apart from immunity an individual has the power of ridding himself of infecting material just as he is capable of becoming infected by it. There is thus set up in a person exposed to a source of infection a struggle between these factors. If the rate of infection is the more rapid the person is finally overcome by a dose of infection capable of affecting his system and so, after a definite period called the incubation period, he will develop the symptoms of the disease. The term "epidemic potential" has been introduced to express the balance between the infectivity of the organism and the susceptibility of the individual or community.

Improved Machinery

The question is how far have we benefited by these discoveries, and in what way we have improved our

seriatim with each of these objections, taking the last first.

It is generally agreed that administration of serum is contra-indicated after the fifth day of illness. In an analysis of the day of illness on which the patient was admitted to hospital, in 200 cases of Types I. and II. pneumonia we found that 70 per cent. were admitted within the first four days of infection; a commendable achievement when it is remembered that the cases were mostly derived from the poorer classes.

The value of antiserum in the treatment of Type I. pneumonia is now undoubted. There is less convincing evidence of its efficacy in Type II. pneumonia. Two factors are responsible—the greater severity of the infection and the difficulty of producing a highly potent Type II. antiserum. The first difficulty can be overcome by earlier diagnosis and much more massive dosage, while the production of a potent Type II. antiserum is being tackled by the producers with, I understand, considerable success.

The expense both of producing and refining antipneumococcus serum is very considerable, and the cost of the product cannot commercially be much reduced, even if there is a wider demand for it. This high cost of antipneumococcal serum is a real obstacle to its use by public bodies and practitioners, and it is not particularly creditable to our country that the use of remedies which are to be beneficial to the community should be made almost prohibitive because the production has to be left entirely to the enterprise of commercial firms.

Regarding the specificity of the serum and the need for bacteriological typing, there are two advantages to offset the disadvantage. If we accept the usefulness of Type II. serum and administer primarily a bivalent (Types I. and II.) serum, there are three chances in four of doing good, since about 75 per cent. of the cases of lobar pneumonia in this country are due to Types I. and II. In addition, pneumococcal typing can now be effected in the majority of cases within one to six hours of the diagnosis, either by direct typing from the sputum (Armstrong (1932), Logan and Smeall (1932), Fleming (1933)) or by Sabin's rapid mouse method (Sabin (1929), Cruickshank (1933)). Furthermore, a knowledge of the infecting type is of considerable prognostic value to the physician, whether or not serum is being given. Incidentally, recent work by Day (1933) raises a hope that it may soon be possible to prepare a pan-pneumococcal antiserum.

The results from the serum treatment of lobar pneumonia have been recently and adequately discussed (Cole (1929), Cecil (1932), Park (1930), Cowan, Harrington, et al. (1930, 1932, 1933)). The therapeutic use of a specific antiserum may be expected to result in amelioration of the symptoms, shortening of the infection, and saving of lives. The importance of the first two uses must not be minimised or too much stress laid on the comparative mortality of groups of serum-treated and non-serum-treated cases. Such a comparison is only possible with very large numbers since there are so many variables influencing mortality in pneumonia (see Table III.). Amelioration of the toxæmia is a clinical evaluation—I quote the opinions of experienced physicians. "In Type I. pneumonia the results of serum treatment are excellent; in Type II. pneumonia the effect of serum while not so striking as in Type I. cases is nevertheless definite" (Cecil). "Serum and oxygen should be available for the treatment of pneumonia in every hospital" (Cowan, Harrington, et al.). The shortening of the infection by the use of antiserum in Type I. and less surely in Type II. pneumonia may be most readily appreciated by examination of the temperature charts of a consecutive series of treated patients (see Table IV.). The question is sometimes raised as to whether the serum exercises a non-specific effect such as any foreign protein might do. A considerable number of Group "X" pneumonias in our series were given serum, partly to test this possibility. There was no marked effect either in shortening the infection or in influencing the mortality (Table IV.).

TABLE III

Mortality-rate for Serum-treated and Non-serum-treated Cases of Lobar Pneumonia (Types I. and II.)

Collected—U.S.A. and Britain

Type.	Serum-treated.			Non-serum-treated.		
	Cases.	Deaths.	Mortality per cent.	Cases.	Deaths.	Mortality per cent.
I.	547	94	17·3	477	148	31·0
II.	415	139	33·4	367	159	43·3

TABLE IV

Duration of Pyrexia in Days of Serum-treated and Control Cases of Lobar Pneumonia: aged 15–70 years

—	Serum-treated: G.R.I.	Control cases: Belvidere Hospital.
Type I.	4·7 days (40 cases)	7·6 days (100 cases)
„ II.	6·6 „ (40 „)	7·7 „ (100 „)
Group X	6·3 „ (38 „)	7·5 „ (60 „)

Summary

The serological determination of the pneumococcal type in lobar pneumonia has in the past been regarded more of academic interest to the bacteriologist than of practical importance to the clinician. In the foregoing lecture I have tried to indicate that, apart altogether from serum treatment, a knowledge of the type of infecting pneumococcus is of considerable prognostic value. Quantitative as well as qualitative differences in the capsular or specific soluble substance of Types I., II., and III. pneumococci have been shown to exist, and the intimate association of the pneumococcal soluble specific substance with the degree of toxæmia has been stressed as explanation of the difference in the severity and mortality of Types I., II., and III. pneumonia. Because of the antileucocytic effect of this substance the leucocyte count is believed to be as valuable in prognosis as the presence or absence of bacteriæmia. Infection is overcome naturally by a general humoral antibody response. It may be considerably shortened in Type I. pneumonia and less surely in Type II. pneumonia by the use of specific antipneumococcal serum.

EPIDEMIOLOGY APPLIED TO SCHOOL LIFE*

By J. A. H. BRINCKER, M.B., D.P.H. CAMB.
PRINCIPAL MEDICAL OFFICER, PUBLIC HEALTH DEPARTMENT,
LONDON COUNTY COUNCIL

MEDICINE has advanced considerably during our lifetime along certain lines—e.g., medical and surgical treatment—but progress has been slow and erratic in the prevention of infectious disease. We are using to-day practically the same methods of control as when bacteriology and the study of immunity were in their infancy ; the same procedure of notification, isolation, and disinfection as that to which our grandfathers pinned their faith. Yet there is no excuse, for epidemiology, whether statistical, experimental, or field study, has made great advances and we know to-day much more than we did of how infectious diseases are bred, how they behave, the conditions which help or hinder their spread, and how they can be prevented. As members of this association, we are responsible for the health and physical welfare of a number of young people, living a community life and therefore exposed to the forces which govern epidemics. On our study of the laws of epidemiology we have to base our rules for the control of infection in the schools.

Quarantine

Quarantine is the source of all our preventive methods against the spread of infectious diseases. It took its origin from the sea, and the application of its principles was mainly to shipping and the movements of pilgrims and troops from one country to another. The dominating principle in modern as opposed to the older quarantine is that it must be a sieve and not a dam. Its art consists in regulating the openings so as to hold back certain infections, but to permit all else to pass through. In practice, quarantine has failed in the case of droplet-borne diseases, such as influenza, and in diseases such as poliomyelitis where subinfections and carriers are numerous. Diseases, such as small-pox and cholera, against which a solid immunity can be effected; those, such as pneumonia and plague, in which the disease can be easily identified ; and those transmitted by rats, lice, or mosquitoes are capable of complete control.

Four Interacting Factors

Every epidemic is influenced by the interaction of four variable factors. These are :

1. The reservoir factor,
2. The transmission factor,
3. The infecting factor,
4. The immunity factor,

and the character and progress of the epidemic depend on the dominant factor. This is the basis of C. A. Gill's quantum theory of infectious disease.

Karl Pearson taught (1911) that an epidemic could best be studied by the use of curves, and he introduced the term "*epidemic wave*" in relation to frequency distribution curves. He showed that the number of cases affected in an epidemic rises, more or less rapidly, to a maximum or peak, and then falls with a roughly proportionate rapidity, to the normal or endemic level. J. Brownlee (1905–09), in studying epidemics of small-pox and measles, showed that these waves varied considerably according as to whether the immunity peak was prominent or not. When this was insignificant an epidemic—e.g., variola major—would exhaust itself only after the whole community had been affected ; where the immunity factor was dominant the outbreak either did not occur or came to an end long before the susceptible population had become exhausted. The first phenomenon he describes by a loss of susceptibility curve and the second by a loss of infectivity curve. These phenomena are of particular importance in diseases such as diphtheria and scarlet fever, where the immunity in city populations is very high. It has also been demonstrated that the immunisation of a comparatively small proportion of the population is a powerful preventive in outbreaks of variola major, scarlet fever, and diphtheria.

The dominant factor is that which saves us from epidemics of such diseases as poliomyelitis and cerebro-spinal fever. There are, in an urban community, so many carriers in the population that they keep the immunity potential so high that the virus either does not produce infection or, if it does, only in a very mild and so unrecognised form. This salting of a community continues, provided a certain number of carriers exist in that community. It can be clearly demonstrated in such diseases as scarlet fever and diphtheria, where it can be tested by the Dick and Schick tests. Individuals may be immunised artificially to withstand attacks of these diseases. P. Stocks has shown this immunity to exist in such high velocity diseases as measles and whooping-cough.

Again, S. F. Dudley has shown that apart from immunity an individual has the power of ridding himself of infecting material just as he is capable of becoming infected by it. There is thus set up in a person exposed to a source of infection a struggle between these factors. If the rate of infection is the more rapid the person is finally overcome by a dose of infection capable of affecting his system and so, after a definite period called the incubation period, he will develop the symptoms of the disease. The term "epidemic potential" has been introduced to express the balance between the infectivity of the organism and the susceptibility of the individual or community.

Improved Machinery

The question is how far have we benefited by these discoveries, and in what way we have improved our

seriatim with each of these objections, taking the last first.

It is generally agreed that administration of serum is contra-indicated after the fifth day of illness. In an analysis of the day of illness on which the patient was admitted to hospital, in 200 cases of Types I. and II. pneumonia we found that 70 per cent. were admitted within the first four days of infection; a commendable achievement when it is remembered that the cases were mostly derived from the poorer classes.

The value of antiserum in the treatment of Type I. pneumonia is now undoubted. There is less convincing evidence of its efficacy in Type II. pneumonia. Two factors are responsible—the greater severity of the infection and the difficulty of producing a highly potent Type II. antiserum. The first difficulty can be overcome by earlier diagnosis and much more massive dosage, while the production of a potent Type II. antiserum is being tackled by the producers with, I understand, considerable success.

The expense both of producing and refining antipneumococcus serum is very considerable, and the cost of the product cannot commercially be much reduced, even if there is a wider demand for it. This high cost of antipneumococcal serum is a real obstacle to its use by public bodies and practitioners, and it is not particularly creditable to our country that the use of remedies which are to be beneficial to the community should be made almost prohibitive because the production has to be left entirely to the enterprise of commercial firms.

Regarding the specificity of the serum and the need for bacteriological typing, there are two advantages to offset the disadvantage. If we accept the usefulness of Type II. serum and administer primarily a bivalent (Types I. and II.) serum, there are three chances in four of doing good, since about 75 per cent. of the cases of lobar pneumonia in this country are due to Types I. and II. In addition, pneumococcal typing can now be effected in the majority of cases within one to six hours of the diagnosis, either by direct typing from the sputum (Armstrong (1932), Logan and Smeall (1932), Fleming (1933)) or by Sabin's rapid mouse method (Sabin (1929), Cruickshank (1933)). Furthermore, a knowledge of the infecting type is of considerable prognostic value to the physician, whether or not serum is being given. Incidentally, recent work by Day (1933) raises a hope that it may soon be possible to prepare a pan-pneumococcal antiserum.

The results from the serum treatment of lobar pneumonia have been recently and adequately discussed (Cole (1929), Cecil (1932), Park (1930), Cowan, Harrington, et al. (1930, 1932, 1933)). The therapeutic use of a specific antiserum may be expected to result in amelioration of the symptoms, shortening of the infection, and saving of lives. The importance of the first two uses must not be minimised or too much stress laid on the comparative mortality of groups of serum-treated and non-serum-treated cases. Such a comparison is only possible with very large numbers since there are so many variables influencing mortality in pneumonia (see Table III.). Amelioration of the toxæmia is a clinical evaluation—I quote the opinions of experienced physicians. "In Type I. pneumonia the results of serum treatment are excellent; in Type II. pneumonia the effect of serum while not so striking as in Type I. cases is nevertheless definite" (Cecil). "Serum and oxygen should be available for the treatment of pneumonia in every hospital" (Cowan, Harrington, et al.). The shortening of the infection by the use of antiserum in Type I. and less surely in Type II. pneumonia may be most readily appreciated by examination of the temperature charts of a consecutive series of treated patients (see Table IV.). The question is sometimes raised as to whether the serum exercises a non-specific effect such as any foreign protein might do. A considerable number of Group "X" pneumonias in our series were given serum, partly to test this possibility. There was no marked effect either in shortening the infection or in influencing the mortality (Table IV.).

TABLE III

Mortality-rate for Serum-treated and Non-serum-treated Cases of Lobar Pneumonia (Types I. and II.)

Collected—U.S.A. and Britain

Type.	Serum-treated.			Non-serum-treated.		
	Cases.	Deaths.	Mortality per cent.	Cases.	Deaths.	Mortality per cent.
I.	547	94	17·3	477	148	31·0
II.	415	139	33·4	367	159	43·3

TABLE IV

Duration of Pyrexia in Days of Serum-treated and Control Cases of Lobar Pneumonia: aged 15–70 years

—	Serum-treated: G.R.I.	Control cases: Belvidere Hospital.
Type I.	4·7 days (40 cases)	7·6 days (100 cases)
„ II.	6·6 „ (40 „)	7·7 „ (100 „)
Group X	6·3 „ (38 „)	7·5 „ (60 „)

Summary

The serological determination of the pneumococcal type in lobar pneumonia has in the past been regarded more of academic interest to the bacteriologist than of practical importance to the clinician. In the foregoing lecture I have tried to indicate that, apart altogether from serum treatment, a knowledge of the type of infecting pneumococcus is of considerable prognostic value. Quantitative as well as qualitative differences in the capsular or specific soluble substance of Types I., II., and III. pneumococci have been shown to exist, and the intimate association of the pneumococcal soluble specific substance with the degree of toxæmia has been stressed as explanation of the difference in the severity and mortality of Types I., II., and III. pneumonia. Because of the antileucocytic effect of this substance the leucocyte count is believed to be as valuable in prognosis as the presence or absence of bacteriæmia. Infection is overcome naturally by a general humoral antibody response. It may be considerably shortened in Type I. pneumonia and less surely in Type II. pneumonia by the use of specific antipneumococcal serum.

(*Continued at foot of opposite page*)

In both types of the disease adequate drainage, with the resulting increase in oxygen tension of the part affected, and massive dosage with iodides appear to give the best results.

Prognosis depends upon the anatomical site of the lesion and early recognition of the disease.

My thanks are due to the surgical staff of the London Hospital for permission to publish these cases, and especially to Mr. Hugh Cairns, who was in charge of the isolation block at the time of the investigation. I am also indebted to Dr. Paul Fildes for his advice on the bacteriology, and to Prof. H. M. Turnbull for permission to make use of the post-mortem records, and for his advice.

THE GRASS-POLLEN ANTIGEN FOR HAY-FEVER DESENSITISATION

BY JOHN FREEMAN, D.M. OXF.

LECTURER IN BACTERIOLOGY AND DIRECTOR OF THE DEPARTMENT OF CLINICAL BACTERIOLOGY, ST. MARY'S HOSPITAL, LONDON

I.—POLYVALENCY

WHEN in 1908 the late Leonard Noon and I began experiments to see if inoculated doses of a grass-pollen extract would in any way modify (or might even cure) hay-fever symptoms, we were naturally faced with the problem whether the extract from any grass-pollen would do, or whether we ought to get extracts from a number of the grasses, and if so, which of them? This was a vital point because there are 41 genera, 108 species, and innumerable varieties of grasses in the British Isles alone. The pollen of any one of them will fly for 30 or 40 miles on a brisk summer breeze, therefore the air-passages of any hay-fever patient must in the course of nature be subjected to the action of a great variety of grass-pollens.

EXPERIMENTS ON GRASS-POLLEN

First phleum testing (1908).—To settle this point we tested a number of hay-fever subjects with three extracts from different grass-pollens—namely, *Phleum pratense*, *Alopecurus pratensis*, and *Poa annua*. We argued that if these three grasses did contain different antigens, presumably some patients would react to one and others would react to another; or at least it might be presumed that one of these pollens would react more strongly on some of the patients, while another pollen would react more strongly on others. As a fact, we found that if any patient was sensitive to one he was sensitive to all three, and that with these particular extracts the strongest reaction was always given by phleum, the next strongest by alopecurus, and the least by poa. Arguing from these three pollens to all grass-pollens, we decided that phleum would serve as an antigen to all hay-fever cases—i.e., it was immunologically "polyvalent." So we used phleum.

A year or two later, after the untimely death of Noon, I corresponded with Dunbar, of Hamburg, who informed me that he was using rye pollen as an antigen, and very courteously sent me a supply. Testing this against *Phleum pratense* I came to the conclusion that they contained the same antigen.

Second phleum testing (1920).—In the course of years other workers entered this field of investigation and many of them advised that patients should be tested to see to which particular grass they were sensitive, thinking that variety of sensitisations might account for failures in treatment when using phleum alone. Also it was thought by them that the differing cutaneo-reactions of the various grasses indicated differing antigens. The old problem was therefore re-examined in my laboratory soon after the war, with the amplification of the experiment by two new pollens, *Dactylis glomerata* and *Anthoxanthum oderatum*. Again it was found that if any patient reacted to one he reacted to all grass-pollens; and, within the limits of accuracy of the experiment, no particular grass-pollen gave a relatively strong reaction with one patient and a relatively weak reaction with another patient. It was also observed that cured patients—i.e., those who had previously been (for therapeutic purposes) heavily inoculated with *Phleum pratense* for several years and who had thereby lost their reaction to phleum—had lost their reaction also to the other grasses. This result might have been anticipated, because they could not have been cured unless they had failed to react spontaneously in response to all the varieties of grass-pollen grains that the atmosphere might send them during the hay-fever season. Thus the polyvalency of phleum seems to be reaffirmed.

Third phleum testing (1932).—However, writers of books and papers on hay-fever continued to suggest that it was desirable to test the patient to a variety of grasses.[1] One such writer stated that holcus and dactylis certainly yielded different antigens from that which could be extracted from *Phleum pratense*. I therefore decided to make another and more elaborate testing, and to test especially these two suspect grasses.

During the summer of 1931, beside the customary pollen from phleum, pollen from seven other grasses was collected and extracted for testing purposes, and a special quantity of dactylis and holcus was collected for heavy immunisation. Work during 1932 showed that no hay-fever patient who reacted to any *one* of these pollens failed to react to all eight of them; and, within the limits of the experiment the more powerful pollen extracts reacted powerfully on all, the less powerful reacted less powerfully on all. Thus our original experiment was confirmed again. Furthermore, it was observed that heavy desensitisation with extracts of phleum, dactylis, or holcus, or with any combination of these three, when carried far enough, not only reduced and finally obliterated the skin reactions to the particular pollen that was being used as an antigen, but abolished them to all the other pollens also. All this is shown graphically in the accompanying Figure. This result was found whenever the doses were carried high enough, and was supplemented by the fact that any patient whose skin reactions had wilted under the influence of massive doses of any of these three antigens suffered no trace of symptoms from the naturally occurring pollen-cloud at midsummer.

One further test I am still carrying out which bears on the polyvalency of phleum, &c., and that is to see how rapidly the various skin reactions return after they had become obliterated by treatment last spring or summer. So far as I have had time to test, the skin reactions from no one of the pollens returns more quickly or more slowly than the others do.

If there is any difference of antigen between the different grasses it has not been detected by me, and

---

[1] The extracts used for these tests usually come from U.S.A.; it should have caused misgivings that occasionally the species of grass selected in this way for use as the antigen "because it causes most of the mischief" is only to be found on the other side of the Atlantic.

Both the thoracic cases were characterised by a steady spread of the disease in spite of treatment. Subcutaneous abscesses appeared, and one patient showed at one time 14 abscesses, all about 1½ in. in diameter, over the lower part of the back. In the same patient the streptothrix was present in the sputum.

POST-MORTEM RECORDS

Owing to the chronicity of the disease patients suffering from actinomycosis are frequently discharged from hospital before death. For this reason post-mortem records were available in only one of the five deaths in this series (No. 9 in the following summary). Therefore, in order to investigate the mode of death in actinomycosis an examination was made of the pathological records of patients dying from the disease prior to this series. The following are extracts from these records. The first eight cases represent the deaths which occurred in the London Hospital over a period of four years.

CASE 1 (1912).—Actinomycotic pyæmia. Abscess (1 cm. diam.) in ileocæcal valve. A few small submucosal abscesses in ascending colon. Thin pus and organising fibrin throughout peritoneum. Purulent thrombosis of right branch of portal vein. Fibrotic honeycomb abscess in right lobe, and a few discrete abscesses in left lobe of liver. Small subpleural abscesses in all lobes of lungs. Inflamed spleen. Operation: appendicectomy four days before. Appendix 4·5 cm. long; fibrotic obliteration of lumen in distal 2 cm.

CASE 2 (1912).—Actinomycotic pyæmia. Submucous abscesses in cæcum, last inch of ileum, ascending colon, hepatic flexure, and jejunum adherent thereto. Chronic abscesses in right iliac and lumbar muscles. Focal purulent peritonitis in right iliac fossa. Large groups of abscesses in right lobe of liver. A few subpleural miliary abscesses in lower lobe of right lung. Grey-red inflamed spleen. Operation: appendicectomy three months before, "appendix found in hard tangle of adherent growth." Appendix with focal constriction by fibrous scar of mucosa and submucosa.

CASE 3 (1912).—Actinomycotic pyæmia. Large submucous hæmorrhagic areas and a few small ulcers in cæcum. Numerous submucous hæmorrhagic abscesses throughout colon and in lower 18 in. of ileum. Hæmorrhagic cellulitis of bed of cæcum. Abscess in right psoas and iliacus. General organising fibrino-purulent peritonitis. Subpleural purulent inflammation in base of lower lobe of right lung. Rounded group of walled abscesses (largest 3 cm. diam.) in right lobe of liver. Abscess within and purulent infiltration of bed of right suprarenal body. Submiliary abscesses in left kidney. Miliary abscess in apex of urinary bladder. No enlargement of spleen (3½ oz.). Operation: appendicectomy three months before. Actinomycotic granulation tissue found in peritoneum at site of appendix.

CASE 4 (1912).—Actinomycotic pyæmia and lardaceous disease. Right psoas and iliacus riddled with abscesses. Extraperitoneal pelvic abscess. Large abscess in left psoas. Pus in right hip-joint. Cutaneous sinuses in right groin and appendix region. Submucous abscess in ileum 2 in. above termination; close to this a perforation of ileum into retroperitoneal tissues. Focal fibrino-purulent peritonitis in right iliac region and pelvis. Scar in cæcum of appendicectomy. Miliary subpleural abscesses throughout both lungs. Abscess in spleen. General amylosis of liver and suprarenal bodies. Sago-waxy spleen. Operation: appendicectomy ten months before.

CASE 5 (1912).—Actinomycotic septicæmia. Hæmochromatosis. Fibrous scar in proximal end of appendix. Peritoneal adhesions round appendix and cæcum. Numerous groups of actinomycotic abscesses in liver. Reticular fibrosis and great hæmosiderosis of liver. Deep blue pigmentation of lymphoid tissue throughout intestines. Slight chronic inflammation and extensive hæmosiderosis of spleen.

CASE 6 (1913).—Actinomycotic cerebro-spinal meningitis. Purulent infiltration and destruction of tissues in right false pelvis, extending to and involving the right lobe of the diaphragm and the lumbosacral vertebral muscles. Purulent erosion of posterior surface of bodies of third, fourth, and sixth lumbar vertebræ. Extrathecal pus in lumbosacral portion of spinal canal. Thick gelatinous pus in subarachnoid space of cord and brain. Slight chronic inflammation of spleen.

CASE 7 (1915).—Actinomycotic septicæmia. Perforated ulcer (1·2 cm. diam.) in cæcum. Abscess in right false pelvis. Almost complete destruction of right iliacus muscle. Small abscess in adherent fimbriæ of right Fallopian tube. General organising fibrinous peritonitis. Direct extension of abscess from right false pelvis under Poupart's ligament and over lesser trochanter of femur into thigh. Abscesses in intermuscular septa of outer surface of right thigh and leg. Red, diffluent inflamed spleen. Operation: appendicectomy 13 days before.

THORACIC TYPE

CASE 8 (1913).—Death during anæsthesia. Acute superimposed on chronic rheumatic endocarditis. Actinomycotic abscess in muscles of back from right ninth to twelfth ribs, and in subcutaneous tissues from ninth rib to right iliac crest. Purulent infiltration and great thickening of retropleural tissue from fourth rib to first lumbar vertebra. Dense adhesion between pleuræ over postero-inferior angle of lower lobe of right lung. Purulent infiltration of subjacent lung to depth of 1·5 cm. Grey inflamed spleen. Operation wound exposing eleventh right rib.

CASE 9 (1928).—Heart failure. Actinomycotic pericarditis. Area of fibrosis (2 × 1·5 cm.) containing multilocular abscess (1 cm. diam.) in centre of anterior margin of upper lobe of left lung. Area (8·5 × 5 × 4 cm.) of organising purulent broncho-pneumonia in lower part of anterior margin of upper lobe of right lung. Continuous with these a dense fibrosis containing chronic abscesses in the anterior mediastinum below level of fourth rib. Extension of dense fibrosis with more recent abscesses to the intercostal and subcutaneous tissues from the second to fifth costal cartilages and to the pericardium. Surface of superjacent skin studded with ulcers exuding pus. Numerous minute and one large abscess (9 × 5 cm.) in thickened adherent pericardium. Œdematous "back pressure" spleen.

It will be seen from these pathological findings that actinomycosis causes death in three ways: (1) by direct extension to and destruction of vital structures; by (2) generalised pyæmia; or by (3) amyloid disease. Although the gut was perforated in two cases, there was never fæcal peritonitis, and perforation was never a cause of death.

It is commonly stated that the lymphatic glands are not affected in this disease (Zachary Cope). That the glands do become infected is shown by the two sternomastoid cases quoted above. But the lymphatic glands do appear to be resistant and in most cases unaffected.

Spread of the disease takes place in two ways: at first by direct extension alone, and later, when abscess cavities have formed, by the blood stream. The degree of spread possible by direct extension alone is well illustrated in Case 6. It must be emphasised that these methods of spread apply to the deep variety only. In the superficial cases extension is slow, and infection by the blood stream with the formation of "metastatic" abscesses does not occur.

CONCLUSIONS

Human actinomycosis appears to be invariably an infection with the non-acid-fast anaerobic streptothrix *A. bovis.* The superficial variety of actinomycosis occurs more commonly than is usually supposed. In cervico-facial cases, before the formation of pus, trismus is the most important sign.

Early diagnosis by a bacteriological examination of pus in all cases of alveolar abscess and early treatment with iodides will prevent the terrible scarring and repeated relapses associated with the disease. If a test-tube containing actinomycotic pus is tilted the granules are visible to the naked eye as greenish-grey specks adhering to the glass. Even, therefore, when a routine bacteriological examination of all pus is impossible, this method of tilting the test-tube and examination through a hand lens would indicate the suspicious cases which need fuller investigation. In the deep variety there is such a high mortality that a routine bacteriological examination of pus in cases of empyema, appendix abscess, and subdiaphragmatic abscess is imperative. Where cases are allowed to suggest the disease by their very chronicity the disease has usually spread beyond human aid.

places, we might hope to lower considerably the mortality in pyogenic infections. The treatment of the following cases was founded on this conception. I do not intend here to advocate the use of this treatment, but to discuss points in the pathology of the condition on which the cases throw some light.

No special merit can be claimed for four successive recoveries, even in severe cases of this infection; recoveries may follow almost any treatment. The point is that these cases, in addition to the appropriate surgical treatment, were given benzol by mouth. Benzol has the effect of diminishing the blood-cells, especially the leucocytes, and was given with that express purpose.

Following the life-work of Metchnikoff on phagocytosis, and the further work of Sir Almroth Wright and his school on the opsonic and bactericidal factors of the blood, so much has been said and written on the protective value of the leucocytes in infections that it will be difficult to carry conviction in explaining the rationale of a therapy that seeks to limit leucocytosis during a pyogenic infection. A simile may help. The Bishop of Oxford has lately quoted Mr. Charles Dodgson (Lewis Carroll) as asking the following question of his mathematical students: "If three men can build 10 yards of wall in so many days, how long will it take 300,000 men to build it?" The answers in theory and practice are clearly very different, and it must often happen that 300,000 leucocytes are crowded into a spot where only a very small number could possibly be of use. Wright[1] himself points out that from a practical point of view normal blood contains phagocytes "far in excess of any conceivable requirements."

We are considering here the apparently excessive degree of leucocytosis that infection may cause. An example is seen in scarlet fever, which is to-day a much milder disease than formerly, since, as Prof. Okell[2] points out, the streptococcus in scarlet fever is now less pyogenic and invasive, and more toxigenic. The idea that disease as we recognise it is, in many cases, chiefly the reaction to infection is no new one; it must go back at any rate to the time of Sydenham, and morbid anatomists especially are driven to feel that the patient quite often dies from the violence of his reaction rather than from the virulence of the infection. In some conditions, such as hyperpyrexia for instance, we do not hesitate to limit Nature's activities, and the question raised here is whether in some markedly pyogenic infections we ought not to try to limit the excessive leucocytosis with its attendant localisation and abscess formation.

INFECTING AGENT AND LEUCOCYTIC RESPONSE

For all practical purposes the infecting agent is the staphylococcus, almost always *S. aureus*. This organism may be very virulent and may cause an acute toxæmia, sometimes rapidly fatal, but, as a rule, in its less acute rôle of pyogenic agent, it leads to the formation of local bone abscess and later to embolic abscesses.

On opening the bone in an early case the surgeon may find no pus, but bright red and bleeding marrow, and may doubt whether he has opened at the right spot. The fragment of bone removed in such cases should always be cultured; a fragment of the marrow laid on agar will often grow *S. aureus* abundantly. The infecting agent is present, and from the clinical signs is causing a marked toxic effect, but as yet there is no pus; the organisms are highly virulent and are not exerting a positive chemotactic influence on the leucocytes. If an effective phagocytosis could take place at this stage it would be of the highest value, but unfortunately it is not a function of the leucocyte to take up and digest such highly virulent organisms. At this time the blood picture may show no marked change from the normal.

After surgical intervention the fever usually begins to fall or to intermit, pus comes from the wound, and the blood count rapidly rises, in favourable cases perhaps to about 15–20,000 and, in spite of a positive blood culture in the early stages, the patient may steadily progress towards cure. In other cases, in which the cell count commonly rises higher, the second phase of the disease proceeds with the formation of a series of collections of pus in one site and another. The surgeon now adopts an attitude of tempered optimism, for he rightly feels, in severe cases, that localisation of pus is associated with a better prognosis than is a pure staphylococcal septicæmia. Why is this? A current view is that the leucocytes have now arrived at infected spots in such numbers that the foe may be expected soon to be vanquished. But we have already seen that when the organism is really virulent there is no leucocytic or phagocytic response, and thus, if we choose, we can take as an alternative explanation that the virulence or toxicity of the organism has diminished, or has been relatively diminished by the development of some form of immunity, and for that reason the bacteria now exert a positive chemotaxis, and a leucocytic response with phagocytosis follows. Thus we arrive at the conclusion that the patient is not now likely to be killed by the toxic virulence of the infecting organism, as seemed possible in the early stages. But we know he may yet die from the fortuitous collections of pus, and especially from purulent emboli in which leucocytes and blood-platelets play a large part.

On the basis of this view it will not be unreasonable if we attempt to check this excessive reaction. Two questions now arise: (1) is it possible to control the leucocytic response in spite of the infection? and (2) if we produce a relative leucopenia, will the infection be correspondingly exaggerated?

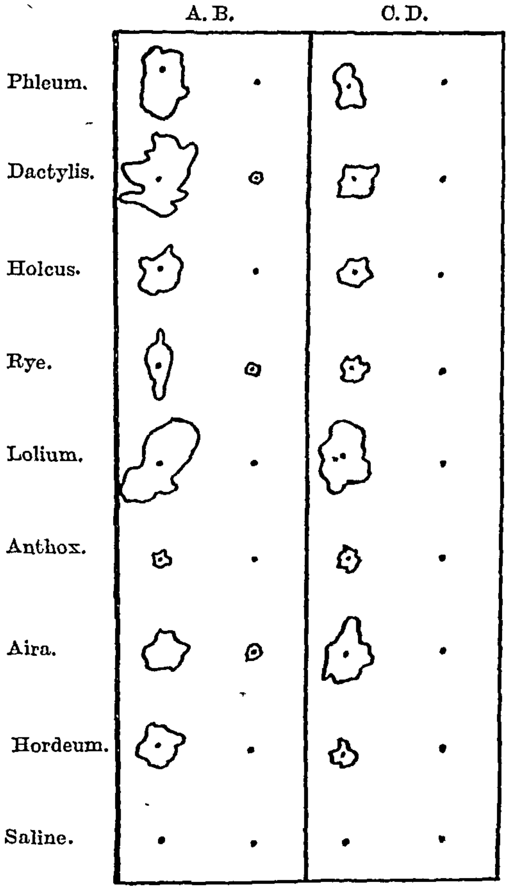
(1) *Is it possible to control leucocytosis in the active stages of a pyogenic infection?* It is certain that benzol is at the best a slow and clumsy agent for this purpose; in normal rabbits at any rate I have found it extremely difficult to produce a leucopenia with benzol, and it is impossible to say from these few cases how far it did act as a controlling agent. On the other hand, experience of blood counts of numerous untreated cases makes it practically certain that it did act in this way. What is certain is that in three of these cases there was in the later stages a degree of leucopenia with an increasingly watery rather than purulent discharge whilst the infection was still relatively active. In the fourth case a very profound leucopenia had developed by the fifth week in spite of the presence of a new infection with a pyogenic organism in the pleural cavity.

(2) *Is there any evidence that an infection becomes exaggerated in leucopenic conditions?* It is common knowledge that a leucopenia is associated with the most severe and toxic infections and that such infections tend to a fatal result. Agranulocytic angina, the worst cases of pneumonia, and very severe cases of typhoid fever are typical examples. It is a tempting assumption that these cases are severe because of the leucopenia, but experimental evidence shows that a leucopenia is definitely the effect of a heavy dose of bacterial toxin, and phagocytosis of such highly toxic bacteria would probably not be effected even if leucocytes were present in abundance. It is claimed by Camp and Baumgartner[3] that a local pyogenic reaction to infection occurs

it certainly seems not only permissible but the only practical course to regard all the grass-pollen antigens as one. Pollen from any one of these grasses is therefore polyvalent and is sufficient for treatment of hay-fever.

POLLEN-FEVER IN SUMMER, AUTUMN, AND WINTER

Pollen-fever from the flowers in summer.—Perhaps, to clear up the question of diversity of pollen antigens, I may here deal briefly with sensitisations to pollens other than grass. Of course a number of hay-fever patients, and more in the old days than now perhaps, put down their troubles to some conspicuous or heavily scented flower which happened to bloom during the time of the grass-pollen cloud—"It is only the syringa that affects *me*" or "My hay-fever begins directly the may blossom is out, so it must be that." It is true that there is a difference of sensitisation between the grass-pollens and the pollens of what are popularly called flowers. Some hay-fever subjects will react to hardly any of the flower pollens, while most will react in varying degree to an apparently capricious assortment of them. There are in fact flower-pollen "diseases" running parallel but not identical with true hay-fever, but for a variety of reasons[3] which I will not detail again here, it is unlikely that any conspicuous or heavily scented flower can give much trouble, even to a person who happened to be sensitive to it; and I am doubtful if I have ever come across a case of reputed hay-fever which can really be ascribed to some midsummer flower or flowers.



Urticarial weals given by prick-reactions at the beginning and end of treatment in two cases of hay-fever last year. Note that each case before treatment reacts to all eight grass-pollens employed, and that though they were inoculated with only one of the pollens (*Phleum pratense*) they lost the reactions to all the eight after treatment. A. B., who was first tested on May 24th, with a dose of 40, had only a fortnight's treatment quickened by a "rush"[2] in the middle of it; the second test was on June 8th, when the dose was 20,000. C. D.'s first test was on Feb. 10th, when the dose was 20, and he had four months—chiefly by self-inoculation—before the second test, with 50,000, on June 15th. Both experienced complete relief from hay-fever.

Pollen-fever from the trees in late winter.—Many of the big trees pollinate at the end of the winter. In America, to judge by the literature, there is a definite so-called hay-fever season at that time of year from this cause. Here in England I think I have come across two or three cases with symptoms derived from tree pollination in February, but the symptoms have never been severe enough to make it worth tackling immunologically.

Pollen-fever from compositæ in autumn.—In the autumn, in the "fall" as they say, they have in both Canada and U.S.A. a so-called hay-fever due to the pollen of lowly organised compositæ, and by common consent in America this fever in September and October is much worse than their midsummer trouble due to grass-pollen—i.e., is worse than true hay-fever.

The actual antigen of this autumn disease varies apparently in different places, but opinions in America have hardened in the direction of *Ambrosia trifida*, popularly called ragweed, which is a wind-fertilised composite. Fortunately this genus is not to be found on this side of the Atlantic (usually not even in the botanical gardens because it is an ugly plant). Let us hope no foolish person introduces it into our countryside for fun. I have come across a number of cases (a couple of dozen maybe) that get an autumn fever due to the pollen of compositæ; certainly in some cases, and so far as I know almost invariably, this is derived from the Michaelmas daisies which flower at the end of September and beginning of October. I have made an extract from this pollen and find it works well in such cases; but usually it is easier for patients to avoid the Michaelmas daisies.

CONCLUSION

Taking it all round, in England the true hay-fever due to grass-pollen is a hundred times more important than all the other pollen fevers rolled into one.

Extracts from all the various grass-pollens furnish one and the same antigen for purposes of desensitisation to hay-fever.

The question of dosage will be discussed in a second part of this article.

SOME ASPECTS OF THE PATHOLOGY OF PYÆMIC CONDITIONS

BASED ON A STUDY OF FOUR CASES OF SEVERE ACUTE OSTEOMYELITIS TREATED WITH BENZOL

By T. H. C. Benians, F.R.C.S. Eng.

PATHOLOGIST TO THE PRINCE OF WALES'S GENERAL HOSPITAL AND THE NORTH MIDDLESEX COUNTY HOSPITAL

PYÆMIA is common in severe cases of acute osteomyelitis. The prognosis depends mainly on the site and accessibility of the secondary abscesses; in other words, provided the patient survives the first few days, the outlook is related to the condition of pus-formation rather than to the actual toxic virulence of the infective agent. It seems reasonable, therefore, to suggest that if we could check the formation of pus, at any rate in difficult and dangerous

---

[2] THE LANCET, 1930, i., 744.

[3] *Proc. Roy. Soc. Med.*, 1920, xiii., 8.

CASE 3.—A boy of 12 years. Infection of the lower end of the femur. Count at time of first operation: 15,000. Case put on benzol ♏ 10, t.d.s., at once. Count rose in the next five days to 23,000, fell again to 10,000 in a further five days, and then to 5000 in a further 15 days. Taken off benzol. The count continued gradually to fall during the next 30 days to 4000. During this time, as the temperature remained irregular and the count under 5000, the bone was guttered, without ill-effects. The count gradually rose to about 10,000 during the next three weeks and the patient became convalescent. During the two and a half years since leaving hospital three residual subcutaneous abscesses have formed and been opened. His general health has been excellent.

CASE 4.—A boy of 5 years. Infection of upper end of tibia. Early operation, no pus, *S. aureus* grown from bone-marrow. White cell count at operation: 12,500; rose to 35,000 on third day. Benzol ♏ 5, t.d.s. for ten days, when the count had fallen again to 12,500. Twelve days later the count had fallen to 5000, and in a further three weeks to 1000, with 50 per cent. polymorphonuclear leucocytes. It gradually rose in the next ten weeks to 8500. Very little in the way of secondary abscesses formed, but at the time the count was down to 1000. A large effusion in the chest was drawn off. The fluid was clear and contained practically no cells, but large numbers of pneumococci were present. Fluid was also present in the pericardium and peritoneum.

A fifth patient died 24 hours after treatment with benzol was started, and is not included in the series.

EFFECTS OF TREATMENT

Treatment of these cases with benzol was adopted with the object of preventing metastatic abscesses; can it be said to have been effective? If a purulent reaction to infection occurs, as Camp and Baumgartner[3] claim, unless the white count is reduced below 1000 cells per c.mm. it is clear that only in the later stages of the last case could we have hoped to achieve that end and completely abolish suppuration. It is not even certain that the degree of abscess-formation will be proportionate to the number of leucocytes in the circulation, since extensive cold abscesses may occur with quite low cell counts, though of course they are a long while accumulating. It is, however, likely that the number of abscesses formed will be fewer and their development less progressive as the white cell count falls. We can put on one side for the present the question of leukæmic states of the blood for, while it is true that there seems no tendency to excessive purulent reaction to infection in myeloid leukæmias, even when an enormous excess of adult polymorphonuclear leucocytes is present, it is equally true that in lymphatic leukæmias, when polymorphonuclear leucocytes may be practically absent, there seems no marked tendency for bacterial infections to take hold and spread unchallenged.

Exactly what would or would not have happened in these cases if benzol had not been given it is impossible to say, but in three of them a definite note was made that the discharge from the wounds quickly became less purulent as the count fell and in the last case of the series pneumococci were present in a serous pleural fluid which was practically clear of cells.

SUMMARY

Four cases of acute osteomyelitis with septicopyæmia were treated with benzol with the object of diminishing the leucocytic reaction. In three of them there was a marked fall in the white cell count, and in the fourth a profound leucopenia set in. The purulent discharge diminished and became more watery. The patients all recovered and no after-effects of the benzol have been noted. (The most recent of the cases quoted was two years ago.) It is claimed that in these cases there was an artificial restriction of the output of leucocytes in the later stages of the disease and that this was an advantage rather than the contrary. Though a consideration of the part played by leucocytes and their products in immunity is omitted, it will be seen that a leucocytosis and localisation of pus is represented here as an index rather than as a necessary adjunct of immunity.

The object of the paper is not to advocate benzol as a method of curing pyæmia but to consider whether in this condition we ought not to seek for a direct method of preventing the over-production of leucocytes and their localisation into abscesses.

My thanks are due to my surgical colleagues for their consideration of the point of view set forth in this paper, and their courage in adopting an apparently reactionary treatment.

MAGNESIUM SULPHATE IN THE TREATMENT OF ANGIOSPASM

BY N. PINES, M.B. KIEFF, L.M.S.S.A. LOND.

SPASTIC conditions of the arterial wall, in the light of our inadequate knowledge of vascular disease in the living human body, may be roughly divided into two groups. The first includes hypertonus of the arterial wall of the large and medium-sized vessels, usually but not necessarily associated with arterial hypertension.[1 2] It is probably toxic in origin, and its classical example is the vascular picture in chronic interstitial nephritis. Our only method—a very imperfect one—of diagnosing hypertonus is by palpation of the vessels. The second group consists of angiospasm. It may affect any part of the arterial tree right down to the capillaries. The veins are not affected because of the weakness of their muscular wall, although there is abundant evidence that they too are submitted to the influence of the vasomotor system.

Hypertonus of long standing is injurious in itself, but it also leads either to atheromatous degeneration of the intima or to vascular spasm. The only defensive reaction of the artery to a stimulus being its contraction, it is easy to appreciate that spasm of the vessels may be brought on by many factors. The most essential are:—

(1) General or localised toxæmia acting directly on the arterial wall.
(2) Hypertonus.
(3) Atheromatous degeneration of the intima.
(4) The influence of the vasomotors.

Vascular spasm may be diagnosed by inspection; by palpation; and, if practicable, by oscillometry and by the ophthalmoscope in the extremely rare cases where the retinal vessels are involved. The duration of vascular spasm may be a few minutes or a few hours, but the mischief done may be immense if a portion of a vital organ is affected and is unable to recuperate quickly. Therefore medication must also be rapid and, of course, harmless.

Whilst searching for such a drug I remembered the efforts made to cure tetanus by subcutaneous or intrathecal injections of magnesium sulphate,[3–5] and decided to try it in cases of vascular spasm. It took a considerable time to find the most suitable unless the leucocytes are diminished below 1000 per c.mm. We seldom see a leucopenia of this degree, even in the severest infections, but we do see such a diminution in some anæmic and leukæmic cases. There must be abundant opportunity for infection during the months that these cases survive, and yet they commonly die of exhaustion rather than of infection. In Case 4, quoted later, the total white cell count fell below 1000 per c.mm. and the leucocytes below 500 per c.mm. at the time when pneumococci were present in a clear pleural fluid, but the infection subsided without the help of a leucocytosis. It is, of course, not to be forgotten that in these cases there had been, a few weeks before, a high leucocytosis and that the products of these cells might still be available in the body. There is some evidence in these data that infections do not progress or disseminate as the direct result of a leucopenia.

THE FATE OF BACTERIA IN THE BODY

It is necessary that substances coming into the body should be made harmonious with the tissues, if they are not to act as irritants or poisons. The mechanism of harmonisation in the body appears to be either by digestion into simpler bodies and then, if necessary, reconstruction into more complex harmonious bodies, or, as in the case of toxins, a direct neutralisation by preformed antitoxins. When bacteria get into the body three fates may commonly befall them if the host survives: (1) they may become walled in by inflammatory and fibrous tissue; (2) they may be lysed; or (3) they may suffer phagocytosis and intracellular digestion, and this may be carried out either by the migrating leucocyte or by fixed phagocytic cells of the reticulo-endothelial system.

Where lysis occurs we must assume that bacterial toxins are set free and, in the non-immune animals, their effects are soon seen. In such conditions, phagocytosis with the digestion of the infecting bacteria would be of the greatest value, but this process requires some degree of humoral immunity. As the tide turns in infection, and immunity begins to develop or virulence to decline, we get both leucocytosis and phagocytosis, and it is at this stage that the cure is apt to become worse than the disease, or indeed to constitute the disease. It is not as though wherever an abscess forms we find the whole or even the bulk of the bacteria ingested and destroyed; on the contrary pus teems with dead leucocytes and living bacteria. Barring mechanical difficulties, such as the presence of bone, it is true that an abscess once drained usually clears up quickly, but we have to consider abscesses in situations that are not or cannot be opened, such as the lung, heart muscle, and hip-joint, and, however much we may value the leucocytes, we are forced to the conclusion that we should be better off without these collections of them.

A neutralisation of the toxins is apt to increase the pyogenic capacities of an infecting organism, that is to say, leucocytosis increases as immunity develops; so that animals with a high antitoxic immunity may yet die of abscesses produced by an infection with the organism to the toxins of which they are quite immune. Panton and Valentine [4] have, however, produced an antitoxic serum which, so far, they think diminishes secondary abscess-formation in staphylococcal pyæmia. Although patients rarely die in the early toxic stage of the disease, it seems that the early stages should be treated with a serum and after that, if possible, we should control the leucocytic response and localisation so as to prevent secondary abscess formation.

ACTION OF BENZOL

This drug is given mainly in cases of myeloid leukæmia with the object of diminishing the number of white cells. In due course it also diminishes the number of blood platelets [5] and of red cells. In the first place it is said usually to lead to a slight rise in the number of both red and white cells, and then to a gradual fall, mainly of the white cells. The fact that the fall in the white cells is slow, and also that it continues after the drug has been withheld, makes benzol a clumsy agent for this purpose. Moreover, if pushed it is likely to damage the liver cells, and this effect also must be taken into account in using the drug in an already toxic case and one which has had and may require again to have anæsthetics.

Since the cases described in this paper recovered we must also consider any other possible action of the drug on the disease in general. Benzol may possibly have a directly injurious action on the staphylococcus in the way that arsenobenzol has been shown to have on anthrax and on some streptococci; also, as a lipoid solvent, it may become attached to the nerve tissues of the body and so act, in the "phylactic" sense of Bichât, in protecting the nerve centres from toxic absorption. We have no proof that it functions in either of these ways.

TREATMENT OF THE CASES

In each of these cases an opening in the bone had been made by the surgeon in charge, and drainage established. We cannot say that this is absolutely essential in all cases, but it does seem to have a useful effect in letting some of the toxic matter escape and perhaps in that way helping the development of immunity in the host, or (what for our purpose anounts to the same thing) diminishing the virulence of the infecting organism. After the operation, as soon as the blood count was found to be actively rising, the cases were put on benzol by mouth, 10 minims twice or thrice daily or for the younger children, 5 minims three times a day, according to the degree of the white cell count and also the amount of red blood available, for this may in time also be affected. The drug is given in capsules or in milk. The progress of the white cell count was followed every few days and when the count had fallen, say to about 10,000, the drug was discontinued. It has to be remembered that the fall may continue after the drug has been stopped so that where the administration had been continued for some time it was stopped while the count, though falling, was still relatively high, say 12,000 to 15,000.

Cases.—Protocols and charts of three of these cases were shown before the Pathological Section of the Royal Society of Medicine in March, 1930, and will only be abstracted here.

CASE 1.—A boy aged 7. Osteomyelitis of lower end of tibia. White cell count: 45,000, five days after operation, benzol ♏ 5, t.d.s. by mouth in capsules. In 14 days the count had fallen to 5000; the benzol was stopped, and the patient steadily progressed to convalescence.

CASE 2.—A boy aged 11. Infection of the lower end of the femur. Count at the time of operation: 25,000; put on benzol ♏ 5, t.d.s. Count rose to 05,000 during the next seven days, benzol increased to ♏ 10, t.d.s. Count fell to 20,000 during the next week, but rose again to 35,000 and remained thereabouts for a further two weeks, when two large subcutaneous and intramuscular abscesses were drained. It fell in the succeeding three weeks to 8000, during which time no further abscesses formed; the benzol was then discontinued. In the next 14 days the count rose again to 30,000, and during this period four additional abscesses formed and were drained. No further benzol was given and the count gradually fell in the next two and a half weeks to 15,000, and the patient became convalescent.

About half a minute after the commencement of the injection the patient feels an intense heat in the body. This is first experienced at the back of the pharynx, then in the face and neck, then in the thorax, and sometimes in the upper limbs, and it proceeds down to the rectum and genitalia, the lower limbs being the last to react. The face is sometimes intensely flushed and may even perspire: the skin of the limbs and body hardly alters in colour or temperature. The pulse becomes moderately quickened. The blood pressure is unaltered. On ophthalmoscopic examination the retinal vessels show no change.

In my opinion the magnesium sulphate probably relaxes vascular spasm by direct action on the vasomotor centre of the brain (either cerebral only or spinal as well). If it acted directly on the arterial wall, there would not be the constancy in the order of the sensation of heat. The more spastic or more clogged the vessel, the less is the sensation of heat and the less effective is the injection. The patient can tell exactly where the sensation of heat ceases, and I have found that the oscillometric index invariably corresponds to the patient's sensations. For example, if the patient does not feel the heat in his calf, the oscillometer will not show any increase in the index. I was, therefore, always pleased if the patient felt the warmth throughout the whole body.

If the intravenous mode of injection is for some reason impracticable the solution of magnesium sulphate without the glucose is well tolerated intramuscularly, but the intravenous route is the one recommended.

It is rather strange that the retinal vessels remain completely unaffected in spite of the general vasodilatation and the fact that the face is the most responsive part of the body. This retinal inaction corresponds to the findings of Baillart,[10] H. Claude,[11] and others, who have observed that the retinal vessels are unaffected by ordinary vasomotor drugs. In my opinion this is further evidence that the retinal vessels may be almost independent of the general vasomotor centres.

I did not observe any discomfort in any of my patients, although several of them were well over 60 years of age, and I think that the alarming signs of respiratory distress that have been seen in the cases of tetanus treated with magnesium sulphate may be explained as due either to the intrathecal method of injection or to excessive dosage. I usually administer the treatment to my patients twice a week.

FORTUNE FOR MELKSHAM COTTAGE HOSPITAL.—The late Mrs. Ludlow Bruges, formerly of Seend and Bath, who died in Jersey in July last, left the residue of her estate to Melksham Cottage Hospital on condition that a new wing should be built at a cost not exceeding £10,000. It is presumed that Mrs. Bruges intended the remainder of the estate to be used as an endowment fund. It is believed that the hospital will benefit to the extent of about £100,000.

Clinical and Laboratory Notes

CEREBRO-SPINAL FEVER

TREATED WITH LARGE DOSES OF MENINGOCOCCIC SERUM

BY J. TODESCO, M.D. FLORENCE, M.R.C.S. ENG.
RESIDENT SUPERINTENDENT, BOROUGH HOSPITAL, CROYDON

A BOY, aged 7, was admitted to the Borough Hospital on March 11th, 1932, as a case of cerebro-spinal fever. There was a history of sudden headache, vomiting, and fever on March 8th, with subsequent marked head retraction and rigidity of neck and spine. Four days previously he had been struck on the head by a stone. In 1930 he had had scarlet fever and measles.

On admission the boy was semiconscious, very cyanosed, with extreme head retraction, opisthotonos, and marked general hyperæsthesia and rigidity. The pupils were large, equal and fixed, photophobia being present. The knee-jerks were absent, and the plantar reflex flexor; bilateral Kernig's sign and tâche cérébrale were present. He was very irritable, feverish, wandering and restless at times, and resented examination. Lumbar puncture soon after admission yielded 60 c.cm. of turbid, blood-stained fluid under pressure, the fluid containing excess of polymorphs and meningococci, which were recovered on culture. He was given 20 c.cm. of meningococcic serum intraspinally. On the evening of March 13th he had severe epistaxis.

Between March 15th and 24th he was worse, being very drowsy, with marked general rigidity and head retraction, and very poor colour and pulse. There was marked general body wasting: he was reduced to "skin and bone" and had extreme general weakness. Subsequently he developed large abscesses over the right knee-joint, left side of face and neck and left iliac crest. The abscess of the jaw was drained on April 16th and contained thick pus and large sloughs. All the abscesses were healed by April 25th.

A week later the boy began to improve: the head retraction was almost gone and the general rigidity less marked. He now appeared to understand when spoken to, but his speech was slow and hesitating. Right internal strabismus was noted. He was convalescent by May 12th and, though the right internal strabismus persisted, his mental condition was normal. He made an uninterrupted recovery.

From the time of admission until April 7th the patient was treated constantly by lumbar puncture and injections of meningococcic serum, both intrathecally and intramuscularly, as will be seen from the accompanying Table, the doses varying between 10 c.cm. and 25 c.cm. daily. He was given 320 c.cm. in all. The temperature kept between 99° and 103° F.

dose and the best way of introducing it into the body. The results in many cases were so gratifying that I venture to publish them with a plea for its further trial by the profession.

INTERMITTENT CLAUDICATION

CASE 1.—A male Jew, 49 years old, a heavy smoker, complained of cramps in the legs when walking, and frequent attacks of severe pain in the big toe at night. His brachial blood pressure was 160/90; the oscillometric index of the brachial artery was 4, of the right calf ½, and of the left 1. After the first injection the index was 2 in the right leg and 3 in the left, and the patient felt much better. Later, immediately before the intravenous injection of magnesium sulphate, the brachial blood pressure was 150/90, the brachial oscillometric index 4, that of the right leg 3, and that of the left leg 8. Immediately after the injection the blood pressure was 150/90, and the brachial oscillation 4½, that of both legs being 8. After the third injection the patient felt fit and walked without any difficulty, and attacks of pain at night disappeared. Before the injection the index for the right leg was 6 and for the left leg 8; after the injection both legs were 8. Now he comes once a month for examination; the oscillometric index in both legs is 6. This is an early case, where the anatomical changes have probably not yet taken place in the most distal vessels and the spastic element is predominant. The result in the following case was less dramatic.

CASE 2.—A male Jew, aged 49 years, a smoker, could not walk upstairs or uphill; his walking distance was approximately 100 yards. The oscillometric index in the right leg was ¼ or ½, in the left leg 3. After three injections the indices were ¾ and 4; he walked and felt better. At the completion of the treatment the indices were 1 and 4. He visited a spa and underwent a treatment of hot mud-baths. Three months later the indices were unaltered. There was no limit in his walking distance, but if he had to climb up to the third floor he had to do it slowly and stop once or twice for a rest.

Some benefit from the injection of magnesium sulphate was observed in all cases of endarteritis obliterans or Buerger's disease. Success depends upon the part played in the clinical picture by the arterial spasm which is invariably present.

CASE 3.—A spinster, 24 years old, had disseminated sclerosis. When she attended my surgery I noticed dead fingers in both hands with the exception of the thumbs. The normal colour returned within a few minutes of an intravenous injection of magnesium sulphate.

MIGRAINE

CASE 4.—A married woman, 32 years old, had nocturnal attacks of severe headache with vomiting and palpitation. I had the opportunity of witnessing an actual attack and I realised that I was dealing with a case of real migraine. A dozen injections of magnesium sulphate cut short the attacks and she has now been free from them for a year.

SPASM OF THE BRACHIAL ARTERY

CASE 5.—A man, 64 years old, complained of giddiness. I could not feel his pulse in the radial, brachial, or temporal arteries; by auscultation of the heart, the pulse-rate was found to be 150 per minute. The oscillometric index of the brachial artery was ¼. The arteries of the fundi were not narrowed. The day after a magnesium sulphate injection intramuscularly he felt better; his blood pressure was 100/50 and his pulse-rate 60. Two days later, seen at my surgery, the oscillometric index of the brachial artery was 2½.

ACUTE PULMONARY ŒDEMA

Several cases of this distressing condition have left me with the impression that cardiac failure was secondary to the onset of the attack. When seen very early, where the blood pressure was previously known, I found it at the usual level, but falling quickly with the progress of the attack. A paper on this subject has been published by M. Cohen.[6] Fischer[7] may be correct in attributing some cases of acute pulmonary œdema to spasm of the bronchial arteries.

CASE 6.—A married woman, aged 45, with six children, had a blood pressure of 200/220 systolic and 100/120 diastolic, and well-marked sclerosis of retinal vessels. Once in three to six months she suffered an attack of acute pulmonary œdema. She became pregnant, and from the third month of gestation the attacks increased in frequency, the blood pressure remaining at the same level. After one or two very severe attacks the patient, having learned by bitter experience the uselessness of waiting in the hope that the attack would pass off, came to see me immediately she felt a tightness of the chest. I invariably found the pulse-rate quickened, the blood pressure at its usual level, and the respiration frequent and shallow with ominous râles all over the chest. Intramuscular injection of magnesium sulphate always checked the attacks, the patient recovering in six or twelve hours.

ANGINA PECTORIS AND CORONARY THROMBOSIS

Only in some of these cases did magnesium sulphate bring relief.

CASE 7.—A married woman, 62 years old, had had essential hyperpiesis for the last few years, her blood pressure being 180/200 systolic and 100/110 diastolic, with marked sclerosis of the retinal vessels. Occasionally her blood pressure dropped to 135/80 without any sign of cardiac failure. One Thursday she experienced retrosternal discomfort and general weakness, and went to bed. On Friday she felt better and walked about. On Saturday at 10 P.M. I was called to see her; she had agonising retrosternal pain, a pulse-rate of 84, and a blood pressure of 190/110. She became easier immediately after an intravenous injection of magnesium sulphate. On Sunday she was quite well. On Monday at 4 A.M. I saw her again; she had similar pain, this time radiating down the left arm; vomiting; and the same pulse and blood pressure. She was slightly better for a while after an intravenous injection of magnesium sulphate, but the pain returned very soon. At 7.30 A.M. she presented a typical picture of coronary thrombosis; gr. ¼ of morphine was injected and she fell asleep soon afterwards.

CEREBRAL ANGIOSPASM

The diagnosis of vascular spasm in the terra incognita of the cerebral circulation is hazardous and difficult. The phenomenon is almost a new idea in medicine, and has lately been ably dealt with by Gubb[8] and Allen.[9] Angiospasm of the retinal vessels was recently discussed by Mylius (with excellent photographs) and by the author. Baillart's "La Circulation Retinienne" gives a very remarkable description of the living fundus.

I have not seen any harm result in cases of cerebral "vascular accidents" from the injection of magnesium sulphate; sometimes a striking improvement seems to follow. The ophthalmoscope does not help much in such cases.

CASE 8.—A married woman, 61 years old, had been suffering for years from essential hyperpiesis, 200/210 systolic and 110/120 diastolic, well-marked retinal sclerosis, and occasional attacks of bronchial asthma. One morning she woke and found herself unable to speak or to move her right arm and leg, the face not being involved. A neurologist who saw her in consultation diagnosed cerebral thrombosis. I saw her the following day and diagnosed influenza with broncho-pneumonia; the movements of the limbs were restored but the speech remained difficult. In my opinion the cerebral symptoms were probably due to a vascular spasm. Three weeks later speech was still improving and movement of the limbs was quite free, but cerebration at times was confused and rather childish.

CASE 9.—A childless widow, 55 years old, awoke one morning with a mist before her right eye. The pupil of this eye was enlarged nearly ad maximum, but still reacted sluggishly to light; all ocular movements were normal; the retinal vessels were slightly sclerotic, but a few arteries showed changes in their lumen. The blood pressure was 200/100. Magnesium sulphate was injected; she was ordered to bed and given a mixture of bromide, mercury, and iodide, and placed on a fruit diet. On the third day she returned with a blood pressure of 150/95 and the eye quite normal. The urine was normal and the Wassermann test repeatedly negative.

TECHNIQUE OF INJECTION AND PROBABLE MODE OF ACTION

The patient lies on a couch with the head and shoulders slightly raised, and a solution of magnesium sulphate and glucose is slowly injected into the vein. The dose is 5–10 c.cm. of a 20 per cent. solution and an equal volume of 10–40 per cent. glucose.

About half a minute after the commencement of the injection the patient feels an intense heat in the body. This is first experienced at the back of the pharynx, then in the face and neck, then in the thorax, and sometimes in the upper limbs, and it proceeds down to the rectum and genitalia, the lower limbs being the last to react. The face is sometimes intensely flushed and may even perspire; the skin of the limbs and body hardly alters in colour or temperature. The pulse becomes moderately quickened. The blood pressure is unaltered. On ophthalmoscopic examination the retinal vessels show no change.

In my opinion the magnesium sulphate probably relaxes vascular spasm by direct action on the vasomotor centre of the brain (either cerebral only or spinal as well). If it acted directly on the arterial wall, there would not be the constancy in the order of the sensation of heat. The more spastic or more clogged the vessel, the less is the sensation of heat and the less effective is the injection. The patient can tell exactly where the sensation of heat ceases, and I have found that the oscillometric index invariably corresponds to the patient's sensations. For example, if the patient does not feel the heat in his calf, the oscillometer will not show any increase in the index. I was, therefore, always pleased if the patient felt the warmth throughout the whole body.

If the intravenous mode of injection is for some reason impracticable the solution of magnesium sulphate without the glucose is well tolerated intramuscularly, but the intravenous route is the one recommended.

It is rather strange that the retinal vessels remain completely unaffected in spite of the general vasodilatation and the fact that the face is the most responsive part of the body. This retinal inaction corresponds to the findings of Baillart,[10] H. Claude,[11] and others, who have observed that the retinal vessels are unaffected by ordinary vasomotor drugs. In my opinion this is further evidence that the retinal vessels may be almost independent of the general vasomotor centres.

I did not observe any discomfort in any of my patients, although several of them were well over 60 years of age, and I think that the alarming signs of respiratory distress that have been seen in the cases of tetanus treated with magnesium sulphate may be explained as due either to the intrathecal method of injection or to excessive dosage. I usually administer the treatment to my patients twice a week.

Fortune for Melksham Cottage Hospital.—The late Mrs. Ludlow Bruges, formerly of Seend and Bath, who died in Jersey in July last, left the residue of her estate to Melksham Cottage Hospital on condition that a new wing should be built at a cost not exceeding £10,000. It is presumed that Mrs. Bruges intended the remainder of the estate to be used as an endowment fund. It is believed that the hospital will benefit to the extent of about £100,000.

Clinical and Laboratory Notes

CEREBRO-SPINAL FEVER

TREATED WITH LARGE DOSES OF MENINGOCOCCIC SERUM

By J. Todesco, M.D. Florence, M.R.C.S. Eng.
RESIDENT SUPERINTENDENT, BOROUGH HOSPITAL, CROYDON

A boy, aged 7, was admitted to the Borough Hospital on March 11th, 1932, as a case of cerebro-spinal fever. There was a history of sudden headache, vomiting, and fever on March 8th, with subsequent marked head retraction and rigidity of neck and spine. Four days previously he had been struck on the head by a stone. In 1930 he had had scarlet fever and measles.

On admission the boy was semiconscious, very cyanosed, with extreme head retraction, opisthotonos, and marked general hyperæsthesia and rigidity. The pupils were large, equal and fixed, photophobia being present. The knee-jerks were absent, and the plantar reflex flexor; bilateral Kernig's sign and tâche cérébrale were present. He was very irritable, feverish, wandering and restless at times, and resented examination. Lumbar puncture soon after admission yielded 60 c.cm. of turbid, blood-stained fluid under pressure, the fluid containing excess of polymorphs and meningococci, which were recovered on culture. He was given 20 c.cm. of meningococcic serum intraspinally. On the evening of March 13th he had severe epistaxis.

Between March 15th and 24th he was worse, being very drowsy, with marked general rigidity and head retraction, and very poor colour and pulse. There was marked general body wasting; he was reduced to "skin and bone" and had extreme general weakness. Subsequently he developed large abscesses over the right knee-joint, left side of face and neck, and left iliac crest. The abscess of the jaw was drained on April 16th and contained thick pus and large sloughs. All the abscesses were healed by April 25th.

A week later the boy began to improve; the head retraction was almost gone and the general rigidity less marked. He now appeared to understand when spoken to, but his speech was slow and hesitating. Right internal strabismus was noted. He was convalescent by May 12th and, though the right internal strabismus persisted, his mental condition was normal. He made an uninterrupted recovery.

From the time of admission until April 7th the patient was treated constantly by lumbar puncture and injections of meningococcic serum, both intrathecally and intramuscularly, as will be seen from the accompanying Table, the doses varying between 10 c.cm. and 25 c.cm. daily. He was given 320 c.cm. in all. The temperature kept between 99° and 103° F.

Date.	Cerebro-spinal fluid withdrawn.	Serum given		Date.	Cerebro-spinal fluid withdrawn.	Serum given	
		Intra-thecally.	Intra-muscularly.			Intra-thecally.	Intra-muscularly.

22	45	10	5				
23	—	—	10	Total	488	145	175

for over four weeks, showing marked daily variations; it then became subnormal and remained so.

The points of interest in this case are: (1) The recovery of the patient after a severe and progressive attack of cerebro-spinal fever, with strabismus as the only permanent disability. (2) The treatment by repeated lumbar puncture and administration of meningococcic serum over a long period, 14 lumbar punctures and a total of 320 c.cm. of serum being given. This may have influenced favourably the subsequent course of the disease. (3) The development of multiple abscesses and synovitis of the right knee-joint which, according to Netter,[1] is a favourable sign as regards recovery in cerebro-spinal fever. (4) The appearance of severe epistaxis during the first week, with temporary improvement, this not being a usual complication of cerebro-spinal fever.

I wish to thank Dr. Oscar Holden, medical officer of health for Croydon, for permission to publish this case.

RECOVERY FROM THE EFFECTS OF SYMPATHETIC DENERVATION

By Lambert Rogers, M.Sc. Wales, F.R.C.S. Edin., F.A.C.S., F.R.A.C.S.

ASSISTANT DIRECTOR OF THE SURGICAL UNIT OF THE WELSH NATIONAL SCHOOL OF MEDICINE, ROYAL INFIRMARY, CARDIFF

The fact that recovery gradually takes place from the ocular changes produced by cervical sympathectomy is not generally known, though the late Sir Percy Sargent was aware of it.[1] It has been observed, however, that the pupil of the rabbit subjected to cervical sympathectomy gradually recovers its size, and recently I have had an opportunity of observing a similar recovery in man. Four years after a cervical sympathectomy, recovery from its effects was almost complete, despite the fact that at the operation half an inch of the cervical sympathetic trunk with its middle ganglion had been removed.

In January, 1928, a railway guard, aged 25, was transferred to the surgical unit of the Welsh National School of Medicine with acute exophthalmic goitre. The goitre was very small, diffuse, and highly vascular. He was treated by stage ligation of the thyroid arteries, and his general condition, including that of his cardiovascular system, improved considerably. Exophthalmos, however, persisted and was so pronounced on the left side, that it appeared as if this eye might become dislocated or meet with some injury. Accordingly, on Dec. 3rd, 1928, cervical sympathectomy was carried out on the left side, the middle ganglion and half an inch of the sympathetic connecting trunks above the ganglion being removed through an incision along the anterior border of the sternomastoid. As a result of the operation, the left *palpebral fissure immediately diminished in width, and the* pupil of the same side contracted to a pin-point and remained so contracted when the other pupil dilated in weaker light. He made a gratifying recovery and returned to work. It was not considered necessary to perform a similar operation on the other side. Although the right eye was somewhat protruded this did not inconvenience him.

At the present time, over four years since the denervation, both palpebral fissures *are the same width; the left pupil* in strong light contracts more than the right but dilates well in shade, and when the right pupil is at its maximum width the left is only very slightly smaller. A very considerable degree of recovery has therefore occurred.

The mechanism of the compensation which takes place when such recovery occurs is being investigated. The fact that recovery from the ocular changes comes about, brings this feature of sympathetic activity into line with the vascular responses to sympathectomy which, as is well known, are soon recovered from. The rapidity of adjustment following the changes induced by peri-arterial denervations has previously formed the subject of communications by Hemingway and myself[2] [3] and others.

A CASE OF GENERALISED VACCINIA

By C. J. de Vere Shortt, M.B. Dub., D.P.H.

LATE MEDICAL OFFICER OF HEALTH AND PORT HEALTH OFFICER, ABADAN, SOUTH PERSIA

Although after vaccination secondary pustules are sometimes seen round a primary mark, generalised vaccinia is comparatively rare.

On Dec. 1st, 1932, I vaccinated a well-nourished healthy baby weighing 15 lb., aged 3 months, using Government Establishment lymph, and making one scar on the left arm. At the same time I vaccinated an elder child, aged 10 years, in the same house, using the same lymph. On Dec. 7th I inspected both arms, and found them both clean and healthy, presenting the features of a normal six-day vaccination. On Dec. 20th I was asked by the medical officer of health if I would call and see the younger child as some spots had broken out over the body. When I arrived I learned that about three days previously the spots began to appear. The outer surface of the left arm was bright red, the redness extending from 1 in. below the shoulder to about 1½ in. above the elbow. This arm was covered by necrosed skin, and presented the appearance of a large blister out of which the fluid had been withdrawn. There was a slight temperature (99° F.). The child was restless, fretful, irritable, and refused food. On the wrists, thighs, legs, and head, there were raised pearly spots in varying stages of development, and of various sizes, some of which were umbilicate and some appeared more like alastrim spots than those of small-pox.

On Dec. 21st the child was admitted to Fazakerley Hospital under the care of Dr. C. Rundle. On admission there were numerous small vesicles around the original larger one on the left arm, and the spots on the body had developed into typical vaccination pustules. The distribution was then face, back of scalp, both wrists, left thumb, right buttock, and several on the right leg and thigh, and soles of both feet. The temperature was 99°; pulse 132; respiration 34. On Dec. 23rd the temperature went up to 100·4°. The pulse-rate was 144, and the lesions were spreading with copious eruption on both legs and buttocks, and on the face some of these were the size of a shilling. The temperature then fell to normal and remained so till Dec. 26th. On the 25th fresh pustules developed on the back and front of both thighs, but with no rise of temperature. On Dec. 26th the temperature again rose to 99·6°, and the arm became very baggy and was inclined to slough. There were numerous water vesicles at the outer edge. The child was taking food well. On the 27th the temperature rose still further to 100·4°, with pulse-rate 178, and the child developed convulsions and died.

The *post-mortem findings* were as follows:—

The body was that of a well-nourished child. Over the outer surface of the left upper arm was a bare bright red inflamed area 4 in. long by 3½ in. in diameter, and extending approximately from the shoulder to the elbow. There was some deeper coloration of the central portion, suggesting that this was the oldest portion of the lesion and that it had commenced there. The body was covered with raised pearly spots varying in size from about ⅛ in. in diameter up to ¼ in. The larger of these were depressed in the centre and had thickened edges resembling blebs and giving the appearance of developing vaccination pocks. The largest and oldest lesions showed necrosis in the centres and the formation of crusts. There was little or no pustulation. The distribution of the lesions was general but they were more numerous on the lower limbs than on the trunk and upper part of the body. The thoracic organs were healthy, except for some terminal congestion and œdema of the lung bases. The liver and spleen both showed areas of necrosis having the characters of vaccinia lesions. The other abdominal organs showed no abnormality.

---

[1] Quoted by Rolleston, H. D.: The Lancet, 1919, i., 600.

Microscopical examination of the skin lesions showed these to have the character of vaccinia papules. The same characters were found in the focal lesions of the spleen and liver. No changes of importance were found by microscopical examination in the brain and spinal cord or in the other organs (suprarenal, heart, kidneys, pancreas) which were examined in this way.

It is obvious from the pathological report that this has been a blood-borne infection. Dr. J. H. Dible, professor of pathology in the University of Liverpool, has stated that he has never seen a case of this kind. It can hardly arise from any septic infection, for the parents and home were extremely clean and there is no evidence of such infection being present. While I was in Persia several thousand vaccinations were done either by me or under my supervision. The scar was made and the lymph was allowed to dry on. It was impossible to keep either pads or bandages on the natives' arms, so after drying they were left uncovered. No untoward result was ever seen. I have had several letters on the subject, and in one the writer has reported to me a case of general vaccinia which occurred in a baby that had been washed in water with which an elder child, who had been vaccinated, was bathed.

I am indebted to Prof. Dible for the report on his post-mortem and bacteriological findings, and to Dr. C. Rundle, the medical superintendent of Fazakerley Fever Hospital, for his notes on the case whilst it was under his care.

MEDICAL SOCIETIES

FELLOWSHIP OF MEDICINE

On March 9th Lord MOYNIHAN took the chair at a meeting of the Fellowship of Medicine and Post-Graduate Medical Association which was held in the rooms of the Medical Society of London and was occupied by a debate on

Operation for Appendicitis

Mr. R. M. VICK said it was a tragic thing that in the year 1933, so long after Treves, so many doctors were willing to discuss whether or not the appendix should be removed when inflamed. He hoped that the revived expectant treatment would be stamped out and its ghost laid. He spoke only of those cases in which the diagnosis had been made as certainly as was humanly possible and where the condition had not subsided by the time the surgeon arrived. In all such cases operation should be performed at once. This battle had been fought out long ago, and the need for operation established. Hundreds of people to-day owed their lives to that recognition. Yet the devil of doubt had arisen again—partly because of the universal fear of operation, partly because not all operations were done by surgeons of experience, and partly through the eternal desire for change. A rising mortality in appendicitis was coming, owing to this pernicious revival of expectant treatment. Sooner than proffering statistics he would say: "Behold, I have passed through the valley of the shadow and I have seen terrible things." Why should we postpone an operation which was always successful, easy to perform, and which transferred the patient from a state of danger to a state of safety: the operation within 48 hours of onset? He would, indeed, go further and advise operation on every inflamed appendix. What applied to adults applied a hundredfold more to children. There would be no great danger and a certain amount of sense in waiting, if it were possible to know what was happening to the appendix, but it was not possible. He proposed "That in every case of acute appendicitis immediate operation was indicated."

Mr. V. ZACHARY COPE opposed the motion, particularly the words "immediate" and "in every case." There were cases in which immediate operation would be disastrous. He agreed with operative measures in unperforated cases, in cases of doubt about perforation, in cases of well-formed abscess, and in most children, but he did not operate in advanced peritonitis; or in cases with a well-formed lump not apparently getting worse; or on patients whose general condition was very bad, and in whom preliminary recuperative treatment, such as saline infusion, might make the operation safe after 12 hours. Many patients had had no treatment before they saw the surgeon and needed preparation for operation. Every case must be judged on its merits, or what was the use of surgical skill and experience? Expectant treatment had not been tried in past years because most of the measures concerned had been unknown in those days. Was the rule of thumb to displace experience? A skilled clinician could tell how the pathological process was going in most cases. In doubt, operation should be performed. There would be no danger of calamity if the patient were put immediately under the care of a skilled surgeon.

Mr. W. H. OGILVIE said that appendicitis was an everyday problem and must be approached with an open mind. He felt almost inclined to agree with Mr. Cope. There were cases of appendicitis in which immediate operation was unwise, but he doubted if these cases were "acute." They were subsiding by the time the surgeon saw them, and were not manifestly ill. Nor was operation desirable in bad surroundings. Nevertheless he only felt justified in withholding operation in 1 or 2 per cent. His experience had impressed him with the fallibility of human judgment. With exactly the same history and physical signs, the appendix might be found distended with pus and about to burst, gangrenous and not distended, or apparently healthy with a little inflammation inside only. Nor could he forecast what was going to happen, and he had much fear for the watched case. The demand for revision of treatment was based on the Registrar-General's figures, which showed that the total mortality had not decreased. These figures, however, did not indicate the great increase in the number of operations and the improvement in diagnosis. He believed the mortality to be no more than a third of what it had been. In Denmark the mortality had been shown to increase steadily with every day that elapsed between onset and operation. The real bone of contention was the third- to fifth-day case with rising temperature and pulse-rate. Mr. Ogilvie confessed that he lacked the courage to wait. At the beginning the risks could be foretold, but as time passed the gamble became greater. He had always operated and had lost only one case: from pulmonary embolism on the tenth day. He put in a plea against being too clever in surgery. The general and the particular aspects of a case were apt to be in conflict. Brilliant surgeons and prognosticians had led humbler men into paths of danger. Appendicitis was the job of the journeyman surgeon, and for him operation was the right course and the safe course.

Mr. **R. J. McNeill Love** divided cases of appendicitis into four groups. Everyone agreed that the early cases demanded operation and the subsiding ones to be left alone. The third group was that complicated by general peritonitis. The fourth was the one needing careful consideration: the patient was seen about 48 hours after onset and showed some elevation of temperature and pulse-rate, localised rigidity, and tenderness per rectum. These cases were what older practitioners had termed perityphlitis. Operation was difficult, drainage was usually necessary, and localised peritonitis became potential generalised peritonitis. On the fifth day the patient was in a negative phase of resistance, and the operative mortality was about 5 per cent. Complications, also, were encouraged by untimely operation. Expectant treatment must rigorously enforce the four F's—Fowler's position, fluids only, fomentations, and a four-hourly chart. Water only must be given by the mouth, and this did not mean beef-tea and custard. Children should not be treated expectantly, for they had usually had purgatives. If the case were watched the inflammation might subside in 50–70 per cent. of cases, and a clean operation without complications could be performed later. An abscess might form in 25 per cent., but this was no occasion for panic; it showed that the resistance could arrest spread of infection. Usually the abscess would resolve, but should be opened if it increased in size or was absorbed too slowly. Gas-and-oxygen and a small incision were adequate. Thirdly, in 10 per cent. of cases, the patient might require emergency operation, but even here the mortality was only about 6 per cent. The average mortality after expectant treatment was no more than 3 per cent. The patient must be under surgical observation the whole time. Localisation would probably occur if the appendix were retrocæcal or paracolic, and infection would spread from an appendix pointing inwards or upwards. Psychology played an important part in the public estimate; for if the watched patient succumbed everybody felt he might have survived if operation had been performed at once; but if he died after immediate operation he was soon buried and forgotten.

Mr. **W. Turner Warwick** said he would operate a little earlier without the help of an experienced surgeon than he would if this were available. The retrocæcal type of appendix might or might not develop an abscess; these could be operated on at any time. The pelvic type should always be operated on at once. Those that spread to the left fossa should be opened up or there would be several separate collections of pus. The retro-mesenteric appendix was very dangerous, producing thrombosis or a small abscess with obstruction of the ileum; but when treated early these gave a good prognosis. When the appendix ran behind the peritoneum on the posterior wall a spreading cellulitis might result, and be almost impossible to treat if suppuration were allowed to supervene. His advice, therefore, was to distrust philosophy and operate on the acute appendix.

Mr. **A. Tudor Edwards** agreed that a waiting policy was advisable in two kinds of case—the subsiding case, and the abscess in a patient whose temperature and pulse were settling down. Otherwise he was in favour of immediate operation.

Mr. **Hamilton Bailey** advocated the method o Sherren. In acute cases with a localised palpabl mass, the mass usually disappeared; if the absces burst, prompt treatment would save life. Two and preferably three months should elapse between resolution and appendicectomy. The rule of letting out pus whenever it was present could frequently b broken and, if so, the day of surgical judgment could not be said to be past.

Mr. **W. B. Gabriel** was in favour of immediate operation, and believed that the mortality was extremely small. The expectant treatment of abscess had found favour because some abscesses had been injudiciously and crudely operated on.

Mr. **H. J. Paterson** said that appendicitis, if treated intelligently, was not nearly such a serious disease as was supposed. He opposed the motion. A perforated appendix was not necessarily fatal. Nature was a far better surgeon than even the youngest of us. In 1911 he had opened a debate at the British Medical Association on the side of operation, but since then he had learned wisdom. Thorough preparation was absolutely essential for any operation, and particularly in acute cases. Very often the preparatory treatment produced such improvement that operation was unnecessary. In the last two and a half years he had had 59 delayed cases with no deaths, and 26 immediate operations with 2 deaths. He could see no objection to drainage; better a weak spot in the abdomen than a coffin, however well padded. That sepsis required drainage was one of the eternal verities of surgery. Was operation always desirable from the patient's point of view? Immediate operation was not necessary in most cases of acute appendicitis, and cases of general peritonitis were better left alone. Surgery was still an art, and there was still room for common sense and clinical judgment.

Dr. **A. Campbell** pleaded for the young graduate who had been urged to let out pus whenever it was present. The expectant treatment demanded a degree of skill that could not be demanded of a young man. It was safer for the young man to operate, provided he worked with skill, and when he had had experience he could select cases for watching.

Mr. **Sinclair** thought that the expectant treatment sometimes left patients with unresolved lumps. He operated in all cases, except that he did not remove the appendix from a localised abscess, especially in children, in whom the risk was very great.

Mr. **C. E. Shattock** was in favour of operation, and emphasised the importance of the technique.

Dr. **Bateman** was also in favour of operation.

Mr. **Stanford Cade** said that all acute appendices should be removed early and then there would be no abscesses and fewer cases of peritonitis. He classified appendicitis into two groups—the early in which the surgeon operated, and the late in which the undertaker officiated. Very few surgeons could say what a particular appendix would do; the risk of operation was known and justifiable; the risk of waiting was unknown and unjustifiable. Conservatism in operation was in direct proportion to the amount of arterio-sclerosis in the surgeon's arteries. There was only one treatment for appendicitis.

Dr. **Walker** (Sydney) argued that no surgeon was thinking of making appendicitis a medical disease. It was a disease that must be treated by operation; but the question was: when? In some cases it was wise to stay the hand. The question was one of life. The figures demanded some improvement in treatment, and the improvement lay in the selection of cases. Young men need not fear the difficulty of judgment; in 20 years' time all surgeons would be able to make the decision with ease.

Mr. M. J. **Petty** agreed that early cases should have immediate operation, but if complications arose the younger man should seek help. In the Argentine patients travelled great distances to hospital, and signs of previous perforation were sometimes found. Many cases could survive non-interference. For amœbic appendicitis operation should be immediate.

Mr. **Cope**, in reply, pointed out that "early" cases were not mentioned in the motion; Mr. Cade's remarks were beside the point. The motion declared that every case was to be operated on immediately, however ill the patient, however bad the conditions, however inexperienced the surgeon. Every speaker on the other side had immediately began to make excuses and beg the terms at issue. Only through bitter experience, and not arterio-sclerosis, had Mr. Cope come to the opinion that there were some few cases which should be left, and if there were some few cases the motion must be lost.

Mr. **Vick** accused Mr. Cope of playing with words. Nobody in his senses would operate on a patient dying of acute peritonitis. The people who had spoken against operation had failed to appreciate the danger of spread. General practitioners taught to watch their cases would not call in surgeons to help them.

The **Chairman**, summing up, said that years ago he had opened a debate in favour of immediate operation. The really essential point in the debate had been entirely omitted: the aperient treatment. Patients never died of appendicitis: they died of its treatment. All acute appendicitis was obstructive, and if no aperient treatment were ever given no case would ever become really active. He had never seen a gangrenous perforated appendix in which an aperient had not been given and had not been the cause of the flagrancy. No danger would derive from expectant treatment if aperients were withheld and if nothing whatever—particularly not water—were given by the mouth. A single drop of water caused intense writhing activity of the ileocæcal valve. Geographical and surgical conditions might be bad, but if they were satisfactory and the case was seen early there could be no question at all that operation was the best thing, and no patient ought to be lost. The question could not be answered with an absolute affirmative or negative, but only by the exercise of clinical sagacity. Only in children was the greatest expert apt to be at fault: no child should be left alone with his appendix for half an hour. Whatever the surgeon might feel about prognosis he must inevitably and without exception operate if an aperient had been given. If not, the best conditions might be sought even at the price of some delay.

On a show of hands the motion was declared passed by 54 votes to 49.

MEDICAL SOCIETY OF INDIVIDUAL PSYCHOLOGY

At a meeting of this society held on March 9th, with Prof. W. **Langdon Brown**, the president, in the chair, a paper on the

Psychological Surroundings of the Surgical Patient

was read by Mr. W. **McAdam Eccles**. He began by speaking of some general aspects of his subject, including the terror with which the word "operation" fills many people. He then considered specifically the characters taking part in the drama of the surgical operation. The general practitioner, he said, took the part of the prologue. He selected the surgeon; and incidentally his implicit confidence in the man he chose was a valuable preliminary to the establishment of that mutual confidence between surgeon and patient. But not only confidence of the sufferer in the surgeon, but confidence of the surgeon in himself and in his team was essential. Certain minor pre-operative details helped to render the mood of the patient suitable for undergoing an operation. It was of value to permit him to enter the hospital or nursing-home two nights before the operation. On the first night the bed was strange and the surroundings unfamiliar, so that in any case sleep might not be good, especially if an aperient was given. It was better to give the aperient early next morning, and to allow the bowels to act during the day. The second night could be made more comfortable by a simple sedative, and a small, hot cup of tea should replace a distressing early morning enema. The time of the operation should be fixed definitely, and the patient should be in the hands of the anæsthetist five minutes before. Those last five minutes before the hour were apt to be filled with dread, and the minutes after were regarded with veritable horror.

Speaking of the psychological effects of local, spinal, or rectal anæsthesia, Mr. Eccles pointed out that some people dread loss of consciousness. On the other hand to be wholly or partially conscious during an operation might have a disagreeable and lasting effect upon memory, even upon mentality. In addition, a very definite, though often unmeasurable mental element entered into the causation of "shock."

The period after the operation was also important. To find oneself alone when returning to consciousness might be a real shock, and to be deadly sick without a receptacle for the vomit was very distressing. Nothing in convalescence was more encouraging than the prospect of a speedy recovery, if such could be foretold. If, on the other hand, the surgeon knew that recovery might take a long time, it was well to introduce this necessity gradually to the patient's mind, and to prepare to mitigate its irksomeness.

A discussion followed.

ROYAL ACADEMY OF MEDICINE IN IRELAND

A meeting of the section of medicine was held on March 3rd, with Dr. W. G. **Harvey**, the president, in the chair.

Pernicious Anæmia

Prof. **Henry Moore** and Dr. W. R. **O'Farrell** described the case of a woman, aged 58 years, with anæmia, Addisonian in type, but with a normal curve of gastric hydrochloric acid in the fractional test-meal (done on three different occasions).

The patient, Dr. Moore said, complained of weakness, dyspnœa on exertion, looked sallow, and the appearance of the tongue was typical of pernicious anæmia (beefy-red, furrowed, with atrophic papillæ). The red cell count was 2,490,000 per c.mm., the leucocyte count 2000, the hæmoglobin 63 per cent., and the colour-index 1·32; there was a distinct megalocytic tendency, the average size of the red cells, with a Price-Jones count, being 8·13 μ; there was slight but distinct poikilocytosis, polychromatophilia, and punctate basophilia: no normoblasts were seen. The differential count was normal. The blood bilirubin was 1·9 mg. per 100 c.cm.

Liver treatment by mouth gave a reticulocyte response (10 per cent. in ten days) and in two months, with no other form of treatment, the blood count showed red cells 4,640,000, leucocytes 4800, hæmoglobin 100 per cent., and colour-index 1·08; aniso- and poikilo-cytosis were slight, with absence of punctate basophilia and polychromatophilia, and the blood bilirubin content became normal. The patient has remained quite well up to date. She took liver extract or liver by mouth for one year but has discontinued the treatment for the past six months without relapse.

Dr. O'FARRELL said it was very uncommon to find a patient with pernicious anæmia with free hydrochloric acid in the gastric juice, but he felt very strongly that this case was one of pernicious anæmia. Megaloblasts were seldom seen except in very bad cases, and he would not lay much stress on their absence, because the patient's anæmia was never low enough to show them. He was of opinion that in any case the presence of megaloblasts was not sufficient to establish absolutely the diagnosis of pernicious anæmia.

The PRESIDENT agreed that pernicious anæmia without achlorhydria was very rare, but thought that Dr. Moore had made out a good case for their existence.

Dr. V. M. SYNGE suggested that pernicious anæmia was not a definite disease, and said that he frequently came across borderline cases which did not exhibit the complete picture of that disease, though they improved more under liver treatment than other cases of anæmia did.

Dr. W. R. F. COLLIS said he had under his care a patient who was exactly the opposite of Dr. Moore's. The case was one of microcytic anæmia with achlorhydria, and iron had no effect at all on the condition. He had given iron and was now giving vitamin C, in the form of a tumblerful of orange juice three times a day.

Dr. G. T. O'BRIEN referred to the case of a woman, aged 38, who was suffering from pernicious anæmia. A test-meal a week after admission gave a high gastric curve and demonstrated the presence of free hydrochloric acid in the stomach. She was treated by Hepatex and improved rapidly. In the first blood count nucleated red cells were found, but not in subsequent-counts. Tests of fæces for occult blood were negative.

Dr. GEOFFREY THOMPSON said that pernicious anæmia, as originally described by Addison, undoubtedly included a number of cases which nowadays would not be given the name. The question now was, What is pernicious anæmia? He thought that it should be regarded not as a definite disease but as a syndrome characterised by certain features —namely, anæmia, increase in the size of the red cells, active destruction of the red cells in the body, and achlorhydria. It was only when the disease was in the stage of active hæmolysis that any reaction from liver treatment would be obtained.

Dr. MOORE, in reply, said he thought that undoubtedly there were borderline cases, but he himself had never come across one.

Dr. MOORE also showed a patient with atrophy of the metatarsals and of the phalanges of the feet; Dr. SYNGE showed a patient with a lump on the skull; and Dr. G. BEWLEY described a case of peripheral neuritis followed by acute necrosis of the liver.

CORRIGENDUM.—Dr. E. ff. Creed writes: "The report of my remarks at the last meeting of the Medical Society of London (as given on p. 475 of your issue of March 4th) omits the vital point in establishing the diagnosis of this ten-day case of undulant fever—namely, that the agglutination tests were repeated four days later—i.e., 14 days from the onset, and four after the temperature had fallen, and the agglutinin titre to *Br. abortus* had then risen to 1 in 200."

NORTH OF ENGLAND OBSTETRICAL AND GYNÆCOLOGICAL SOCIETY

A MEETING of this society was held at the University, Sheffield, on Feb. 24th, with Prof. LEYLAND ROBINSON (Liverpool), the president, in the chair.

Gynæcological Cases

Prof. MILES H. PHILLIPS showed a specimen demonstrating an unusual source of severe *post-menopausal bleeding*.

The patient, a multipara aged 61, had two severe floodings 15 years after the menopause. Her regular periods had ceased in 1916 at the age of 44. Thereafter she had a period lasting five or six days in the February of each second year until 1930, when she had a menstrual-like loss lasting for six months. At no time had there been any pain or discharge.

On examination the cervix was free from any signs of new growth and the uterus was felt to be rather larger than a cricket ball. On the assumption that the case was one of malignant disease of the corpus uteri a panhysterectomy was performed without preliminary curettage. The specimen showed a hard fibroid projecting into the cavity of the uterus, the mucosa being slightly ecchymosed in several places and showing a black area suggestive of a clot in a small vessel.

Prof. Phillips concluded that the source of the hæmorrhage was a ruptured vessel in the capsule of the fibroid.

The PRESIDENT and Dr. M. DATNOW (Liverpool) showed a case of *very early tubal pregnancy*.

The patient, a parous woman of 36, was admitted to hospital on account of some slight menstrual irregularity which led her doctor to suspect ectopic gestation, her last period being a week overdue and having been followed two days later by acute pain in the lower abdomen. Bimanual examination failed to reveal any pelvic abnormality, but posterior colpotomy revealed two small blood clots in the pouch of Douglas, so laparotomy was performed. There was no free blood in the peritoneal cavity but the left tube was found to be distended to the size of a man's little finger, with a distinct bulge about its mid-point. There were no adhesions to surrounding viscera. The tube was removed and the patient made a complete recovery.

Serial sections through the tube revealed embryonic elements in 120 sections through a thickness of 0·48 mm., and the sections showed that an ovum had become embedded in the submucosa of a plica at the blind end of a diverticulum and had developed in the tissue between the lumen and the mesosalpinx.

They thought this was a very early example of an ectopic gestation where the ovum had perished at a time antecedent to that in which the trophoblastic epithelium is differentiated into branched processes containing mesothelium, and they considered the ovum, as shown by the sections, to be a little more than a week old.

Mr. W. GOUGH (Leeds) showed a case of a *sarcomatous polypus* treated by radium and later by hysterectomy.

A woman, aged 46, gave a history of the passage of clots per vaginam for 16 days, and between the passage of clots there had been an offensive discharge. She had had slight pain in the lower abdomen and also some difficulty in the commencement of micturition for one week. Examination had revealed the fundus uteri one inch above the symphysis and a large rounded smooth mass protruding from the cervical canal through a widely dilated cervix. At operation the mass was found to be very friable and as much as possible was removed piecemeal, but examination showed a considerable amount of growth still within the uterine cavity. Radium was inserted in the uterine cavity for 75 hours, the total dosage being 4160 mg.-hours. Pathological examination showed it to be a polymorph-celled sarcoma. One week later she was readmitted to hospital and panhysterectomy was performed. On pathological examination of the uterus no trace of sarcomatous tissue could be found in four separate areas.

Prof. PHILLIPS also demonstrated a case of *ante-partum moulding of the head in a breech presentation due to oligohydramnios*.

MEDICAL SOCIETY OF LONDON

Chronic Pancreatitis

Sir JOHN BROADBENT took the chair at a meeting of this society held on March 12th, and Mr. A. J. WALTON opened a discussion on Chronic Pancreatitis.

THE SURGICAL SIDE

He described an investigation he had undertaken into 165 cases of cysts, pseudo-cysts, calculi, and chronic pancreatitis, and 47 cases of pancreatic carcinoma. Chronic pancreatitis with calculi was, he said, very rare, but the differentiation between the interlobular and the interacinous forms was important. A pseudo-cyst was caused by an extravasation about the pancreas, usually from trauma; a symptomless tumour appeared and pain intervened later, and a large cystic cavity was found above a normal pancreas. About half the true cysts started as cystic adenomata; they were neoplasms which had undergone a cystic degeneration. Others might be due to definite obstructive lesions in the head of the pancreas. Primary chronic pancreatitis had an ill-defined pathology and was closely related to the acute and subacute forms. The changes were definite enough at autopsy, and fell into two groups: those in which the fibrosis was distributed regularly through the pancreas, and those in which its distribution was more irregular and nodular. At operation it was difficult to detect owing to lack of knowledge of the characteristics of the normal pancreas. Moreover, the irregular type of chronic pancreatitis might be localised to the head of the gland, and be found almost if not quite indistinguishable from carcinoma. Evenly distributed fibrosis led in some cases to a shrunken, distorted, atrophic condition. Under the microscope the two main groups were easy to determine; in the interlobular group relatively large masses of the gland were cut off by fibrosis, and there was thickening and irregularity which did not interfere much with the gland unless it obstructed the common bile-duct. In the interacinous type the fibrosis ran regularly through the gland and tended to interfere with the islets of Langerhans. The two groups might overlap.

A number of cases developed diabetes later—in Mr. Walton's series 4 out of 61. Two cases had developed carcinoma. Conversely, out of 47 cases of carcinoma of the pancreas 4 had previously suffered from chronic pancreatitis. Careful attention to the symptoms could almost entirely obviate misdiagnosis: only one case of carcinoma had been mistaken for chronic pancreatitis, and only one of chronic pancreatitis for carcinoma. His series had, he said, included 30 men and 31 women, and the commonest age had been between 40 and 60. He had not met the disease in adolescents. It was becoming more and more difficult to believe that infection reached the pancreas by the common bile-duct. Evidence was accumulating to suggest that it passed from the gall-bladder by the lymphatics, and that it might be blood-borne.

Symptoms fell into three groups—diabetes, jaundice, and pain. Mr. Walton said that, for administrative reasons, he saw very little diabetes. The majority of cases had obstructive jaundice. The onset of the jaundice was slow; there might be a premonitory attack with freedom for several months, after which the condition progressed with definite characters. The patient lost the bright orange-red of gall-stone jaundice, and became green and grey, and bile disappeared from the stools and appeared in considerable quantities in the urine. Itching became intolerable. Pain, in the early stage, was that of periodic dyspepsia, and might, like jaundice, be manifested in a premonitory attack. It was something like that of peptic ulcer, but there was "something wrong," and the clear-cut ulcer history was absent. If the patient did not come until pain was continuous there was a danger of the misdiagnosis of carcinoma, but there were often superadded attacks of acute pain like that of biliary colic. Sometimes pain was added later to jaundice. Except for the determination of the undigested fat content and of the diastase index, chemical tests were not of great value. X rays had been helpful in a negative way; sometimes a large mass might be seen indenting the duodenum, but the appearance was more common in carcinoma of the pancreas.

The treatment of the diabetic case was essentially medical, in the absence of gross gall-bladder disease. When there was a mild degree of pain suggestive of gastric or duodenal ulcer, and when the patient's weight was reduced, the case was probably one for medical treatment, but it was difficult to make an accurate diagnosis without operation. Calculi must be operated upon. To relieve obstructive jaundice it was necessary to form an anastomosis between the dilated gall-bladder and the stomach or duodenum. This operation was not free from risk. Cases without jaundice fell into three groups. Those with little evidence of obstruction and marked evidence of gross gall-bladder disease were treated by cholecystectomy, the common duct being explored. When the lesion of the gall-bladder was mild and there was a possibility of dilatation of the duct, Mr. Walton did a cholecystoduodenostomy. In mild or invisible infection of the gall-bladder with no obstruction there were two possibilities: cholecystectomy and drainage, or medical treatment after simple laparotomy.

THE MEDICAL SIDE

Sir WILLIAM WILLCOX said that diagnosis was a matter of elimination and was usually made by the surgeon. There were no reliable laboratory tests and no objective signs, for the pancreas could rarely be palpated, and was transradiant to X rays. Diagnosis, therefore, depended largely on subjective symptoms, but in some cases there was a tendency to profuse hæmorrhage. Sir William thought that in many cases, particularly those associated with calculi, infection spread up through the duct, and also that infection might be blood-borne. The ætiology fell into four groups. The most important one was where the pancreatitis was secondary to infections of the gall-bladder and intestinal tract. It might also be due to a general blood infection such as typhoid, food poisoning, or exanthemata, and occasionally to syphilis and tuberculosis. It might follow poisoning by chemicals such as alcohol and lead; and it might be associated with some other lesion of the pancreas, such as cysts, calculi, or traumata. Chronic pancreatitis might resemble a gastric lesion, and might be associated with obstructive jaundice or with diabetes.

It was important to do the van den Bergh or icterus index test for latent jaundice. The urine diastase might be immensely raised, and a low diastase reaction was a strong nidication against pancreatic disease. Glycosuria was not common. The blood-sugar test and glucose-tolerance curve were not sufficiently often determined; in advanced disease there might be a positive result. An increase of fat in the stools was an important sign. If salol and saladine were given, salicylic acid and iodine respectively might be excreted in the urine. Sahli's test—the administration of methylene-blue or iodoform in a gelatin capsule hardened with formalin—was useful.

Medical treatment was disappointing in many cases. Associated lesions should be dealt with, and infection of the intestine by non-lactose fermenting organisms should be combated by irrigation, vaccines, and antiseptics. Saline aperients and iodides might be given. The dietary should be fat free, carefully selected, and pancreatin and alkalis might be administered to aid digestion.

THE CHEMICAL SIDE

Prof. E. C. **Dodds** said that chemical tests were of very little assistance, because the pancreas, like the liver, had such a large reserve of efficiency. The diastase test was absolutely valueless in chronic pancreatitis, though in the acute form it might be of great value when it showed over 200 units. There was no reason why the diastase should be high in a destructive lesion of the pancreas, and the content depended on many factors other than the pancreas itself. Sixty to 100 units might be found in a normal subject. Glycosuria, unless very severe, was not a reliable index of pancreatitis. The glucose-tolerance test had been a complete failure. The fat content of the fæces was always very high in acute pancreatitis, but the normal variation was much wider than the orthodox figure of 25 per cent.

DISCUSSION

Mr. **Zachary Cope** described a case of pancreatic dilatation due to gummata. He asked whether Mr. Walton ever found any difference in the dilatation of the duct in chronic pancreatitis and in carcinoma; he had found the pancreatic fluid under great pressure in two cases of neoplastic obstruction.

Dr. G. E. **Vilvandré** said that he had visualised pancreatic calculi by X rays in six cases.

Mr. **McNeill Love** suggested that chronic pancreatitis might affect the prognosis in abdominal and gall-bladder infections.

Mr. W. E. **Tanner** gave a warning against the hasty removal of the gall-bladder when the abdomen had been opened for chronic abdominal pain and nothing had been found. Mr. Walton's operation, he said, for choledocho-duodenostomy was rather a difficult and dangerous one. He asked the minimum pathological appearance of the gall-bladder which would justify its removal.

Mr. L. E. **Norbury** pointed out the uncertainty of differential diagnosis between carcinoma of the head and chronic pancreatitis, and suggested that the surgeon should not be too pessimistic in telling his prognosis to the relatives.

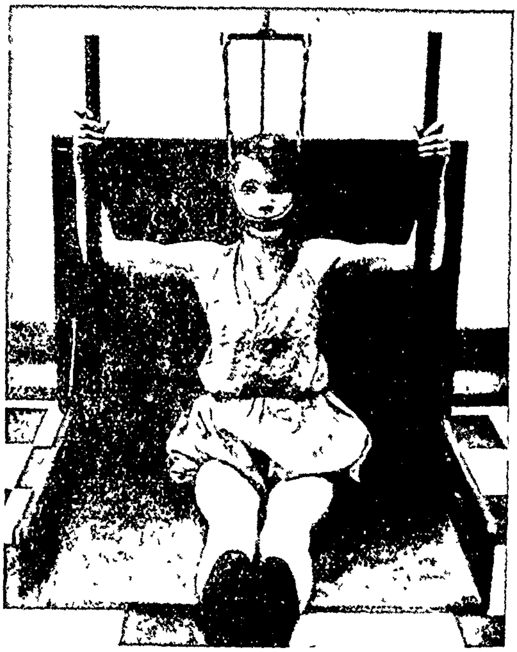
Mr. **Philip Turner** described a case of gummatous infiltration of the alimentary tract which had strongly resembled cancer. He deduced the lesson that, in encountering an unusual and unexpected condition in the region of the pancreas, one should always bear syphilis in mind.

Mr. **Walton**, in reply, laid stress on the analysis of the patient's history as the chief means of diagnosis. The pain was more or less characteristic in its periodicity and in the amount of flatulence associated with it; it was present at night, and not relieved by food, and it alternated with short attacks of severe pain running to the left shoulder. The surgeon was, he said, never justified in removing the viscus purely on symptomatology, and he did not remove a gall-bladder unless it was grossly diseased. If a gall-bladder were white or grey instead of blue, he might explore the interior.

NEW INVENTIONS

BENTLEY PORTABLE HEAD-SUSPENSION APPARATUS

The simple piece of apparatus shown in the illustration is really a portable Fisher frame. On the back of the upright board is a vertical steel mast carrying the usual transverse bar and head sling. The mast can be adjusted so that any patient of reasonable size can be suspended with the buttocks clear of the floor board, thus allowing all the body-weight except that taken by the heels to act through the spine. The particular merits of this apparatus are: (1) it eliminates the fright and faintness that some children experience when slung from the ceiling or from a high bar; (2) the flexion of the hips counteracts any tendency to lumbar lordosis; (3) the arm bars at the side allow the child to brace the shoulders and spine against the frame during the performance of deep-breathing exercises; (4) the child can release herself from suspension when necessary, thus saving the masseuse the trouble of having to leave another patient to release the child who is suspended; (5) its portability and its low cost.



This apparatus may be used for the post-operative treatment of torticollis and for the treatment of all spinal defects in which suspension is desirable. It was designed by Miss Bentley, who is in charge of the remedial exercises clinic at the Royal National Orthopædic Hospital, Great Portland-street, where it is now in constant use. It has been ordered, or is being installed, at a number of the clinics in connexion with the hospital, for it appears to have many advantages over the usual type of suspension apparatus.

It was originally made in the workshops of the hospital, but may now be obtained from Messrs. Stanley Cox, 39, Gerrard-street, London, W.1.

H. J. **Seddon**, F.R.C.S.

Westminster Ophthalmic Hospital.—At the annual meeting last week Colonel Arthur Brodrick, who presided, stated that the ordinary income last year, nearly £21,000, was the highest on record. The debt to the bank, which was £15,000 three years ago, has been reduced to £5750.

ablishment in 1922, owing to the generosity
— the Rockefeller Foundation, of the London
hool of Hygiene and Tropical Medicine; the
cond in some measure by the transference of
oor-law hospitals to the municipalities, which has
sulted, in London at least, in an unparalleled
crease of good internships. The realisation of
e primary object of the Athlone Committee has
rried longer, and it was not until January, 1930,
hen a committee appointed by Mr. NEVILLE
HAMBERLAIN in 1925, with Mr. ARTHUR GREEN-
OOD as chairman, reported, that a practical
ggestion opened the way for immediate action.
his committee recommended "that the British
ost-graduate Hospital and Medical School, com-
ising a hospital with 400 beds, a medical school,
d residential facilities for post-graduate students,
ould be established on a site which will permit of
s future expansion as its services to the science and
t of medicine and to the public are developed and
cognised, by means of the conversion of a public
spital—viz., the Hammersmith Hospital, at which
e 400 beds initially required are already available."
The stage of accomplishment has now been
ched by a decision taken last Tuesday at a
ting of the London County Council. An
ement between the Council and the School
been prepared and the Treasury, after con-
ion with the University Grants Committee,
pproved this agreement and sanctioned the
g in hand without delay of the building
ions. The plans provide for a medical
for casualty, receiving, and out-patient
ments in two new blocks, a new ward, and
ments for such things as massage and light
ent. The new ward will result in a net
e of 28 beds for patients. It is interesting
the way in which the central public health
tee of the L.C.C. set out the advantages
e Council's point of view of the association
Hammersmith Hospital with a teaching
It will, they suggest, improve the medical
ical treatment of the sick of London and
the value of the Council's hospital service.
l be a concentration at the School of the best medical and surgical skill available to teach on modern lines all members of the medical profession who take advantage of the facilities offered. It will thus be possible for members of the Council's medical staff to attend the School for post-graduate study, and the opportunities thereby given for instruction in the most modern methods should be of the greatest benefit to the Council's hospital service generally. In addition patients from any of the Council's hospitals can be sent to Hammersmith Hospital for the purposes of diagnosis and the specialised treatment available there.

The arrangement between Council and School will include the grant to the School of a licence to occupy the school premises for a term of 999 years at a barleycorn rent, the licence being determinable at any time on failure of the School to carry out its covenant. The number, nature, duties, and pay of the professional and technical staff of the school will be agreed jointly, but this side of the staff will be appointed and paid by the School. The nursing staff on the other hand will be appointed and paid by the Council. The domestic, engineering, and maintenance staff will be appointed and paid by the Council, the School repaying the proportion of the cost utilised by it. Either party may appoint and pay additional staff. The two parties will agree as to the number of students resident in the hospital, the present arrangement being that a quarter will be nominated by the Council and three-quarters by the School. The Council provide lodging and maintenance for all of them, recovering from the School the cost in respect of the School's nominees; but the Council will be entitled to the services of the whole of such students in connexion with the work of the hospital. The maintenance expenditure for the first full year is estimated at £23,940, and for later years at £22,665, but should any item of the maintenance expenses be excessive by reason of the presence of the School, the School is to pay some proportion of the excess. All these matters will be determined on the advice of a joint committee of eight members, nominated half by the central public health committee of the Council and half by the School.

ANNOTATIONS

ATIONAL SYMPOSIUM ON CIRRHOSIS OF THE LIVER

ence habit initiated by our political
immediate post-war years seems to
firm hold in governmental circles and
g to other walks of life. There is
in favour of international conferences
subject to be discussed is carefully
hich definite results may be expected
free interchange of knowledge.
etimes happens, the known facts
nder consideration are available
of the subject, and are insufficient
elopment of an agreed policy,
if scientific congresses of the
effort they entail. The Inter-
of Geographical Pathology was
an organisation for the study of the influence of race, environment, climate, habits of life, and so forth on disease. It owes its inception largely to the efforts of Prof. M. Askanazy, of Geneva, Prof. L. Aschoff, of Freiburg-i.-Br., Prof. De Josselin De Jong, of Utrecht, and Prof. C. Roussy, of Paris, and local committees have been formed in some 32 countries. The subject chosen for discussion at the first meeting of the association, which was held under the presidency of Prof. Askanazy in Geneva on Oct. 8th to 30th, 1931, was Cirrhosis of the Liver, and it was hardly to be expected that much new information would emerge from a conference on such a well-worn subject. Nevertheless, the proceedings of the meeting which have recently been published [1] contain much that is of interest and value. The conference was divided into five

---

[1] Comptes Rendus de la Première Conférence Internationale de Pathologie Géographique. Genève: Librairo Kundig. 1932. Pp. 367. Swiss Fr.10.80.

sections, each with its special reporter. Thus Prof. De Jong dealt with the liver in cirrhosis and Prof. R. Rässle with the condition of the organs in cirrhotic subjects. Prof. N. Fiessinger discussed the symptomatology of hepatic cirrhosis, Dr. W. E. Gye experimental cirrhosis in its relation to human disease, and Prof. F. C. Mann disturbances of metabolism in hepatic cirrhosis. Dr. Paul Robert contributes to the report of proceedings an appendix on statistics, classification, and ætiology. As might be expected from the names of their authors, the reports form complete and well-balanced accounts of the different aspects of the condition, and as such will be invaluable as works of reference. It must be acknowledged that little light is thrown by the different authors on the ætiology of hepatic cirrhosis, and it is clear that most of the theories which have been put forward from time to time to explain the occurrence of the more obscure forms of the disease still remain merely theories. Even the great alcohol question remains unanswered, for Prof. Fiessinger claims that to produce cirrhosis alcohol must be taken in small quantities, in a dilute form, continuously but in not sufficient quantities to produce much intoxication. He suggests that aperitives, or wine taken on an empty stomach, exactly fulfil the necessary conditions. This conception of ætiology, however, would doom far more people to suffer from a hob-nailed liver than the clinical incidence of the condition would support. The report has been admirably edited by Prof. Askanazy.

IN DEFENCE OF MARY STUART

Sir George Turner is a fearless advocate of Mary Queen of Scots. He examines the Campbell Letters—we refer readers to this closely written narrative[1] for the story of these letters and their relation to the Casket Letters—and roundly describes them as forgotten forgeries. Further, he finds that their application to previous historic arguments throws a new light upon incidents hitherto used entirely for the detraction of a terribly maligned woman. Sir George is the first medical man, we believe, to have been attracted by the problems with which Mary's dramatic and tragic career is beset, and undoubtedly analysis from a medical point of view of Mary's health has a direct bearing on the understanding of her behaviour at certain junctures. Sir George finds her to have been an emotional hysterical subject, and gives reasons for believing that she suffered from gastric or duodenal trouble, attacks of hæmatemesis having twice jeopardised her life. Later, anæmia associated with the gastric disorder and complicated by a uric acid diathesis and rheumatism made of her a prematurely aged woman. With the allegations against Mary's moral character the author deals contemptuously. In the sixteenth century, and especially in the circles where rulers and princes moved, sudden illnesses or unexpected deaths were commonly attributed to the poisoner, especially if it should be in the interests of any religious creed or political or dynastic ambition to remove an obstacle. Mary did not escape the accusations of murder, and one example of these rumours Sir George describes as "infernal nonsense," while in respect of others he has no difficulty in showing that natural causes, then unknown, lay in all probability behind the episodes. Mary had been accused on no grounds whatever save his premature death of murdering her first husband. He was a wretched weakling by whose death she lost precedence, and the accusation is generally regarded as merely malicious. Still, it was certain to have been remembered against her when it was rumoured that she had tried to poison Darnley. Of this Sir George writes as follows:—

> "With reference to the presumed poisoning of Darnley, when he left Mary he broke into a pustular eruption all over his body; he had pains in his head and throughout his bones and he had a very bad sore-throat, and lost all his beautiful hair. This eruption was either that of small-pox or syphilis."

There is no doubt either about the acumen or the ardour with which Sir George Turner makes this addition to the controversial literature evoked by Mary's tragic life. He has used the methods of the diagnostician to arrive at the general conclusion that Mary was innocent of charges brought against her on political grounds, and was in effect sacrificed in the interests of the Protestant succession.

NORMAL HÆMOGLOBIN

THERE still seems to be some uncertainty about the normal level of hæmoglobin in the blood stream which is to form the basis of the scale on which we calibrate anæmias and polycythæmias. A year or two ago Dr. C. Price-Jones examined[1] 100 healthy men and 100 healthy women, obtaining his samples by pricking the skin and measuring the concentrations of hæmoglobin by a verified Haldane hæmoglobinometer. For the men he obtained a mean of 105 per cent. on the Haldane scale, with a range from 96 to 116; for women, a mean of 98 with a range of 90 to 110. These figures were higher than the level originally determined by Haldane and Lorrain-Smith, but substantially less than the normals of about 112 per cent. which had in recent years been measured by various workers in other countries, notably in America. A visit to Boston enabled him to be sure that the difference was not due to the use of different methods of measuring the hæmoglobin, and he suggested that some degree of polycythæmia was caused in the United States by chronic carbon monoxide poisoning from petrol engines. Some doubt has since been cast on his facts and inferences by Drs. C. E. Jenkins and C. S. D. Don of Salford. A series of 53 Salford males gave[2] a mean of 115 per cent., and no clear connexion could be found between the concentration of hæmoglobin and the presence of CO in the blood. It does indeed seem from the work of, for example, A. O. Gettler and M. R. Mattice,[3] that though many city dwellers who use motor transport have a certain quantity of CO in their blood, the amount of hæmoglobin so rendered useless is not enough to cause a compensatory rise of hæmoglobin from 105 to 112. In a second paper they deal with 118 males and 116 females from Lancashire and other parts of England, and by van Slyke's gasometric method obtained means which were equivalent to 115 and 100 per cent. respectively on the Haldane scale. The difference between 105 and 115 is well beyond the errors of random sampling and can be hardly due to errors of technique; as Dr. Price-Jones showed, the van Slyke and Haldane methods give almost identical results. The only explanation which seems to remain is that Dr. Price-Jones used cutaneous samples of blood and Dr. Jenkins samples drawn from veins, as did the other workers who have obtained similar high values. It is generally accepted that a free-flowing prick in the ear or finger yields arterial blood. As this is what is supplying the tissues and what is commonly examined in clinical hæmatology, it certainly seems desirable that the normal standard should be expressed in these terms. But curiously enough no extensive comparison of the hæmoglobin of venous and finger blood seems to have been made, so that the tentative conclusion that the former gives higher concentrations of hæmoglobin than the latter is no more than inferential. It is, too, perhaps a little difficult to believe that something like 15 or 20 per cent. of the plasma leaves the blood in its passage through the capillaries. It appears to be clear, however, that samples obtained in the two ways cannot be assumed equivalent until direct evidence to that effect is available.

THE HEALTH OF THE AMERICAN STUDENT

AN interesting article was contributed recently to the *Journal* of the Association of American Medical Colleges by Dr. E. B. Heck, the physician-in-charge of the Student Health Service, attached to Columbia University College of Physicians and Surgeons. The report is founded on figures gathered from the examination of 1124 students over a period of eight years, commencing with the results of the examination of 104 students who underwent voluntary scrutiny in 1924, since when a physical examination has been a compulsory feature of the curriculum of the College. Dr. Heck supplies no detailed analysis of the figures nor correlation of the findings or the year by year changes, so that health alterations which may have occurred during the period must be estimated by a general impression of the facts, but the messages are usually clear, the notes on the incidence of diseases being sufficiently ample for this purpose. The College draws its students mainly from urban communities. More than half of those forming material for the report have been resident at home, and of the residue a quarter are housed in dormitories—i.e., in sleeping accommodation definitely connected with the organisation of the University. The residue live in lodgings of their own choice, usually with fellow students. Fifty-nine per cent. of all the students were obtaining their meals at their places of residence, the others being dependent on the irregularities of restaurant catering. With regard to the habits of the students, taking them in the lump, one is surprised to find that regular outdoor exercise was exceptional, until it becomes clear that a considerable number live far away from the educational centre and are thus forced to spend much time in their to-and-fro journeys, having the double advantage that outdoor exercise is thereby compulsory and good sleep easier to obtain, for the group residing in the University dormitories suffer from the noise at night. The work of the residents is also interfered with by "other distractions," among which we presume must be placed the "occasional parties" alluded to, which may account for an admission on the part of 20 per cent. to the use of alcohol. But there is no evidence of undue use of alcohol or of excessive smoking. Five per cent. of the students were found to be wholly self-supporting, in other words they were carrying on occupations as wage-earners; and a further 29 per cent. of them were partially paying for their medical education by outside activities. The general health status of the student groups has been estimated by Dr. Heck through an investigation into "time lost" through sickness, when the reflection is made that here a comparison with the sickness records of the ordinary industrial group would not be fair, as the tendency of the medical student when sick would be to remain at work, while the tendency of the salaried worker would be to obtain time off. The material for verifying the correctness of the reflection exists, as a proportion of the students were wage-earners, but the collection of the figures might have been difficult. It is suggested that among the students who drop out from what are called "nervous conditions"—being "run down" and other indefinite plights—many were on the verge of examinational failure and went sick just before sitting for their tests; the condition is prettily termed by Dr. Heck "a physical expression of a lack of adjustment to prescribed routine," a definition which should commend itself to the ingenious student for use in the home circle. The general conclusion of Dr. Heck is that the work on which he is engaged is justified by its results; he is convinced that a student health service should be associated with every medical school curriculum. He does not suggest that the director of such clinical investigations would be dealing either with a physically inferior group or with a group that is particularly incompetent to look after itself, for the reverse conditions seem to obtain; but there are many errors of habit and many needless anxieties among students which could be corrected or removed by sagacious inquiry into habits and domestic background as well as physical symptoms. We can well believe that the student pursuing a very strenuous career has often been valuably helped by Dr. Heck, and incidentally the annual examination of medical students has something of a didactic value, for it is the application to the students of the procedure which they will later have to apply to others.

OSCILLOMETRY AND THE "MEAN" PRESSURE

THE importance of the "mean" blood pressure has been established in recent years. H. Vaquez and D. M. Gomez[1] have published accounts of mean pressure hypertension accompanied by normal extremes of pressure—that is to say, normal systolic and diastolic readings. They state that wide variations of the extremes of pressure are not fatal provided the mean pressure remains relatively stable, whereas changes of the latter induce, even when the extremes of pressure remain normal, a serious disturbance of the circulatory system. The instrument used by them is Pachon's oscillometer, or one of its modifications. It consists of an aneroid capsule enclosed in a rigid and airtight metal box—the box, capsule, and cuff being in communication. A pump is attached to the box by means of which the pressure in the circuit is raised and registered on an attached manometer. A compression is provided which disconnects the aneroid capsule from the main box, when the pulsations from the vessels are transferred by means of the cuff along the connecting tube to the recording needle. The pressure is first raised above the systolic reading and at this point only small deflections of the needle are seen, the result of the waves in the patent part of the artery beating against the occluded part of the vessel; then as the pressure is lowered, at the point where blood is just able to enter the compressed vessel, there is a sudden increase in the needle's deflection corresponding to the systolic pressure. The deflections increase in amplitude as the pressure is lowered to a point of greatest oscillation; this point is taken as the "mean" pressure which according to Vaquez is about 8—this figure being the height in centimetres of the greatest deflection. It is reached when the counter pressure in the armlet equals the pressure within the artery. The minimum pressure is admitted to be the most difficult reading to get with accuracy. Gomez collected 300 curves from subjects in Vaquez's clinic, and an *analysis of these curves shows that there are three* broad types: (*a*) where the change to the diastolic descent is abrupt and therefore easily determined; (*b*) where *the change is indefinite, and therefore can* only be guessed at; (*c*) where there is no change at all, but a gradual descent making reading impossible. *Gomez's findings have been confirmed by* C. Shellshear and C. Sippe.[2] The peculiar value of the oscillometer, as has already been pointed out by J. F. Halls Dally, *is that it gives an indication not* only of the arterial condition but also of the cardiac condition. Further, although it is not a means of comparison between two individuals, it is a constant, given good health, for any one person and is a delicate indication of vascular and cardiac change should it be found to vary at subsequent examinations; hence the value of being able to get photographic records As long ago as 1921 Pachon found that the oscillometric index (greatest deviation of the needle) corresponded to the "mean" pressure; this was confirmed by P. Gley and Gomez[3] by means of experiments on living animals. This mean pressure or oscillometric index has been claimed as a gauge of the functional capacity of the heart, and Vaquez, Kisthinios, and Papaioannou have recently supported this claim. This reading has been found to be the same for both sexes, to increase slightly with age, to be unchanged by exercise or digestion, but to rise whenever there is any decompensation of the heart. Since the recognition of the mean pressure a clinical condition named by the French "hypertension moyenne solitaire" (H.M.S.) has been described; the associated symptoms, if any, are mainly headache and dyspnœa on exertion. The importance of the recognition of this condition would e *to make an early diagnosis possible in hypernsion*, before the appearance of signs and symptoms, nd before there is any appreciable rise in either the *systolic or diastolic pressures. At this stage* the kidney function is said to be normal which suggests that in certain forms of hypertension there is no *primary renal lesion, but that the raised pressure* precedes the renal changes. Some cases of eclampsia show a raised mean pressure and Bailliart and Gomez[4] *have found a similar condition in a number* of cases of glaucoma; this confirms a view long held by Vaquez that the absence of altered blood pressure in this class of case has been due to the lack of adequate means for detecting its presence. If the mean pressure is as constant and as easy of estimation as *many observers claim, and if, on the contrary,* the diastolic reading on any instrument is a very variable and unreliable figure, it would seem desirable to make a routine *examination of the mean pressure,* particularly if it makes possible an early diagnosis in a group of important diseases. C. Lian and C. Zamfir,[5] however, *consider that H.M.S. is a rare condition, more in the nature of a clinical curiosity,* and an examination they undertook on seven cases of glaucoma failed to reveal a single example. They stress, however, the constant character of the measure between the median and minimum pressures as compared with the variation between the *maximum* and minimum pressures in any individual case and they endorse the view that the variation between the maximum and mean figures is more accurate a reading because of the difficulty in obtaining a *precise reading of the minimum pressure.* The natural conclusion, as already suggested, would be to substitute the exact method of measuring the *mean pressure for the uncertain estimation of the* minimum pressure. More investigations will certainly be essential before oscillometry becomes generally *adopted as a routine examination; that such work is being done is shown by the detailed account given* by L. Blavier[6] of research on certain anomalies of the oscillogram and their interpretation. There is still a wide divergence of opinion about the normal figure for the mean pressure; Lian considers that 8 for the mean pressure is pathological hypotension, whereas Vaquez accepts it as normal and says that the figure may vary from 8 to 12 c.cm. between the ages of 10 to 50 years. In some oscillometric curves a plateau is present which makes it impossible to detect any highest point; recently, however, Vaquez, Gomez, and Lajoie have demonstrated that by using a large cuff—15 cm.—the plateau can be obviated, and that the correct reading proved to be as much as 10 to 20 mm. above or below the centre of the plateau. When an instrument is constructed which is generally accepted as reliable, oscillometry may become widely used for estimating the blood pressure, and the significance and importance of the mean pressure will be generally recognised.

EXPERIMENTAL CARCINOGENESIS

BREEDING experiments with mice carried on over a number of years at the Institut du Radium in Paris by Madame Dobrovolskaia-Zawadskaia have resulted in the production of strains of mice with a very high incidence of spontaneous tumours. Among the males spontaneous tumours appear no more frequently *than in the males of the ordinary stock,* but among the females mammary carcinomata are unusually common. This idiosyncrasy stimulated curiosity as *to what would happen if the formation of mammary* tissue could be induced in males, and particularly in males of a cancer strain. L. Loeb and others tried to *answer this question by transplanting ovaries into* castrated males, but failed to observe the development of mammary carcinomas. A. Lacassagne[7] injected *folliculin daily into castrated adult males, again* with negative results. But when very young males —10 to 18 days old—from a cancer strain were taken and *injected daily with small doses of folliculin,* small islets of mammary tissue developed and these became the seat of carcinomata. The injections were carried out with a litter of three males and two females; all three male animals developed mammary carcinomata, the first tumour appearing about five *months after the onset of treatment. One of the* females also developed a mammary carcinoma at the age of 4 months. This is exceptionally early, since even in a cancer strain spontaneous *tumours never* appear before the sixth month, and the average age at which they develop is about 1 year. Curiously enough the other female is *still alive, but, in spite of the injections, has not yet developed a malignant* growth. Further experiments will have to decide whether *the folliculin acted indirectly in inducing* the appearance in the males of mammary tissue, which then, owing to the hereditary predisposition *latent in the strain, developed malignancy; or* whether the folliculin had in addition a more direct exciting action in producing malignancy. Dr. Lacassagne has also been successful in producing malignancy by an entirely different route. Three years ago he showed with Dr. R. Vinzent [8] that by a single irradiation of an abscess produced in rabbits by the injection of *Streptobacillus caviæ* sarcomata were produced in three animals out of twelve. The tumours represented three different histological types: an osteosarcoma, a fibrosarcoma, and a rhabdomyosarcoma. No tumour developed in rabbits which had received injections of the streptobacillus but had not been irradiated. It appeared from these experiments that the development of malignancy was the result of the combined action of the micro-organisms and the irradiation. Quite recently, however, Dr. Lacassagne [9] has been able to obtain similar results by irradiating a sterile granuloma produced in rabbits by the injection of kieselguhr. The kieselguhr was injected under the mammary gland on the right and left side, and only one side was irradiated. In two rabbits malignancy developed on the irradiated side, one tumour being a carcinoma and the other a sarcoma.

SAFETY IN CHILDBIRTH

AMONG the changes which have been taking place in obstetric practice during this century one of the most important is the increasing use of hospitals for delivery. Both in Europe and in America new institutions have been built and existing ones have been enlarged to accommodate more cases of both normal and abnormal labour. In a recent paper J. B. DeLee and H. Siedentopf [10] discuss whether these recent changes in the practice of obstetrics have resulted in better welfare of mother and child, less loss of life, greater protection of health. They come to the depressing conclusion that the increasing preference of the hospital as a place of delivery seems not only not to have bettered the results but seems actually to have made them worse. In support of this conclusion they cite the Aberdeen report by Parlane Kinloch, J. Smith, and J. A. Stephen,[11] and a report from New York City, to show that "there is a serious risk in the usual maternity ward which is absent in the usual confinement at home." In the Aberdeen report the high institutional death-rate is ascribed to the influence of "gross contagion," but the British Maternal Mortality Committee thought that this analysis of conditions should not be assumed to apply to the whole country because the available evidence suggested a different conclusion. They found that the majority of deaths from puerperal sepsis do not occur in epidemics but in single or sporadic cases; nevertheless they recognised the danger of outbreaks of infection, and agreed that the aggregation of maternity cases is by no means free from risk. DeLee and Siedentopf quote reports of 38 epidemics of puerperal infection, of which 35 occurred in the maternity wards of general hospitals. They ascribe a large part of the high institutional mortality to the spread of infection among puerperal patients, to contagion by carriers, and to the presence of gynæcological, surgical, and medical patients in the same building; and they therefore recommend isolation of the clean maternity patients in separate buildings with separate nursing and domestic staff. Fewer outbreaks of infection have been reported in this country than in America, but the danger is a real one, and this recommendation should be borne in mind whenever new hospitals are to be built. The most careful and expert nursing cannot prevent the occasional transport of organisms, and the fact that epidemics of wound infection have been known to occur in clean surgical cases shows that their proximity to obstetric cases may be dangerous.

Ease of intervention and a false sense of security in hospital have contributed to the increase in the number of artificial deliveries, which bring with them an increased mortality risk. Premature and unnecessary intervention have also been alleged as a reason why maternal mortality is higher in the practice of doctors than in the practice of midwives, though this difference must be partly due to the great preponderance of normal cases in midwives' practice. Bethel Solomons [12] holds strong views about the high maternal death-rate in private medical practice. From his experience as Master of the Rotunda he has found reason to ascribe many deaths either to "wilful negligence or abysmal ignorance" on the part of the attendant. Without in any way subscribing to such a damning indictment, it is possible to agree that the practitioner should receive a better obstetric training than has hitherto been available in most medical schools. Bethel Solomons holds that a compulsory period of three to six months' residence in a maternity hospital should be insisted on before a doctor should be allowed to practise. This would raise issues far beyond obstetrics, but need hardly be discussed at present because there are certainly not enough hospital positions available to make it practical politics. Solomons lays stress on good aseptic technique. Infection with organisms carried in the throats of the attendants is not regarded by Solomons as of any importance; he lays stress on the teaching of good aseptic technique. DeLee is a believer in droplet infection, which has been definitely proved in certain epidemics, and he also suggests the possibility of air-borne infection. These communications from Ireland and America are really complementary; the one emphasises the danger of hospital delivery, the other the importance of improved training for the student and post-graduate instruction for the doctor and the midwife in order to improve the standard of private practice. It is clear that a substantial decrease in maternal mortality and morbidity can only be expected if a combined attack is made from many angles.

RAPID DIGITALISATION

BY digitalisation is meant the attainment of the maximum therapeutic effect of digitalis or strophanthin. Auricular fibrillation is, of course, the condition in which the drug exerts the most spectacular effects, and the one in which the efficacy of any special method of administration can best be judged. Dr. Elsie Porter reports [13] the results of giving in a single dose, by various routes, a quantity of digitalis or strophanthin calculated to produce full digitalisation. The estimation of this dose is still a difficult matter, particularly as full therapeutic and toxic effects are not far apart. The investigation was made on cases of auricular fibrillation with rapid heart-rates, to whom no digitalis had been given for three weeks. The drug was given in a single dose by mouth in an amount corresponding to 0·125 c.cm. of tincture (international standard) per lb. of body-weight. Within eight hours the ventricular rate was slowed in nearly all cases, about 40 or 50 beats per minute (the rates being calculated from electrocardiograms). In cases where congestive failure might lead to vomiting the rectal method of administration was used, similar results being obtained with a dosage of 0·1 c.cm. of tincture per lb. body-weight. A third group was treated with intravenous strophanthin. Initial experiments with a dose of gr. 1/100, which would generally be considered quite a high one, showed no slowing of the heart-rate. Finally, a dose of gr. 1/33 was found usually to produce an adequate slowing within half an hour, any larger dose leading to toxic symptoms. The method appears to be a safe one when no digitalis has been given for two or three weeks, except under two conditions: if the patient is subject to paroxysmal fibrillation with high ventricular rates, and if cardiographic changes indicate considerable myocardial damage. Experiments made on the ability of atropine to abolish the slowing of the heart-beat produced by digitalis and strophanthin showed that these drugs act largely or entirely on the vagus.

FRACTURES OF THE NECK OF THE FEMUR

FRACTURES of the neck of the femur have an unfortunate tendency not to unite after the manner of most other fractures. Nowhere else in the body, excepting perhaps in the scaphoid bone of the carpus, is there anything like the same incidence of non-union. Dr. W. Eugene Wolcott, in a discussion at the 83rd annual congress of the American Medical Association in New Orleans, stated that in a series of 41 cases, all treated by the Whitman method of fixed abduction in plaster, 15 remained ununited. Subsequent speakers at the congress, while considering this figure unusually high, agreed that the average incidence of non-union was high enough to give rise to grave dissatisfaction. There have been various speculations and assertions about the causes of this failure to unite. The favourite teaching has been that the cause is primarily vascular. The blood-supply to the femoral epiphysis is said to be poor and, being damaged at the time of the injury, is no longer able to keep the head of the bone alive. The blood-supply to the head and neck of the femur reaches it by two routes—through the ligamentum teres and along the retinacula of the neck. The neck of the femur is anatomically a part of the shaft; its blood-supply is therefore arried to it by the periosteum. The vessels lie along he retinacula, give branches to the neck, and then, entering foramina at the junction of head and neck, are the main supply to the head. They are of considerably greater importance than the vessels entering along the ligamentum teres, which supply only the "core" of the head. Dr. Wolcott is investigating by injection methods, using fluid opaque to X rays, the anatomical connexions of these vessels. He has traced branches from the obturator and the internal circumflex arteries into the ligamentum teres, but has not had much success with the vessels of the neck. No anastomosis between the two sets of arteries has so far been demonstrated by him. By direct observation of four cases of non-union subjected eventually to open reconstruction operation by the Whitman method, Dr. Wolcott was able to show that the ligamentum teres had vessels of a respectable size, quite patent and spurting when cut across. Dr. Myron O. Henry, in the same discussion, pointed out that the course of the decalcification of the femoral head demonstrates the presence of an active circulation. Less seems to be known about the fate of the vessels in the retinacula in these injuries, although it is by no means certain that their blockage or severance would of necessity interfere with union.

Apart from vascular failure, non-union has at various times been attributed to lack of sufficient hæmorrhage at the site of the fracture, to prolapse of the capsule between the bone ends, and to the action of the synovial fluid. Prolapse of the capsule was looked for by Dr. Wolcott. He did not find it in any of the four cases on which operation was performed; what he did find in all of them was a growth of fibrous tissue over the end of the femoral neck on the distal side of the fracture. This fibrous tissue had a fairly good blood-supply and bled when incised; its presence in one case and not in another may be of the utmost importance in determining whether union will take place.

In attempting to assess the influence of the form of treatment on the occurrence of non-union, it is of interest to note Dr. Wolcott's view that only 35 of his 41 cases were *efficiently* treated by Whitman plasters. Accurate reduction and immediate and prolonged fixation in extension may have an important bearing on the occurrence of union, despite the fact that callus formation in fractures of the *shaft* of the femur occurs quite readily without accurate and complete reduction. The Whitman method of reduction and retention in plaster is probably the commonest form of treatment at present in use for fractures of the neck of the femur. It would appear from the opinion expressed by American orthopædic surgeons that its success is far from certain. Dr. Frederick Gaenslen made a useful suggestion. He has found that a position of slight valgus at the fracture favours a more rapid union. By practice on artificially produced fractures in the cadaver, Dr. Gaenslen has evolved a method of producing this position during reduction. He first flexes the hip-joint and knee-joint to 90°, and then uses upward traction in the line of the femur to reduce the fracture. Manual thrust in the region of the great trochanter produces the valgus deformity. The limb is finally brought into extension with a moderate degree of abduction and internal rotation. The question arises as to whether it is an impaction produced by the method which results in the success claimed for it, or some mechanical advantage in the position to the vessels running along the neck. Some surgeons, believing in the importance of an initial hæmatoma, inject blood to the site of fracture. It is obvious that the process of union and also of the formation of false joints in fractures of the neck of the femur still provides a field rich in problems.

EPSOM COLLEGE

A SHORT time ago the Epsom College Act of 1932 was passed extending the benefits of the Royal Medical Foundation of the College to medical women pari passu with medical men. The Council has now asked medical women to take up administrative responsibilities—namely, Dr. Laetitia Hutchison (Mrs. Robertson Hutchison) as a member of the Council, and Dr. Christine Murrell as the representative of the Medical Women's Federation on the Conjoint Committee of the College, which now elects the Pensioners and Foundationers. The Council of the College has acted promptly under its new opportunities, and will surely reap advantages, academic and material, from the course of action taken.

Sir Charles Sherrington will deliver the Rede lecture, entitled Mechanism and the Brain, in the Arts School at Cambridge on Wednesday, May 24th, at 5 P.M.

THE Lister memorial lecture of the Royal College of Surgeons of England will be delivered in the theatre of the College by Sir Charles Ballance on Wednesday, April 5th, at 5 o'clock.

WE regret to record the sudden death at Cambridge on Monday last of Mr. Arthur Cooke, senior surgeon and ophthalmological surgeon to Addenbrooke's Hospital.

SPECIAL ARTICLES

FOOD AND HEALTH

THE PHYSIOLOGICAL MINIMUM

THE public conscience is becoming more and more disturbed about the distress which is accompanying prolonged and widespread unemployment. In this country insurance benefit has largely prevented physical suffering, and it is generally agreed that minds have taken more harm than bodies. Indeed, various medical officers of health have given their opinion that there is no conspicuous increase of malnutrition in the areas under their charge, and it is stated that the fall in the cost of living has been so great as to compensate for reduction in unemployment benefit. On the other hand it is urged that a weekly dole which will support a man or family in reasonable comfort for a few months is not necessarily adequate as a sole source of livelihood over many years. And repeated statements that it is unreasonable to ask the unemployed worker to keep a wife and children on the allowances now paid have led people to ask exactly what supplies, apart from shelter and clothing, are required for maintenance of health.

During the past few years we have reviewed or published many reports which provide a partial answer to this question, and we think it will be useful to recall them now by summarising some of the information they contained.

What must the Diet include?

Many of the main facts about good and bad diets were set out by the Ministry of Health's Advisory Committee on Nutrition a year ago.[1] For practical purposes, the committee say, one has to judge a diet in four different respects—namely, the supply of calories (units of energy), the quantity of "first-class" protein, the supply of mineral matter, and the vitamin-content.

Calories.—The calorie needs of the adult male may be taken as 3000 (great) calories per day. The needs of women and children can conveniently be expressed as decimals of the adult man's needs, and the following is the scale used by E. P. Cathcart and A. M. T. Murray in a recent report to the Medical Research Council (Table I.).

TABLE I

	Calories	Man Value		Calories	Man Value
Adult woman ..	2500 ..	0·83	Child 6–8	1800 ..	0·60
Boy of 14 or over	3000 ..	1·00	" 3–6	1500 ..	0·50
Girl " "	2500 ..	0·83	" 2–3	1200 ..	0·40
Child 12–14 ..	2700 ..	0·90	" 1–2	900 ..	0·30
" 10–12 ..	2400 ..	0·80	" 0–1	600 ..	0·20
" 8–10 ..	2100 ..	0·70			

(The calorie needs of persons over 65 years of age may be taken as 2250 per day or a "man value" of 0·75.)

These figures are described as "not very generous."

It is also usual to calculate the distribution of the calories between protein, fat, and carbohydrate.

Each gramme of protein, when burnt in the body, yields 4·1 calories, each gramme of fat 9·3, and each gramme of carbohydrate 4·1. In temperate climates the range for protein is from 10 to 15 per cent. of the total calories in the diet: for fat, from 20 to 35 per cent.: and for carbohydrates 50 to 70 per cent. (If the fat is high the carbohydrate is usually low, and vice versa.) If, say the committee, the absolute amounts of protein and fat fall much below 80 and 50 g. respectively per day (per "man"), or the percentage of calories derived from carbohydrates rises much above 66, the diet may be considered to be in need of improvement.

First-class protein.—"The next criterion is that of the supply of first-class protein. Some proteins replace a greater amount of protein lost to the body by wear and tear than others, and are also more adequate for the purposes of growth. Those which are most efficient in these respects are termed first-class proteins, or proteins of high biological value. First-class protein (for practical dietetics) is to be found only in animal protein, such as that in cheese, eggs, fish, meat, and milk. The amount of first-class protein per 'man' necessary per day can be expressed either in absolute amount or as yielding a definite percentage of the total calories. The absolute amount is about 37 grammes and the percentage content of the total calories is 5. . . (Most middle-class diets have about 55 grammes first-class protein or, in other words, about 7·5 per cent. of the total calories is supplied by first-class protein. Working-class diets frequently fall below the standard.) Any deficit of first-class protein is probably detrimental, for the figure adopted as a standard is not high."

Mineral matter and vitamins.—The remaining criteria can be considered together. Unfortunately, there are as yet no quantitative data of the amounts of the different vitamins essential to the human diet. On the other hand, the foods which are useful in supplying mineral matter are often useful in supplying vitamins. These "protective foods" which prevent deficiency diseases are milk and milk products, fresh salad vegetables and fruits, liver (and liver oils), fish (especially the fat fish and fish roes), and eggs. It will be seen, the committee remark, that if a diet contains milk (and dairy products generally), fish, eggs, and fresh salad vegetables, there is little need to criticise it as regards its mineral and vitamin-content.

"Probably if the diet contains per person 1 pint of milk per day, if cheese is partaken of freely, if one orange or one tomato or a helping of raw salad is taken daily, if 1 oz. per day of butter (or of vitaminised margarine) is given, and if some sort of fat fish, such as herring, appears in the winter menu once a week (or if in default of such fish half a teaspoonful of cod-liver oil is taken once a day) the mineral matter and the vitamin content of the diet are satisfactory."

Conclusion.—It is perhaps essential in conclusion to emphasise the fact that the diet must satisfy all the criteria. If it is not complete as regards calories, first-class protein, mineral matter, and vitamins, it is to be condemned. No amount of calories will make up for any other deficiency, and no amount of vitamins or mineral matter can make up for a deficiency in calories or of first-class protein. A diet must stand four-square upon calories, first-class protein, mineral matter, and vitamins.

Common Faults of Diet

With the enormous range of foodstuffs procurable in Great Britain (the memorandum goes on) no person and no institution with money to spend need have a defective diet. But where economy is to be considered it is otherwise. Defective diets are often the result of an unscientific economy. First-class protein and the protective foods are costly, or at any rate are accounted expensive.

Calories.—Most institutions if not most individuals have discovered what are the foods which are extremely cheap sources of calories. They are flour, oatmeal, bread, the pulses, dripping, margarine, treacle, sugar, and, not far behind, butter, cheese, jam, bacon, and dried fruits. Sometimes, however, the proportion of fat is too low.

---

[1] The Criticism and Improvement of Diets. H.M. Stationery Office. 1932. 3d. See THE LANCET, 1932, i., 782.

First-class protein.—" It is not often that the diet of an institution is found to be deficient in first-class protein, but the individual's diet frequently is so. Though this latter is sometimes the result of individual taste, it is usually due to economy. . . Where economy must be considered, the use of cheese, herring, fish roe, and sprats is advisable, and fortunately none of these needs much cooking. Other reasonable sources of first-class protein are cod, milk, ox liver, imported beef, and rabbit. If skimmed milk is obtainable, the first-class protein ration can be obtained as cheaply as with fish roe."

The protective foods.—" It is in the protective foods that deficiency is likely to be met. And first upon the list of protective foods comes milk. It is generally agreed that one pint of milk per head per day is advisable, though the milk consumption in this country does not reach half that figure. The value of milk in a diet is now generally recognised. (Apart from its value as a protective food, milk is not dear for calorie value—i.e., 10*d.* per 1000 calories—nor for its protein ration, 6*d.*–7*d.*) Skimmed milk, where obtainable, is very valuable as a cheap protective food . . . ."

> " The question is bound to arise whether *butter* or *margarine* be employed as one of the sources of fat. Economy suggests margarine. There is the possibility that butter may be devoid of vitamin D in winter and, consequently, if butter is being relied upon as a protective food it would be best to specify butter such as New Zealand butter, which is fairly constant in its vitamin D content. Margarine can be obtained which contains vitamins A and D, and if margarine is used such a product should be specified . . . ."

" Finally, it may be found that a diet is deficient in vegetables, or that the latter are limited merely to potatoes and 'greens.' . . In England and Wales there is little excuse for this, for there is an abundant and cheap supply of tomatoes, celery, hardy lettuce, endive and watercress in the autumn and winter. Indeed, watercress is abundant most months of the year, and relatively cheap. A regular and varied supply of these foods, not necessarily in large quantities, should be used to improve a diet deficient in the vegetable type of protective foods. Other additions which it would be wise to make are carrots (valuable as a source of vitamin A), and oranges and lemons, which are a source of the antiscorbutic vitamin."

Minimal Cost of a Sufficient Diet

Various attempts have been made to estimate the minimal cost of a sufficient diet, and two of these have appeared in our columns comparatively recently.

V. H. Mottram [2] prefaces his calculations by pointing out that the lowest conceivable diet upon which subsistence with efficiency is possible, consists of 7¼ oz. of fresh herrings, 1 lb. 7 oz. of oatmeal, and 4 oz. of cabbage—at a cost (in 1927) of about 6*d.* per day. But of course, he says, such a subsistence diet is impossible.

> " No one could swallow 1½ lb. of oatmeal a day, nor tolerate the monotony of the diet, even supposing he had the physiological knowledge to purchase such a diet and the practical knowledge of how to cook and serve it so that it were not revolting. One thing which has become abundantly clear in physiological research is that appetite, as apart from hunger, has much to do with the proper digestion, assimilation, and utilisation of food. The physiological engines of the body are guided partly by the psychological condition of their owner. Consequently no subsistence diet, however admirable from the theoretical point of view, such as the one given, can be accepted as practical."

Starting from the basis that the diet must be varied and palatable and not depart markedly from what is acceptable to a working-class community, Mottram came to the conclusion that "with skilful purchasing in the cheapest market, based either on a long experience or on a knowledge of dietetics, a dietary can be obtained at so low a cost as 6*s.* 3*d.* per week per adult male, so long as the occupation followed is not a very strenuous one. Below such an expenditure, he said, it is unlikely that bodily efficiency could be purchased.

> " This sum, therefore, sets the limit from which we may proceed to estimate what minimal subsistence will cost. It must be realised, however: (1) that this figure was arrived at when food prices were low, and that any attempt to put it into practice must allow for fluctuations in the prices of foods; and (2) that it demands skill in laying out of money which only one or two housewives in a hundred appear to have. Although this figure is used throughout the rest of the discussion, my own prejudice is in favour of raising it to 7*s.* per week."

Accepting 7*s.* per week per man as Mottram's final estimate, it needs correction in accordance with the fall in the cost of living. In 1927 the cost of food was estimated at 61 per cent. above pre-war values, whereas in February, 1933, it is only 22 per cent. higher. With a corresponding reduction, Mottram's 7*s.* thus becomes about 5*s.* 4*d.*

G. P. Crowden,[3] about a year ago, also reached 7*s.* as the physiological minimum basis per man-value per week. His calculations presuppose, he says, " the most economic purchasing and household management by the mother in the family—an assumption which is rarely justified," and they were made on the basis of a list of foodstuffs compiled by the North Islington welfare centre in July, 1929. This gave a man-value of 8*s.* 2½*d.*, which Crowden corrected to 7*s.* because the cost of living had fallen; and it must be further corrected to about 6*s.* 8½*d.* at present prices.*

Somerville Hastings [4] quotes Caradog Jones's estimate of 6*s.* 3*d.* per week (1931).

Finally, we may refer to G. C. M. M'Gonigle, whose paper was summarised in our issue of March 4th (p. 471). His figure is the lowest, for he believes that in the spring of last year, in the markets of Stockton-on-Tees, is was possible to buy enough food for 5*s.* per " man "; and corrected to fit the further fall in the cost of food this comes to about 4*s.* 10*d.* The estimates may now be summarised as follows (Table II.).

TABLE II.—*Estimated Cost of Subsistence Diets per " Man " per Week*

	Estimate			Corrected to February, 1933	
	s.	*d.*		*s.*	*d.*
Mottram (1927)	7	0	....	5	4
Crowden (1932)	7	0	....	6	8
Caradog Jones (1931)	6	3	....	? 5	10
M'Gonigle (1932)	5	0	....	4	10

In considering these figures it must be borne in mind that the Ministry of Labour's estimates of the rise and fall in the price of foodstuffs are only a rough generalisation. Further, as Mottram says, some modicum of variety is essential. " Psychology invades the problem, for man is no Robot, whom you can stoke with the same monotonous fare day after day."

The Feeding of Children

The problems of the family can also be looked at in the light of institutional experience. The Advisory

[4] Ibid., 1932, ii., 1185.

* Crowden's diet gives 3570 calories per day. In commenting on this and other estimates (*Week-end Review*, March 4th) Mottram says: " Clearly 5*s.* per week per adult male is a figure below which it is not safe to go if the food is bought retail, and the natural assumption is that if 7*s.* supply some 11 per cent. too many calories and 5*s.* some 10 per cent too few, the sanest figure to adopt for practical purposes is 6*s.* per week per adult male."

Committee on Nutrition[5] have inquired into the diets offered in children's homes maintained by poor-law authorities, and have made recommendations about their improvement.

> "In homes visited in the North of England," they say, "the average weekly cost of food per child was said to be 3*s.* 11¼*d.* in the case of certain scattered homes containing 341 children; 4*s.* 8*d.* in certain grouped cottage homes containing 260 children; and 5*s.* in other grouped cottage homes containing 550 children. In each case most of the food was obtained from stores at contract prices. It is interesting to note that the cost of food per head in these homes exceeded that in homes visited in the south (so far as we could ascertain), notwithstanding that on the whole prices seemed lower than in London and the home counties. The additional cost was reflected in the better standard of feeding in the northern homes."

The weekly cost per head of the meals which they suggest in an appendix to their memorandum would vary according to the locality of the home, the number of children in it, and the conditions under which the foodstuffs are purchased. "In a home containing about 200 children we estimate that the weekly cost, allowing 1 pint of milk per child daily, would be about 4*s.* 6½*d.* per head if all provisions were bought at contract prices." (This report is dated November, 1931, and correction for the fall in the cost of foodstuffs would bring this figure down to 4*s.* 3*d.*). Sir George Newman[6] thinks that unless the numbers are large and there are facilities for obtaining foods at contract rates, it may be assumed that 5*s.* 6*d.* per head weekly is a reasonable price to pay. "In schools for delicate children" he adds, "there is, however, a good deal to be said in favour of increasing the milk ration to 1½ pints daily (in which case the supply of meat and fish may suitably be reduced) and of substituting butter for margarine. This will probably raise the cost to approximately 6*s.* per week."

In 1927, after studying the dietaries given by a large number of poor-law authorities, the National Association for the Prevention of Infant Mortality gave the following as the basis of a suitable dietary for children between the ages of 1 and 5 years.[7]

> *Daily.*—One pint of milk, the juice of orange, tomato, grape or lemon. An apple, orange, tomato; some salad or lemon juice (for older children). Two to four ounces of meat or fish, or one egg. Cod-liver oil if the butter ration is reduced.
>
> *Weekly.*—Two to four ounces of butter. Two eggs.

Milk in London costs about 3*d.* a pint or 3½*d.* in the winter. Seven pints cost 1*s.* 9*d.* or 2*s.* 0½*d.*

High Rents and Insufficiency of Food

Food is only one of the necessities of life, and the amount of money available for it depends on the cost of the others. Mottram guesses that 60 per cent. of the income of a person at subsistence level should go towards nourishment, but it is clear that circumstances may decide otherwise. Thus it might be shown that a reasonable average rate of wages or unemployment benefit proved totally insufficient to maintain the health of particular families because, for example, the rent paid was higher than it should be.

It is not our object here to examine the general adequacy of the sums now paid weekly to working-class families in or out of employment; but it is sufficient to demonstrate that there is a problem to be faced. Two or three quotations will suffice for this purpose.

Crowden gives a few examples of family budgets collected in London showing physiologically inadequate expenditure on food; and without drawing conclusions from his insufficient data he notes in passing that on the average the amount spent on rent was about 35 per cent. of the total weekly income, or twice the percentage of 17 on which the Ministry of Labour bases its present calculation of the cost of living index.

> "If a family undertakes such a fixed weekly commitment as rent," he says, "and then finds by bitter experience that insufficient money is left for the provision of adequate food . . . it is inevitable that debt or breakdown in health, or both will follow. . . . Whatever may be the urgency for housing undertakings paying their way, it is bad business from the national health point of view if such can only be achieved at the expense of family health."

M'Gonigle, in the course of his investigation of the standard of living in two parts of Stockton, analyses the weekly budgets of 22 unemployed families who had moved to a new housing area. Their mean income was £1 10*s.* 5*d.* a week, of which 31·3 per cent. (9*s.* 6*d.*) went in rent, 29·3 per cent. in "other necessary expenditure" (including clothing, clubs, and insurance), and 36·7 per cent. in food. The mean "man value" of each family was 3·8, and the amount spent in food per "man" per week was 2*s.* 10½*d.* The diets thus obtained were compared with a "normal" diet, as follows:—

Normal diet.	Unemployed families. Quantities	Unemployed families. % of normal*
First-class protein (37 g.) ..	22·78 g.	55·4
Total protein (100 g.) ..	65·79 g.	59·2
Fats (100 g.)	73·72 g.	66·3
Carbohydrates (400 g.) ..	419·0 g.	94
Calories (3000)	2696	80

* 10 per cent. is deducted for wastage.

It will be noted that the calorie value per "man" in these families was 2696; whereas five employed families on the same estate gave an average figure of 4277. M'Gonigle, calculating that a "normal" diet could be obtained (last spring) at 5*s.* per "man," says that a family consisting of man, wife, and three children, aged 8, 10, and 12 years, ought to spend £1 1*s.* 6*d.* on food. The income of such a family, if unemployed, would be £1 9*s.* 3*d.* The sum of 7*s.* 9*d.* would thus be left for other purposes.

Cathcart and Murray found eight families in Cardiff and twelve in Reading in which the mean calorie value was less than 2500, and three in which it was less than 1800. This shortness of food was not attributed solely to the smallness of the income, but partly to incapacity or improvidence. They came to the conclusion, however, that with very restricted incomes a distinctly smaller proportion of the weekly wages is devoted to the buying of food in these English towns than in Scottish towns—largely because of the higher rents in the south.

Somerville Hastings quotes the annual report of the medical officer of health for Hammersmith (1931), who "examines the budgets of a good many working-class families, both employed and unemployed, and finds that when rents are paid there is in many cases a very small surplus left to provide food, clothing, and other necessities of life. Amongst the unemployed this may be, according to his statements, as little as 2*s.* 8*d.*, 2*s.* 4*d.*, 1*s.* 11*d.*, or even 1*s.* 7*d.* per head, and amongst the employed may come down as low as 3*s.* 8*d.* or 2*s.* 9*d.*" Hastings points out that townspeople with large families are often compelled to pay relatively large sums for accommodation because owners and agents refuse to let rooms to people with children.

We note that the *Week-end Review* (March 11th, p. 264) has formed a small committee which is to make a statement on the minimum standard of maintenance necessary in food, heat, and shelter.

This committee includes an economist, a physiologist, a housewife, a doctor, and a social worker, and it is asked to report by the end of this month.

MEDICINE AND THE LAW

"Misadventure by Narcotic Drugs"

THE inquest on Mrs. Beech, begun at Paddington on Feb. 17th and adjourned to Feb. 28th for an analysis of certain organs, was concluded by Mr. Ingleby Oddie on March 1st. The coroner reached his decision without a jury and recorded a verdict that death was due to misadventure by narcotic drugs. As will be seen, the suggestion of suicide was negatived and there was no evidence of criminal negligence in medical treatment; there was however a prolonged inquiry into the effect of various narcotics; this disclosed a sharp difference between the opinions of Home Office experts and the practice of clinicians especially in respect of the use of nembutal.

Mrs. Beech, aged 34, died on Feb. 13th. She had come to London on her way abroad. Being taken ill on Wednesday, Feb. 8th, she went to see her medical attendant, Dr. C. H. Atkinson, complaining of nerves, insomnia, and colic. He had first attended her in April, 1931, before which date she had been taking omnopon; the dosage of this drug was reduced and she came off it in about three weeks. He next saw her on Dec. 26th, 1931, when she had been taking alcohol and had gastric trouble as well; she had been taking paraldehyde 2½ drachms at night and was also having gastric treatment. Dr. Atkinson was informed subsequently of other drugs being taken. In October, 1932, she came again under his treatment; there was investigation and treatment for duodenal ulcer. Her own doctor had been giving her luminal (substituting somnifain later) and paraldehyde, but by this time the dosage was greatly reduced. The drugs were given because of her mental condition; he was particularly anxious not to give her morphia. On Feb. 8th she was very excitable and he gave her 3 drachms of paraldehyde and 5 grains of medinal. On the Thursday he gave another 3 drachms of paraldehyde. On Friday she told him she had taken 4 ounces of sal volatile in two portions somewhat diluted. He thereupon called in Dr. R. D. Gillespie, who inquired fully into the history of the case and the details of drugs taken. Mrs. Beech, according to Dr. Atkinson, was neither a drug nor an alcohol addict, but, during periods of mental upset, she would take drugs and drink sal volatile or even scent. Dr. Gillespie gave her 3 drachms of paraldehyde followed by two further doses of 2 drachms each. On the Saturday morning she was not much better; he then gave her more paraldehyde and another dose again at night, administering in addition 4½ grains of nembutal. She had not taken nembutal before; he prescribed it to reduce the need of a large quantity of paraldehyde. Mrs. Beech was then moved to a nursing-home where she had three nurses and was constantly watched. That night she was restless and excited under the influence of the two drugs. Very early on Sunday she was given 7½ grains of medinal, then 3 drachms of paraldehyde, followed by a further 2 drachms of the same in the afternoon. At 9.15 P.M. she had 6 grains of nembutal; during the day she had 60 grains of potassium bromide in three 20-grain doses. On Monday, after further doses, she had six hours' sleep and awoke apparently quite bright. She talked, read, brushed her hair, attended to her nails, and spoke of her forthcoming visit to Paris. She was still restless and tried to sleep but failed. She was then given 7½ grains of medinal and gradually lapsed into unconsciousness from which she never recovered, death occurring at 3.30 P.M. Post-mortem examination, according to Sir Bernard Spilsbury's report, disclosed no cause of natural death.

The coroner ordered an analysis, and this, undertaken by Dr. G. Roche Lynch, showed 1 grain of nembutal in the liver and ⅙ grain in the kidneys; there was a smell of paraldehyde in the body, but no trace of medinal. Dr. Roche Lynch believed death to be mainly due to the use of medinal and nembutal; the use of potassium bromide and paraldehyde were to some extent contributory; he thought some of the doses were heavy; he could not exclude the damaging effect of the dose of sal volatile. Sir Bernard Spilsbury, having heard this evidence, agreed. He said he could not entirely exclude the effects of the sal volatile; though it had been taken some days earlier, there were still signs of its injury to the mucous membrane of the œsophagus, stomach, and duodenum. It had caused irritation to the stomach, accounting for the patient's restlessness.

THE CORONER'S VIEW OF THE EVIDENCE

This, said the coroner, perhaps explained why Dr. Gillespie's treatment did not produce the desired effect; paraldehyde sufficient to give six hours' sleep had produced only one hour. The sal volatile, he added, had an effect which necessitated the continued use of large doses of barbiturates. One theory, supported by Dr. J. A. Ryle, was that the ammonia in the sal volatile set up gastric uræmia which might account for death, but the coroner was unable to find characteristic history in confirmation. The coroner did not believe the sal volatile was taken with suicidal intent. The patient's doctor had told her not to take alcohol; if she felt the need of stimulants, she was advised to take sal volatile. She took an overdose to relieve her symptoms, not realising what she was doing.

Dr. Gillespie, said the coroner, believed the failure of his treatment with drugs was caused by the seriousness of the patient's mental condition; he had proceeded to give large doses and to vary the drugs, hoping that they would master the sleeplessness and excitement. "In my opinion," he continued, "the doses, though large, were not excessive; taking into consideration what his special knowledge of the patient was, and the fact that she had swallowed the sal volatile, Dr. Gillespie cannot be criticised." It was true that he was dealing with what Sir William Willcox considered a dangerous drug. Nembutal had been used very largely in similar doses without ill-effects. Once or twice there had been alarming symptoms, but no death was traceable directly to nembutal, though there were cases where nembutal might have played a part in death. It was evidently a dangerous drug and one whereof the effects should be carefully watched. Dr. Gillespie had first given 4½ grains, which the coroner considered not excessive from the evidence. He then gave 6 grains "which again I cannot say was excessive." It was reasonable to believe that, in view of the patient's better condition on the Monday morning, the effect of the drugs had passed off. In view of her condition that morning the coroner saw nothing to criticise in the 7½ grains of medinal which the nurse administered under Dr. Gillespie's orders that day. Paying a tribute to Dr. Gillespie's experience and care, Mr. Ingleby Oddie said there was no evidence of negligence and certainly there was no gross negligence. Dr.

Gillespie was entitled to rely on past experience and on his knowledge of the effect of similar doses of the drug. Mrs. Beech died from the combination of drugs she had taken, including the sal volatile.

EVIDENCE OF THE TOXICITY OF NEMBUTAL

The evidence of Sir William Willcox made clear his profound distrust of the barbituric acid group of drugs. He spoke of their toxic effect upon the brain and other organs. In his opinion death was due to the combination of all the drugs, with (as a possible contributing cause) the sal volatile. He appreciated that the patient had been accustomed to take some of these drugs, but barbituric acids do not produce tolerance as in the case of morphia. It was in his opinion utterly untrue that nembutal was a safe drug. He would prefer not to say what was a safe dose of it. The drug was only recently introduced. When veronal was first brought in, the dosage was reduced by half (from 10 to 5 grains) after a few years' experience. He was aware of four fatal cases following the administration of nembutal for purposes of anæsthesia. In three of these the dose was 7½ grains. It caused fatalities by action on the brain. It was a tissue poison, poisoning the kidneys. It might cause pneumonia. He had seen a case of pneumonia following a dose of 4½ grains. It might also poison the heart. The condition of the patient, very gravely ill, made the case most difficult to treat. He was not prepared to say she might have died from the sal volatile alone, but this was possible in view of her state of health. He was asked by the coroner whether patients, becoming unconscious after a dose of nembutal, can completely recover and then relapse. He said this was possible. The doses prescribed for her were within limits which are frequently prescribed, but he would not himself prescribe them. He would not personally prescribe nembutal at all. He declined to say what he would have prescribed in the circumstances. Dr. Gillespie, said Sir William, had adopted a treatment which is very generally adopted; but he himself was so deeply impressed with the many cases he had seen of poisoning from the barbiturate group that he would avoid them. He would not criticise others who used them, but he desired that their dangers be realised. In cross-examination Sir William said that in his judgment there was, in the barbituric acid group, only a small margin between the therapeutic dose and the dangerous dose. Dr. Mapother had said he had frequently given 6 grains, but he would have been in the danger zone if he had given 12 grains. Nembutal might cause death without producing observable effects. Asked if there were any signs of nembutal poisoning in Mrs. Beech's case, he replied that the only signs were the absence of signs of disease and the presence of nembutal in the liver and kidneys. The analysis was proof that the full dose was given. Tissue might be poisoned without observable signs. He agreed that Dr. Gillespie had no reason to suspect that the patient was particularly susceptible to nembutal and had good reason to believe she was not. She had taken drugs of the barbiturate group such as luminal and dial. The cases he had known where patients recovered consciousness after taking nembutal and then died were three unpublished cases occurring in one day where the drug was in part given intravenously before a severe operation. He agreed that they were complicated and not pure cases: one must not attach too much importance to them. One other case was a case of pneumonia on Feb. 28th with special susceptibility. A passage was put to him from an article in THE LANCET (1932, ii., 136) by Dr. D. Curran and Dr. L. Minski, as to nembutal in doses of from 3 to 6 grains being "certain in its action, devoid of risk, and free from unpleasant after-effects." He entirely disagreed with it. His objection to nembutal was that it was a new drug with very decided therapeutic action, easily misused. He knew it was very much used. He was aware of no case in medical literature, apart from those mentioned by him, of a direct fatality from nembutal. The drug was somewhat uncertain in its action and he had heard of unpleasant symptoms following its use.

EVIDENCE ON THE OTHER SIDE

Dr. Mapother's evidence on the other side described the extensive use of nembutal at the Maudsley Hospital. He had given it to 328 patients and had administered 6116 individual doses. The maximum quantity in 24 hours had been 13½ grains (4½ grains in three doses). Other patients had had 12 grains in 4-grain doses. The average dose was 4 grains: sometimes 6 had been given. The drug could be regarded as very safe for the particular purpose for which it had been used, to produce sleep in quiet cases, or to obtain a definitely sedative effect in cases of restlessness. It had been given to a patient over a period of weeks. Asked if there had been any unfortunate consequences in the hospital from its use, he said that two patients on the occasion of their first dose had shown alarming symptoms, rather sudden collapse followed by quick recovery. They were patients in bad condition. The dose had been 4½ grains. The same dose was repeated without ill-effect. Nembutal was a drug which was excreted quickly; its effect was transitory. At the Maudsley Hospital it had been used in combination with medinal, bromide, chloral, hyoscine, paraldehyde, and somnifain. Dr. Gillespie's doses were, in his opinion, not excessive. Dr. Douthwaite, assistant physician at Guy's Hospital, also gave evidence in support of Dr. Gillespie's treatment. To show that 1½ grains of nembutal (which Dr. Roche Lynch appeared to have regarded as the maximum dose) was not likely to have a serious effect, Dr. Douthwaite swallowed a capsule of 1½ grains in court. He said he himself had been responsible for giving 6-grain doses in 20 cases. In one case the patient had had 15 grains of medinal the previous night. Death from nembutal occurs in a state of coma: Mrs. Beech had been awake on the Monday, after the nembutal: her death could not be due to this drug. Sir Maurice Craig, who also gave evidence, considered that Dr. Gillespie was wise in trying to get Mrs. Beech off paraldehyde and to substitute barbiturates. The last edition of Hale-White's Materia Medica gives the dose of nembutal as from 3 to 9 grains. If the patient was awake and active on the Monday morning, this showed that the effect of the drug had passed off. Dr. Bernard Johnson dealt in the witness-box with the safety of administering paraldehyde and nembutal in combination. Dr. Gillespie had previously described his own experience of the combination of nembutal and potassium bromide.

Thus the proceedings, while attaching no criminal liability to anyone, established a definite cleavage of opinion as to the safety of certain drugs. An important issue remains to be settled in the light of further experience, but it is significant that the coroner, in spite of the evidence of its dangerous nature, saw no negligence in the careful use of nembutal.

Ear-cutting for Rickets

During an inquest at Llanelly last week evidence was given of the curious Welsh custom of cutting the ears of babies as a cure for rickets. The mother of a 4-months-old child, assuming that the child was suffering from rickets, had taken it to a Mrs. Katherine Rosser, of Trimsaran, to have its ear cut. Medical evidence showed that death was due to heart failure following influenza; the child was not suffering from rickets at all. Mrs. Rosser admitted in the witness-box that she had cut the child's ear according to the local custom; she said that large numbers of adults and children were brought to her from the country districts for this purpose. A small cut is made inside the ear with a razor. Students of folklore and magic may be aware of similar custom elsewhere, and may be able to tell us whether the cut is made with the idea of releasing an evil spirit.

Mrs. Rosser declared that she received no pay for her services. The coroner warned her that this ear-cutting practice was illegal and dangerous, and must be stopped at once; she was fortunate that the evidence had not disclosed circumstances in which she would have been liable to a criminal charge. Dangerous the practice certainly is, both because the combination of unskilled diagnosis with useless remedy may easily mean the fatal exclusion of proper medical treatment, and because magical operations may not be conducted antiseptically. Illegal the practice is if, infringing Section 12 of the Children Act, it amounts to neglect of a child through failure to provide proper medical treatment. It may amount to manslaughter if the recourse to magic can be said to have caused or accelerated the patient's death. Merely to make a small cut in a person's ear at his or her request, for whatever purpose, involves in itself no criminal or civil liability. *Volenti non fit injuria.* Such a voluntary operation is no more illegal than the piercing of the lobe of the ear to facilitate the wearing of an ear-ring. Ear-rings, also, by the by, are sometimes associated with magic significance.

Rights of R.A.M.C. Officer

The Court of Appeal on March 6th dismissed Lieut.-Col. Kynaston's appeal against Mr. Justice Farwell's order, described in THE LANCET last year (Dec. 10th, p. 1302). Having retired from the active list of the R.A.M.C. in 1905, and being thereafter an officer of the Reserve of Officers, Col. Kynaston was recalled to service in August, 1914. His grievance is that he then found the conditions of a Royal Warrant of 1900 had meanwhile been altered to his disadvantage, that he was deprived of seniority of rank to which he was entitled, and that he was compulsorily retained in military service after the completion of his contract and after the removal of his name from the active list and from the Reserve of Officers. Legally, however, his claim against the Crown is hopeless. The King can do no wrong and, except in the rare event of Parliament having given a specific remedy, no subject can sue the Crown on any kind of contract of service. Owing to the constitutional doctrine, which bars such proceedings, the law courts decline to listen to a claim since they cannot grant a remedy. If the claim were for a wrong and not on a contract, it could be made only against the person who committed the wrong (whether he did so in the service of the Crown or not). Col. Kynaston brought his action against the Attorney-General; but if Col. Kynaston was right, and his grievances against the military authorities were well-founded, it was not the Attorney-General who had committed the wrongs of which he complained. So on this ground also his claim failed. The only satisfaction which Col. Kynaston can obtain from the proceedings is the publicity they have obtained and the knowledge that he may be altruistically hastening the day when the Crown Proceedings Bill will at last be passed into law. A Lord Chancellor's Committee of the highest authority has given us to understand that the citizens of this country are unfairly deprived of their proper rights against the Crown—i.e., against public departments—by legal principles which ought to be changed, and by procedural obstacles which are anachronistic. A Bill has been officially drafted; when will Parliament find time for this promised reform?

THE MEDICAL SOCIETY OF LONDON

ANNUAL DINNER

THE annual dinner of the Medical Society was held at the Trocadero Restaurant, London, on Wednesday, March 8th, when Sir John Broadbent, president of the Society, received a large assembly of members and a group of representative guests.

After the loyal toasts Lord Hanworth, Master of the Rolls, proposed the toast of Prosperity to the Medical Society of London in an excellent medley of seriousness and the reverse. Expressing the general as well as his own personal gratitude to the services of progressive medicine, he set out the difficulty which medicine must always have in getting its discoveries accepted, not only by the public, but by leading thinkers. He said that he had read Harvey's famous exposition on the circulation of the blood, the "De Motû," the little pamphlet being bound up, in the copy which he consulted in the British Museum Library, with another pamphlet wherein a Dr. Primrose, addressing King James I., unsettled that monarch by "refuting" Harvey's arguments. Not much later he found that the great Pepys had expressed it as his opinion that "it is not known and it never will be known what is the use of respiration." He quoted from the recipe-book of a great lady of that day a cure for ague which consisted in the patient lining the bottom of his shoes with the leaves of lignum-vitæ. Lord Hanworth asked the audience to imagine what a factor in the life of the seventeenth and eighteenth century was the terror of disease. The reign of Queen Anne was sometimes mentioned as the happiest period of our history, but that happiness must have been marred by the perpetual threats of misunderstood disease. Lord Hanworth concluded by finding the advance of modern science, medical and other, to be a story of progress, temporary set-backs only interrupting its course, and he asked for a spirit of confidence as medicine found new fields for development.

Sir John Broadbent, in reply, reminded the audience that this was the 159th anniversary dinner, the Society having been founded by Lettsom in 1773. He sketched the life of Lettsom, the quaker physician, who was born in the West Indies, was apprenticed as a surgeon and apothecary in England and returned without any diploma to the West Indies, where in a short period he made a considerable sum of money as an unqualified practitioner. With this money he returned to England, was licensed by the Royal College of Physicians, acquired a large practice, and founded the Medical Society of London, to which he presented its first home. The Society had at its origin, said Sir John, 30 physicians, 30 surgeons, and 30 apothecaries, and it remained what he would describe as a polyvalent society with a varied programme for its activities. He concluded by a defence of the exclusion of women from the Society, in which he was ingeniously able to exhibit his gallantry.

The toast of the Guests was proposed by Mr. Donald Armour, who alluded to the intellectual prominence enjoyed by the family to which Lord Hanworth belonged, and made appropriate references to Sir Holburt Waring, Dr. J. S. Fairbairn, and Lord Dawson, the presidents of the three diploma-granting Colleges, while the last he described as forming a liaison between the aristocracy and the mass of the profession by combining the office of the president of the Royal College of Physicians with that of the British Medical Association. In coupling the toast with the name of Sir Harold Fawcus he congratulated him on the extension of his post as Director-General of the Army Medical Services.

Lieut.-General Sir Harold B. Fawcus made an excellent recruiting speech. Why on earth, he asked, did the young doctors of the present day seem to regard commission in the fighting services as constituting some separate sort of medical life ? Most of those in the room, he said, would have served during the war and must know that medicine in the services was not separated from general medicine, and he failed to understand why there should be difficulty in recruiting the young officers. The pay was good and was paid by the State, but he did not think that money entered greatly into the question. If a belief that a career in the R.A.M.C. provided but limited chances of professional work was commonly held it could be shown that this view was rubbish by a simple inspection of the annual reports issued by the Department.

The guests included the Presidents of the Royal College of Physicians of London, the Royal College of Surgeons of England, and the British College of Obstetricians and Gynæcologists, the Master of the Apothecaries' Society, the Medical Directors-General of the Navy, Army, and Air Force, Sir Farquhar Buzzard, the Presidents of the Royal Society of Medicine, the Chelsea Clinical, Harveian, Hunterian, and West London Medico-Chirurgical societies, and the editors of the *British Medical Journal* and *The Lancet*.

APPOINTMENT OF AN ASSISTANT MEDICAL OFFICER OF HEALTH

A STORMY protest was made at a recent meeting of the County Dublin board of health when a letter was read from the Department of Local Government and Public Health refusing the consent of the Minister to the proposal of the board to make an appointment as assistant medical officer of health and school medical inspector from the ranks of the dispensary medical officers in the county. The Minister pointed out that the duties of the post were radically different from those of a dispensary medical officer and district medical officer of health, and that experience in the latter capacities was not sufficient qualification for the special duties of the post. He directed that the board should refer the appointment to the Appointments Commission, and he sanctioned a salary of £600 a year with vouched travelling expenses.

ANNUAL MEETING OF THE BRITISH MEDICAL ASSOCIATION

The preparations for the annual meeting of the British Medical Association to be held in Dublin in July next are well advanced. The authorities of the Irish Free State, of the city of Dublin, and of the two universities are giving hearty support to the local committees. Among the social events connected with the meeting, in addition to the annual dinner of the Association, receptions or garden parties will be given by the Government of the Irish Free State, the Trinity College, University College, Dr. Steevens' Hospital, the Rotunda Hospital, the Leinster branch of the Association, and others. A provisional programme of the scientific proceedings will shortly be published.

PARIS

(FROM OUR OWN CORRESPONDENT)

AN ASSOCIATION OF PRACTITIONERS

A RECENT sinister concatination of circumstances has thrown an undeservedly macabre light on the French medical profession. There is the scandal, still fresh in the memory, of the medical examinations for hospital appointments in Paris. There are also the unkindly reflections made on the medical profession as a whole as an elusive tax-payer. The trade-union spirit of various medical organisations has also attracted disconcerting attention and disparaging comment. A happy contrast to this sombre picture is a movement, not yet a year old, which shows what a spirit of disinterested coöperation and scientific research the general practitioner is capable of developing when given the opportunity. The Assemblée Française de Médecine Générale was established on March 15th, 1932. Its subsequent career has recently been reviewed in *Le Siècle Médical* by its enterprising secretary-general, Dr. Godlewski. It has numerous sections scattered throughout France, and a programme which looks at least a year ahead. For each general session, which takes place ten times a year, a special subject is chosen for study and discussion. The practitioner is thus given time to collect and sort his material for inclusion in the pool. This body already has its special organ, *La Médecine Générale Française*. Last May the subject chosen for discussion was rural tuberculosis. The subject chosen for the following session was cancer houses. It was the general opinion that, though they might exist, they were certainly rare. On the other hand, the mass of available information pointed to a very uneven distribution of the disease both in time and place. The subject chosen for the third session was the regional clinical manifestation of alcoholism. The parliament of practitioners was in blissful harmony over the ill-effects of spirits and the iniquity of the Government in putting a premium on intemperance. But where wines and cider were concerned, there was a general tendency not to brandish the hobnail liver in the face of its alleged and hypothetical owner. A discussion on alcoholic polyneuritis suggested the existence of centres and epidemics of this disease associated with a too generous use of arsenic in agricultural or industrial activities. The subject chosen for the meeting last December was infections associated with domestic animals, notably cattle. On this occasion much new and interesting clinical light was thrown on undulant fever and allied conditions. At a more recent meeting, devoted to conjugal tuberculosis, the consensus of opinion was in favour of this condition being rare, even when it was subjected to the searching light of serial radiological examinations. If this movement develops as favourably as it has begun, records of invaluable clinical observations collected by practitioners on generations of stationary rural populations may result.

the ears of babies as a cure for rickets. The mother of a 4-months-old child, assuming that the child was suffering from rickets, had taken it to a Mrs. Katherine Rosser, of Trimsaran, to have its ear cut. Medical evidence showed that death was due to heart failure following influenza; the child was not suffering from rickets at all. PUBLIC HEALTH SERVICES

The Typhoid Fever Epidemic at Malton

THE report to the Ministry of Health on the outbreak of typhoid fever in Malton, Yorkshire, last November has just been published.[1] The main facts appear to be as follows.

The town of Malton, an old country market town with no prominent industries, is situated on the river Derwent in the North Riding of Yorkshire. It stands on permeable oölitic limestone and calcareous grit except for the clay bed of the Derwent, which clay outcrops at its junction with the middle oölite on the north bank. Although Malton is divided into two unequal parts (Old Malton, with a population of 1000, to the north-east of New Malton, which has a population of about 3500) the water-supply and sewage disposal is the same for both. The water-supply has been derived since 1868 from a shallow well, 14 feet deep, known as the Ladywell. Two hundred yards to the west of the Ladywell is a pumping station which raises the water to a reservoir and water tower, half a mile further west, of a total capacity of 300,000 gallons. The rising main between the pumping station and the reservoir supplies many houses en route. The water-supply is constant and was delivered untreated in any way. As regards sewage, out of 1164 inhabited houses 898 were served by cistern-flushed water-closets, 611 had pail privies, and 10 midden privies. The sewers discharge directly into the river Derwent without screening or other treatment. The contents of the pails are tipped outside the town and sold to farmers for manurial purposes, "a proceeding which is not free from danger."

As regards previous incidence of diseases of the enteric group the late Dr. Bruce Low reported[2] in 1892 that enteric fever and diarrhœa had persistently recurred in the town during the previous 20 years. It was known that when flooded the river Derwent was liable to overflow into the Ladywell and "muddy the water." Dr. Bruce Low confirmed the fact that pollution was intermittent, and recommended that the question of obtaining for the town a sufficient and uniformly wholesome water-supply should be considered without delay. Nothing, however, was done except that the banks of the Derwent were raised in 1895 in order to prevent overflow, and when floods threatened pumping was stopped until they had subsided. In the past 21 years 14 cases of enteric fever were notified.

The first notification in the outbreak at present under review was on Oct. 9th, 1932. Following that the notifications were as follows:—

Week ending—		Cases	Week ending—		Cases
Oct. 22nd	..	1	Dec. 3rd	..	6
„ 29th	..	78	„ 10th	..	2
Nov. 5th	..	64	„ 17th	..	1
„ 12th	..	58	„ 24th	..	1
„ 19th	..	26	„ 31st	..	Nil.
„ 26th	..	11			

Dr. W. V. Shaw, one of the medical officers of the Ministry, arrived on Oct. 25th when about 30 cases had been notified, and confirmed the opinion of Dr. L. C. Walker, the M.O.H. of the urban district, who is also in general practice in the locality, that the disease was probably water-borne, in view of cases being of both sexes, all ages, and many occupations, and scattered throughout the town, and of the fact that the Norton urban district, a contiguous area with an entirely separate water-supply, was relatively free from cases. The action taken up to the time of Dr. Shaw's arrival had been to remove a heap of cattle manure which was adjacent to the well, to advise the inhabitants by crier and handbills to boil all water, and to take over the local cottage hospital and use it as an isolation hospital. The above measures were adopted on Oct. 24th. At a special meeting of the council on Oct. 26th the following recommendations by Dr. Shaw were adopted and put in hand immediately: (1) sterilisation by chlorination of the water, pending the resort to an alternative supply which was not immediately available; (2) removal to hospital of all notified cases; (3) the offer of protective inoculation with antityphoidal vaccine by the M.O.H. or private practitioners; (4) a further warning that all drinking water should be boiled pending such time as it could be sterilised in bulk. The chlorinating plant was installed by midnight on Oct. 27th.

THE SOURCE OF POLLUTION

The next step was to search for the source of pollution. A potential danger, the river Derwent, could be provisionally excluded as the month of September had been remarkably dry and there were no floods. The first patient to be notified (on Oct. 9th) was in the public assistance institution (Spring Hall), which is situated 300 yards to the west of the Ladywell and at a higher level. He was a man of 23 who had been admitted on Sept. 23rd. On or about Sept. 20th he had reported to his local doctor (he lived on a farm some miles away), who found him to be feverish without definite physical signs. As the fever persisted he was sent into the institution, where he was placed in the male sick block, which is separated from the female sick block by the "house." The nursing staff consisted of a charge nurse and an assistant nurse living in the male and female sick blocks, and having charge by day of three wards each, on two floors. By night an inmate acted as attendant in each block, the nurses being "on call" if necessary. The patient (X) was seen by Dr. Walker on the day of his admission and again on Sept. 26th, when a note on his record card was made "To be treated as typhoid." The nurses aver that they were not told of this, and knew nothing of the suspected nature of the disease until they were told by Dr. Parkin, Dr. Walker's deputy, to treat the "case as one of infectious disease" on Sept. 28th. The patient was then ordered to stay in bed, but he habitually disregarded this order and used the water-closet of the ward. On Oct. 2nd the result of an agglutination test was negative, but was positive when it was repeated on Oct. 9th, when X was notified as a case of typhoid fever. He was not, however, removed to the York Isolation Hospital, although such removal was provided for by an existing agreement. On Oct. 22nd two further notifications were received by Dr. Walker, one more on Oct. 23rd, and 15 on Oct. 24th. Dr. Walker then concluded that the infection was probably water-borne and that there would probably be many more cases; he thereupon communicated with the county medical officer of health.

The 43 cases notified round about Oct. 24th would probably have been infected about Oct. 3rd–5th.

DIAGNOSTIC PITFALLS IN TEMPORO-MAXILLARY ARTHRITIS

The temporo-maxillary joint is quite superficial. But this fact did not, in a case recorded by Dr. M. Jacod in *La Presse Médicale* for Feb. 1st, save the patient from a series of diagnostic errors with a tragio-comic sequence. The story begins in a river in which a man, aged 26, found his passion for fishing stronger than the discomforts he felt on account of the cold wind. He awoke next morning, the left side of his face feeling stiff, and the pre-auricular region very painful. This pain radiated upwards and downwards to the angle of the jaw, but there was no loss of symmetry of the face, no trismus, no auditory disturbance. So he hied him to a dentist who, finding that the left lower wisdom tooth had not erupted, put the blame for all the symptoms on it. Accordingly, an incision was made over it and mouth washes were prescribed. As the pain had become worse instead of better on the fifth day, the dentist realised that the tooth ought to be extracted, and so it was. The sequel to this step was an increase of the pain. The patient now consulted an otologist who, finding nothing amiss with the left ear, apart from some pain in the external meatus, expressed the opinion that the dental extraction was to blame for the pain. On the ninth day the patient consulted his family doctor who, finding some swelling in front of and below the ear, diagnosed acute parotitis on the left side. Evidently an early case of mumps, and doubtless the disease would appear on the right side in a few days. So the patient was confined to his bedroom, and derived what comfort he could from a local dressing. By the twelfth day the "mumps" had refused to extend to the right side, and the symptoms persisted on the left side. The patient himself now noticed that the introduction of a speculum into the external auditory meatus accentuated the pain. A new examination, made presumably by Dr. Jacod himself, revealed the quite characteristic picture of benign temporo-maxillary arthritis *a frigore*. The jaw was immobilised, and counter-irritation with the galvano-cautery was prescribed, supplemented by salicylate of soda given by the mouth for several days. The pain abated in 24 hours, and the movements of the jaw were normal and painless after five days.

CANCER IN TONKIN

In a communication to the Academy of Medicine on Jan. 24th, Dr. Le Roy des Barres drew attention to certain peculiarities in the incidence of malignant disease in the tropics, particularly in Tonkin. After 30 years in a relatively well-equipped surgical hospital, he has come to the conclusion that malignant disease is quite common in Tonkin—a finding contrary to the common belief that malignant disease is rare in the tropics. In 1929 he saw 162 cases, in 1930 186, and in 1931 as many as 215 cases. While in Europe the ratio of connective tissue tumours to epitheliomas is as 1 to 18, in Tonkin it is as 1 to 7·5. In as high a proportion as 18 per cent. of all the cases the penis was the seat of the disease, and penis cases formed 31 per cent. of all cases of cancer in the male. Cancer of the uterus is set down as occurring in 9 per cent., and cancer of the breast in 8 per cent. of the cases; these figures are, however, valueless, as it is not stated whether the percentages refer to all the cases or only to the cases of cancer in women. Whereas cancer of the digestive tract accounts for more than 50 per cent. of all the cases in Europe, it accounts for only 5 per cent. of the cases observed in Tonkin. The average age-incidence for epitheliomas was only 46 years—much lower than in Europe. The average age-incidence for sarcomas was 35 years. Three-quarters of the cases of cancer affected persons between the ages of 30 and 60, and more than half of all the cases occurred between the ages of 40 and 60. A comparison with Bablet's findings, which concern Cochin China mainly, show that while 21 per cent. of the cases of cancer in Cochin China affect the mouth, only 8 per cent. of the cases in Tonkin show this localisation.

PERIODICAL MEDICAL EXAMINATIONS

The achievements of the Life Extension Institute of New York have made some impression in France. The arguments in favour of a complete periodical medical examination are, indeed, so plausible. You overhaul your car or any other piece of machinery periodically to avoid a breakdown, so why not apply the same rule to the even more valuable and delicate machinery of the human body? And if something is good for the Americans, should it not also be good for the French? In answer to these and similar questions, bodies more or less modelled on the pioneer American organisation have begun to appear in France. But the medical profession has not rallied to them with whole-hearted enthusiasm. In at least one such institution the policy seems to have been adopted of adding treatment to the programme of the exhaustive medical examination. The result has been a vigorous protest from the practitioners in the neighbourhood who have seen in this institution a not altogether fair competitor. Those who are familiar with Latin psychology are inclined to be sceptical as to the immediate future of such institutions in France.

INFECTIOUS DISEASE

IN ENGLAND AND WALES DURING THE WEEK ENDED MARCH 4TH, 1933

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 9 (last week 22); scarlet fever, 1763; diphtheria, 789; enteric fever, 19; acute pneumonia (primary or influenzal), 1362 (last three weeks 4106, 2228, 1436); puerperal fever, 56; puerperal pyrexia, 107; cerebro-spinal fever, 51; acute poliomyelitis, 12; acute polio-encephalitis, 3; encephalitis lethargica, 7; continued fever, 1 (Holywell R.D., Flintshire); dysentery, 11; ophthalmia neonatorum, 97. No case of cholera, plague, or typhus fever, was notified during the week.

The notifications of acute pneumonia (primary or influenzal) were still below the expected number by 34 per cent. in England and Wales and 27 per cent. in the County of London.

The number of cases in the Infectious Hospital of the London County Council on March 7th–8th was as follows:—Small-pox, 52 under treatment, 2 under observation (last week 56 and 1 respectively); scarlet fever, 1000; diphtheria, 1583; enteric fever, 0; measles, 208; whooping-cough, 688; puerperal fever, 31 (plus 1 baby); encephalitis lethargica, 231; poliomyelitis, 2; "other diseases," 341. At St. Margaret's Hospital there were 19 babies (plus 12 mothers) with ophthalmia neonatorum.

Deaths.—In 118 great towns, including London, there was no death from small-pox, 3 (2) from enteric fever, 30 (0) from measles, 7 (2) from scarlet fever, 36 (11) from whooping-cough, 28 (4) from diphtheria, 67 (11) from diarrhœa and enteritis under two years, and 242 (42) from influenza. The figures in parentheses are those for London itself.

The only great town reporting more than 10 deaths from influenza was Bradford (with 12). Preston reported a fatal case of enteric fever. Four deaths from measles occurred at Hull, at Liverpool, and at Birmingham, 3 each at Brighton and Newport. Whooping-cough accounted for 4 deaths each at West Ham and Salford, 3 at St. Helens. Liverpool reported 10 deaths from diarrhœa.

The number of stillbirths notified during the week was 312 (corresponding to a rate of 46 per 1000 total births), including 40 in London.

and money, but it fails to control, inasmuch as infected children are at large, playing in the streets without restriction, and therefore spreading infection." Sir George Newman has said on several occasions that, except for rare instances in rural districts, school closure is rightly becoming an obsolete practice. Dr. Alderton has the consensus of modern expert opinion on his side.

THE DOCTOR'S DAY

"Come, tell me how you live," I cried,
"And what it is you do!"

XIX.—WITH THE GUARDS' BRIGADE

Every young man who joins the Royal Army Medical Corps will find himself, sometime or other, in medical charge of effective troops. Given reasonably good units, there is no job, military or civil, which can be more varied and fascinating, few which provide such opportunities for studying one's fellow men, and none where good honest work can give a more stimulating return. The wise medical officer will proceed with caution until he feels himself firmly established. Then as time goes on, he finds himself becoming more and more a personality, his advice sought after and followed, and in the end he may attain a position of responsibility and influence far beyond his years and military rank. With this introductory note I proceed to describe a day spent as medical officer in charge of troops.

SICK-PARADE BEFORE BREAKFAST

In time to commence work at 7.30, I reach the medical inspection-room where the men reporting sick await me. All four units of my brigade are represented—two famous English battalions, another English battalion, well, not just so renowned, and a battalion of Highlanders a designation which tells their quality, for a second-class kilted regiment has yet to be raised. There are various ways in which the discipline and general efficiency of a unit may be gauged; the quickest is to see the sick-parade. So knowing my battalions, I know in advance that from three of them every man reporting sick will do so with good reason. In the remaining battalion, although I have put an end to attempts at malingering, men still take advantage of trifling ailments in the hope of escaping some duty—sure evidence of lack of discipline and of pride in themselves and in their regiment.

First a batch of men with temperatures have to be examined and sorted out. This needs care, for last week I had the humiliation of missing an early scarlet rash. One man, recently returned from abroad, describes an attack very suggestive of malaria. I make blood smears to accompany him to hospital, in case the pathologist cares to make use of them, keeping back one or two to stain and examine myself for practice. Next, a whitlow to open. A sprained wrist—I *think* there's no fracture, but we'd better have an X ray. "Cough and pain in the chest, sir" proves to be pleurisy with effusion—and so on for a couple of hours, a fine training in quickness and judgment, with the added interest of learning later how the provisional diagnoses finally turn out. Also, during my weekly tour of duty as orderly officer at the hospital, I make a point of seeing every patient from my brigade, medical, surgical, or otherwise, to ascertain exactly how they are progressing. The last case this morning presents no diagnostic difficulty. A Highlander with a large raw sore on his foot, obviously caused by prolonged marching with a neglected blister. He must have suffered torments. I say angrily: "This will take weeks to heal now. Why didn't you fall out on the line of march?" "Sir," replies the man, "I didn't want to give the battalion a bad name." . . . I go off to breakfast feeling privileged to have charge of men like these.

MORNING IN HOSPITAL

Breakfast over, I pay a visit to the main hospital where I have a ward of non-acute cases. One of these is rather puzzling—a man claiming to be deaf, whose auditory tests give such conflicting results that I feel sure he is shamming. I decide to arrange a consultation with the ear specialist, and, if he confirms my opinion, lay a plot to show up the schemer in some dramatic fashion. Then back again to my brigade lines to further several schemes I have in hand for increasing the marching efficiency of the troops. These have been explained to my best battalion, and eagerly adopted. If successful when tested out, as I am sure they will be, two of the others will be keen to follow suit. If the slack battalion prove obstructive, as is their custom, a word to the brigade commander will have them brought to heel. So I see my way clear to achieving the great ambition of my young life—to have the best marching brigade in the army, that is, to go through the strenuous training exercises and manœuvres with the smallest number of march casualties.

In the afternoon a few sets of tennis, then tea and another visit to hospital, this time voluntary. I am working for the M.D., and the specialist in medicine has recommended several "good cases" for overhaul and report. An excellent series, quite as varied as any group I have seen when an H.P., and including one or two diagnostic puzzles which require some study of the Fathers before committing myself. Next week I hope to spend one or two afternoons in a similar way seeing women and children at the Families' Hospital.

GOOD FELLOWSHIP

Only one duty remains for to-night. I have been bidden to a dance given by the sergeants of my Highland battalion, and I feel distinguished by this mark of their esteem. I arrive when the festivities are well advanced, and I am made to realise that I am a welcome guest and among good friends. Indeed, the proffered hospitality is overwhelming—"But, sir, you haven't had a drink with *me* yet!" Alas! the line must be drawn somewhere. My old friend the pipe-major has been less wise, and is now in a high state of exaltation. The whole art and mystery of pipe music, he explains, is behind him; there is no world left him to conquer. "Have you ever heard of *The Lost Pibroch*"? I ask. "Sir," he says, "it is my favourite tune." "But," I protest, "I have read a book which says that in the last 200 years there has been only one man who could play *The Lost Pibroch*, and he, of course, is dead." The pipe-major is no whit abashed. "Sir," he says with emphasis, "that is absolutely true—but before he died he taught it to me."

I walk home under the stars. Doubtless I shall carry out many duties in the Corps; perhaps, who knows, I may one day succeed in obtaining recognition as a specialist in some branch; but whatever happens, I know that I can never have a happier time than my 18 months with the Guards' Brigade.

Amalgamation of Birmingham Hospitals.—It was announced at the annual meeting of Birmingham General Hospital that arrangements for its amalgamation with the Queen's Hospital have now been practically completed, and that when the new hospital centre comes into being it will be financed, controlled, and developed by the amalgamated boards. The General Hospital is governed by trustees, but the Queen's is incorporated by Act of Parliament, and parliamentary sanction to the union will therefore be required.

If X was a cause of the outbreak he must have been a source of infection from the time of his admission on Sept. 23rd. Tests of the drain from the male sick block to a manhole outside the institution showed a considerable leakage, and excavations showed a broken socket in the glazed earthenware pipe at a point where excavation had been made some 18 months previously to lay an electric power cable. Below the break was a large empty cavity into which the water used for testing had flowed and disappeared. Excavations between the Ladywell spring and the broken drain showed by bacteriological examination that the rock was sewage-polluted, and the junction of the clay and the oölite at this point probably determined the seepage of sewage directly into the Ladywell. The distance from the break in the drain to the Ladywell was about 250 yards; this probably accounts for the interval which elapsed between the date of admission of X and the date of the "explosion" of water-borne infections. X was removed from the institution on Oct. 26th and the notification of primary cases ceased about three weeks later; chlorination of the water-supply, begun on the same date, might, however, have had the same result.

The remainder of the report deals with the measures taken to arrange accommodation for the patients in neighbouring hospitals and with the results of inoculation. 1600 persons were inoculated, and no case occurred in individuals inoculated before infection. In persons inoculated during the incubation period there was some evidence that the attack ran a milder course.

SUMMARY AND CONCLUSIONS

The summary and conclusions of Dr. Shaw's report are given below in extenso:—

(1) A total of 235 persons, or approximately 5 per cent. of the population of Malton, contracted enteric fever in the six weeks ended mid-November, 1932. There were 35 secondary cases.

(2) There was no case of enteric fever in the urban district until Sept. 23rd, 1932, when a patient was admitted to the public assistance institution. On Sept. 26th he was found to be suffering from enteric fever, but he was not notified until Oct. 9th, nor was he removed to the York Isolation Hospital until Oct. 26th, although an agreement was in existence between Malton urban district council and the Corporation of York for the admission of cases of infectious disease.

(3) This man's infected excreta were drained into the river Derwent—the common sewer of the town—by a broken drain allowing part of the contents to soak into the surrounding soil, polluting it heavily with the specific infection which gained access to the water-supply, either by drainage from the oölite or otherwise.

(4) The infected sewage probably entered the public water-supply from about Sept. 30th to Oct. 26th, when the patient was removed to the York Isolation Hospital.

(5) The town is sewered into the river Derwent and, apart altogether from the public assistance institution, infected excreta from the water-borne cases of enteric fever had been entering the river Derwent for upwards of a month.

(6) The exceptional incidence of enteric fever in Malton during the seventies, eighties, and nineties of last century, recorded by the late Dr. Bruce Low in his report of May 5th, 1893, has unfortunately been repeated in the year 1932, and although the source of pollution differed the vehicle was the same. I cannot do better than repeat the conclusion of Dr. Bruce Low that "the members of the Malton urban sanitary authority should, therefore, without delay, reconsider the question of obtaining for the town a sufficient and uniformly wholesome water-supply."

School Closure at Barnoldswick

In an address reported on another page Dr. Brincker says that school closure as a method of checking the spread of infection has been discarded in schools where an intelligent method of inspection, surveillance, and control has been instituted. Almost while he was speaking a Yorkshire medical officer of health was defending himself against severe criticism of his action in not closing the local schools during the recent epidemic of influenza. Barnoldswick is an urban district of 11,675 inhabitants in the West Riding, not far from Haworth, whose sometime rector was pilloried by his daughters for his dour expression of opinion; and the Brontë tradition has survived among the members of the district council, but without personal animus, for one member concluded his remarks with the words "We know that Dr. Alderton has been a good servant to us and we wish him well," when the doctor responded, "Every public man must submit to criticism." Another member added that it was not the person of their medical officer but the general attitude of the medical profession towards schools that he was attacking, and he reiterated his belief that "when children are compelled to be herded together they are in more danger of infection than when they are scattered." That this view should still have strong adherents among the public is not surprising, since it is not so long ago that a section of the medical profession thought there was something to be said for it. In former days when there was no close medical supervision of schools the position was quite other than what it is to-day, when the expert services of doctors and nurses are available, and the teachers have acquired skill in observing the earliest signs of ill-health and know which children to watch and refer to the school medical officer or (if he is not immediately available) to private doctors. Without this organisation and unceasing vigilance it would be a very different matter, and it is not surprising that Dr. Alderton was overburdened with the work of keeping fully in touch with the epidemic. Under these circumstances who would not have resented the suggestion that "he had given the matter insufficient attention"? To have closed the school would have been, in the words of a standard text-book, "a confession of failure, a throwing up of the sponge in the contest with disease. The following up of cases, especially of non-notifiable diseases, is lost." There is also the fact that with the improved hygienic conditions of the schools and the present poverty and overcrowding of the homes it is, as Dr. Alderton said, far better for the children to be under cover and in the warmth at school than running the streets. As far back as 1910 Dr. Kerr wrote: "In proportion as the school under present conditions recedes as a factor in disseminating disease, so from the public health point of view do other factors gain in importance. In future the sanitarian must not be hypnotised into regarding the school as a chief centre of disease, but must turn his attention to possibilities of preventing infection in families and houses, courts, and streets." In 1919 a committee of the American Medical Association and the U.S.A. Bureau of Education reported that "the closure of schools is an extremely clumsy, unscientific, and unsatisfactory method of controlling epidemics among school-children. It results not only in loss of school time

CORRESPONDENCE

THE PRODUCTION OF QUININE

To the Editor of THE LANCET

SIR,—In your annotation last week (p. 537) the view is repeated that the present failure to use all the quinine which is, or can be, produced in the world is due solely to the high price of this specific antimalarial remedy. It would be unfortunate if this view alone were to be considered by the proposed International Quinine Conference, mentioned in your leading article of Jan. 28th (p. 206). For it appears that the "Inquiry into the quinine requirements of malarial countries and the world prevalence of malaria," issued by the League of Nations as a preamble to this conference, elicited the information that in several malarious countries the view is held that the cost of the remedy itself is almost the least important factor in the failure to provide for the treatment of malaria in poverty-stricken areas. More important reasons than the cost of the drug itself are said to be: (*a*) the cost of distributing it; (*b*) the apathy of the people and their refusal to take it even when offered free. For these reasons several countries are able to use only a small part of the quinine which they buy; others are only able to use it by adopting special methods of free distribution and of sale under cost price. Lack of sales is not due to the price of the drug; it is due chiefly to the inability of governments to spend money on necessary arrangements for getting it to the people, as well as to the fact that because malaria is not often a fatal disease, the indigenous inhabitants of malarious countries will seldom bestir themselves to obtain quinine except during the periods when the disease is epidemic or unusually severe.

I am, Sir, yours faithfully,

London, March 13th, 1933. S. P. JAMES.

MOBILISATION OF SUGAR INTO THE BLOOD DURING REST

To the Editor of THE LANCET

SIR,—Dr. Martin Raven asks for an explanation why his patient, aged 7½, required more insulin at 12 midnight than he did at 8 A.M. or 4 P.M. It is not easy to give a satisfactory answer. Insulin requirements at night are apt to seem unexpectedly large. Thus, a patient who takes 20 units of insulin at 8 A.M. may eat 100 g. of carbohydrate at breakfast, lunch, and tea, whereas he only eats 50 g. of carbohydrate after 20 units at 7 P.M. This may be partly explained by the amount of carbohydrate used up during the day by muscular activity, and partly by the longer interval between the evening and morning doses (13 hours). It is unusual for the evening dose to be higher than the morning dose, and I have analysed the latest figures of 100 consecutive patients who are eating 100 to 150 g. of carbohydrate in the day and require two doses of insulin. The blood-sugar in these cases is below 130 mg. per 100 c.cm. between 10.30 A.M. and noon, when they are seen at hospital after their usual breakfast and insulin. In 49 cases the morning insulin was 2–6 units greater than the evening dose; in 6 cases it was more than 8 units greater (in one case 14); in 39 cases it was the same, and in 6 cases the evening dose was 2–10 units greater than the morning dose.

When the evening dose has to be definitely higher, say 6 units, than the morning one, I suspect that the patient has some other infection which is associated with a slight rise of temperature at night. It may be possible to discover some source of minor sepsis, but if none can be found the possibility of a tuberculous lesion must be considered. The physical signs of this are often difficult to discover in these mild cases, especially if the mediastinal glands are involved. In some cases I have watched the evening dose gradually decrease without the appearance of any signs of a tuberculous lesion. It is possible that Dr. Raven's patient has some other infection responsible for the great increase of insulin demands during the night.—I am, Sir, yours faithfully,

GEORGE GRAHAM.

Harley-street, W., March 13th, 1933.

RAW AND PASTEURISED MILK

To the Editor of THE LANCET

SIR,—In his review of the effect of pasteurisation upon the nutritive properties of milk Dr. Savage tells us (p. 485) that there are scarcely any studies which are of use for a comparison of raw cow's milk and pasteurised cow's milk; but in his references to my own work no one of the statements he attributes to me is correct. Let me take his remarks seriatim.

Concerning 40 children I tabulate Dr. Savage states that I "examined them at various periods subsequently, the average being about four years." Each of these statements is incorrect, as he will find if he reads the paper.

With regard to my statement that these children were on raw milk, he imagines that it may "easily have been at temperatures equivalent to flash pasteurisation." If he will again refer to my paper he will find that I define what I mean by raw milk —viz.: "Milk which has at no time been heated to more than a few degrees above body temperature," whereas in flash pasteurisation it is heated to at least 154·4° F. and sometimes higher.

Dr. Savage states that I give "no comparable data dealing with pasteurised milk"; but let him compare my Tables I. and II. with Table VI., and read my comments thereon.

He states that I "agree that there is no exact knowledge whether or no effects comparable would result with pasteurised milk"—again quite incorrect. There is some exact knowledge in the comparison of Tables I., II., and VI. as quoted above, and this, though in older children, shows caries in second permanent molars occurring in the ratio of 11 to 77 with raw and pasteurised milk respectively a few years later. What I did write was that I had no exact knowledge of children "*brought up* on sterilised or pasteurised milk." Now it so happens that the 750 boys reported on as having raw milk was the total number of children in the home in which Dr. Corry Mann had conducted his pasteurised milk work, and his work was done during the few years immediately prior to these boys being put on to raw milk, they being under my dental care during this whole time—and before; I did not notice any essential difference in the incidence of caries while pasteurised milk was being used, but two or three years after raw milk had been started the lessened incidence was amazing—and started my inquiry. I had no *exact* figures referring to the incidence of "return" cases of caries in Dr. Corry Mann's time, and so, wishing to be meticulously accurate, forbore to publish a generally noticed clinical phenomenon without *exact* figures for comparison.

Again, Dr. Savage says I infer that "all children get a considerable milk ration during the first three

PANEL AND CONTRACT PRACTICE

The Fund

THE central practitioners' fund for 1932, after 10 per cent. deduction, is £6,055,323. The corresponding sum for 1931 was £6,467,625. The provisional estimate for 1933 is £5,868,000.

What are the Terms of Service?

Any registered medical practitioner can join the panel by writing to the clerk of the insurance committee for his area, and provided that his name has not already been removed from the panel by the Minister of Health after official inquiry the clerk must put his name down on the local list of practitioners for panel service. This is the position in general terms. But on looking a little deeper the matter is not so simple as that, for the practitioner has to sign a form in which he says (among other things) that he desires "to undertake the medical attendance and treatment of insured persons in the area of the committee *upon the terms for the time being in operation in that area*, and for this purpose I hereby accept service *under those terms.*" What are these terms of service? Are they the same for all areas—i.e., the general terms of service as agreed between the Ministry and the Insurance Acts Committee? Presumably not, because the words "in that area" are in the practitioner's agreement. How then is the applicant to know the local difference between his terms and those of other areas or the general terms of service? He will probably be supplied, after he has signed his agreement, with the local allocation scheme which deals with the problem of insured persons not on any list, of treatment in emergency, of refusal to accept insured persons for treatment, or of the method of getting an insured person removed from a list. He will also be supplied, after he has signed his agreement, with the local distribution scheme which will explain how he is paid, the methods of calculating lists, the payment for temporary residents, emergency treatment, mileage, and so forth. Both these schemes will have been approved by the Ministry of Health after agreement between the panel committee and the insurance committee, but difficulties may apparently be raised by the insurance committee about other matters such as hours, place, and other occupation, of which the practitioner knows nothing before signing. From the regulations it would appear that the insurance committee can hold up his admission to the panel until they get their way on such matters.

Let us take a supposed case. Can the insurance committee force a doctor, applying to go on the panel, to increase the number of his surgery hours, or to have a consultation time on Sundays? Can the insurance committee refuse permission to go on the panel to a doctor who is also carrying on business as a chemist, or who wishes to continue in practice as a dentist at the same time? Is there any statutory difference between going on the panel and being admitted to the list? How soon after applying to go on the panel can the doctor accept patients by signing medical cards? Can the insurance committee refuse permission to join the panel until these questions of hours, places of occupation, or other occupations have been settled? In the event of a qualified doctor being refused permission to go on the panel owing to "unsatisfactory hours" would he have the right of legal action against the committee?

The answer to these questions is by no means clear. In certain areas precedents have been created by the refusal of the insurance committee to allow a doctor to have his surgery in a building which was regarded as unsuitable—e.g., a farm building; and recently when a dentist, being also a qualified doctor, applied to go on the panel the application was adjourned for consideration until the next meeting, in order that his hours and place of work might be investigated. Some members of the committee seem to have thought that as he was a dentist he could not also be an insurance doctor. These happenings are contrary to the common view that any qualified man (not being an excepted case) may join the panel by simply writing to say he wishes to do so. It would be interesting to hear from insurance practitioners who have met with other restricting or overriding decisions from their insurance committees.

Count of Register

The movement of the panel population continues to show a slight tendency towards the country from industrial areas. The count of the register for the following areas is going up:—

Brighton.
Blackpool.
Southend-on-Sea.
Southport.
Croydon.
Oxford.
Worcester.
Portsmouth.
Essex.
Kent.
Bude.
Cambridge.
Middlesex.
Somerset.
Surrey.
Sussex.
Devon.

The count is tending downwards in the following areas:—

Barrow.
Birkenhead.
Bristol.
West Hartlepool.
Bolton.
Bootle.
Burnley.
Halifax.
Huddersfield.
Middlesbrough.
Oldham.
Bradford.
Preston.
Durham.
Lancashire.
London.
Yorkshire, W.

Own Arrangers

Croydon still maintains the lead in giving permission to insured persons to make their own arrangements with other doctors: 84 permissions per 10,000 insured persons as against 85 last year. The county committees keep to the same average this year as last—viz., 7 per 10,000—whilst the county boroughs have increased to 17·9 per 10,000 against 14 last year. These applicants deserve some sympathy. Some of them are homœopathic patients who cannot find an insurance doctor who shares their view; sometimes they have been under the care of a non-panel doctor for a long time before they became insured persons. There seems to be some hostility towards "own arrangers" on the part of insurance committees, dating perhaps from a distant time when non-panel doctors advised their insured patients to remain under their care by contracting out of the Act. There are still many committees in England which do not allow any such claims to go through, and we think the time has come for more sympathetic attention to be paid to them.

GENERAL LYING-IN HOSPITAL.—Last week the Queen opened the new out-patient department, welfare centre, and nurses' home of the General Lying-in Hospital, York-road, Lambeth. Her Majesty succeeded as patron Queen Alexandra, whose predecessors were Queen Victoria and Queen Adelaide. The nurses' home on the upper floors of the same building contains 74 bedrooms and bed-sitting rooms; on the lower floors are a lecture hall and a museum. The cost has been £57,000, of which £1500 only remains to be raised.

RAW AND PASTEURISED MILK

To the Editor of THE LANCET

SIR,—In his review of the effect of pasteurisation upon the nutritive properties of milk Dr. Savage tells us (p. 485) that there are scarcely any studies which are of use for a comparison of raw cow's milk and pasteurised cow's milk; but in his references to my own work no one of the statements he attributes to me is correct. Let me take his remarks seriatim.

Concerning 40 children I tabulate Dr. Savage states that I "examined them at various periods subsequently, the average being about four years." Each of these statements is incorrect, as he will find if he reads the paper.

With regard to my statement that these children were on raw milk, he imagines that it may "easily have been at temperatures equivalent to flash pasteurisation." If he will again refer to my paper he will find that I define what I mean by raw milk —viz.: "Milk which has at no time been heated to more than a few degrees above body temperature," whereas in flash pasteurisation it is heated to at least 154·4° F. and sometimes higher.

Dr. Savage states that I give "no comparable data dealing with pasteurised milk"; but let him compare my Tables I. and II. with Table VI., and read my comments thereon.

He states that I "agree that there is no exact knowledge whether or no effects comparable would result with pasteurised milk"—again quite incorrect. There is some exact knowledge in the comparison of Tables I., II., and VI. as quoted above, and this, though in older children, shows caries in second permanent molars occurring in the ratio of 11 to 77 with raw and pasteurised milk respectively a few years later. What I did write was that I had no exact knowledge of children "*brought up* on sterilised or pasteurised milk." Now it so happens that the 750 boys reported on as having raw milk was the total number of children in the home in which Dr. Corry Mann had conducted his pasteurised milk work, and his work was done during the few years immediately prior to these boys being put on to raw milk, they being under my dental care during this whole time—and before; I did not notice any essential difference in the incidence of caries while pasteurised milk was being used, but two or three years after raw milk had been started the lessened incidence was amazing—and started my inquiry. I had no *exact* figures referring to the incidence of "return" cases of caries in Dr. Corry Mann's time, and so, wishing to be meticulously accurate, forbore to publish a generally noticed clinical phenomenon without *exact* figures for comparison.

Again, Dr. Savage says I infer that "all children get a considerable milk ration during the first three or four years of life.” That is an exaggeration, as I say “practically all”—and from extended inquiries among medical officers and others having knowledge of children in Surrey, Essex, and London, and my own observations, that statement is true; and if it is not true of Somerset then, in view of the present regulations concerning milk distribution to children, it seems to be rather a reflection on those in charge of such matters in that county.

Nor do I infer that the milk practically all children have is “sterilised by boiling or pasteurisation.” (Surely it is common knowledge that pasteurisation does not sterilise milk.) What I do say is that it is “almost universally sterilised by boiling or pasteurised.” The “incorrect generalisation” to which Dr. Savage refers, is drawn from his misreading of what I wrote.

Apparently Dr. Savage’s views on the effects of pasteurisation are by no means in accord with those of the research workers if they consist only of the meagre items on p. 487. He states, regarding vitamin C in milk, that all experts regard it “as an inadequate source of supply,” but Providence evidently did not agree with these experts, as milk was provided as the sole infant nutriment of the whole mammalian creation, which still seems to be carrying on very well.

Dr. Savage’s conclusion that my paper “offers no evidence either way as regards the relative value of raw or pasteurised milk in preventing caries” seems to me to be based on false and imaginary premises. Indeed, if he realised what an amazing experience it was to see 70 children consecutively (or 95 if I count those under 2 years old) of whom 63 (or 88) were absolutely free from caries in spite of their diet, and the remainder had caries only in teeth erupted before admission (except two who had the milk ration, but there were grave doubts if they had had it raw), and mostly physically subnormal at that, he might see fit to change his views.

I am, Sir, yours faithfully,

EVELYN SPRAWSON.

FILARIAL PERIODICITY

To the Editor of THE LANCET

SIR,—The observations by Dr. Carmichael Low, Dr. Manson-Bahr, and Mr. Walters, published in your issue of March 4th (p. 466), together with animal experiments by Dr. Hanschell, raise again the interesting question of the mechanism of filarial periodicity. It has been the source of much speculation and its investigation the subject of much work, but so far there has been no record published of the behaviour or survival of microfilaria bancrofti artificially inoculated into man, an experiment which Dr. Manson-Bahr himself suggested some years ago (THE LANCET, 1929, ii., 45).

Recently I transfused a human volunteer intravenously with citrated blood containing 720,000 embryos, obtained from a case showing nocturnal periodicity. The ear blood of the recipient was then examined at the end of the transfusion, at 3, 6, 12, and 21 hours later, and also at frequent intervals for several subsequent days; but no embryos were found. It must be admitted, however, that between the drawing-off of the blood for transfusion and its injection there was an unavoidable delay of two hours, during which the embryos showed signs of commencing ecdysis. Whether this had any influence on the result of the experiment it is impossible to say, but it makes it desirable that the experiment of transfusing man with blood containing a sufficient number of living microfilariæ be repeated under more favourable conditions, especially as the only vertebrate host of *W. bancrofti* appears to be man himself.—I am, Sir, yours faithfully,

FREDERICK MURGATROYD.

Liverpool, March 6th, 1933.

“EXCITABILITY: A CARDIAC STUDY”

To the Editor of THE LANCET

SIR,—It is so difficult for anyone to collect and collate a series of new facts, running counter to current theory, without first meeting considerable opposition that I am greatly indebted to your reviewer of my book,[1] for his acknowledgment that the experiments eliciting the facts have been carefully carried out. I wish, however, to point out that readers themselves must take over some part of the difficulty of its understanding. It took me several months to convert the late Prof. Waller to the view that excitability was not a primary property of excitable tissue, but that there were instead behind this two deeper properties, the kinesiphores. He informed me of his difficulties after his conversion. He had first taken the facts given in my tracings and attempted to fit them in with the idea that excitability was a tissue-property which could be either raised or lowered. The result of these efforts was an attack of mental indigestion obtained through trying to visualise something being both raised and lowered at once. He next tried a diphasic idea by which the property was to be first raised and then lowered, or vice versa, but that was no better because at the end of the two processes the property had still to be imagined as both up and down. Eventually he recast his original theories on these matters, a process which, as he pointed out to me, grows more difficult as we grow older.

Every reader of my book who attempts to fit the facts in with current theory—i.e., with current understanding—will necessarily find that I have made matters more difficult than ever to understand. The difficulties, however, are not created by the facts, but by attempting to fit them into theories for which they are not adapted. I should like to be given the opportunity of denying the paternity, now seemingly attributed to me, of the “frothy” theory of psycho-physical parallelism, a theory which so many physiologists and psychologists have found quite credible. I merely pointed out that the views concerning muscular functioning which the facts lead me to form would lead also, if they were regarded as of general applicability, to a theory having many resemblances to that of psycho-physical parallelism. This idea, unfortunately, is inconsistent with the theory that the psychologists have been following the muddier path; they seem instead to have marched on the firmer ground. I thought also, when noting these points, that there might be quite a large number of medical men who would be interested in what now seems quite possible—namely, that the organ of mind may include a structure which does not necessarily belong to the order of things we call material.

It seems to me further possible that it would have been better if I had omitted my remarks about Freud—even though I only attempted to give him some of his due—because so many people believe that he is a charlatan whose theories have no scientific basis whatever. To anyone who has committed himself to such a view, it can certainly be most annoying to meet new facts not only capable of being interpreted as the evidence that Freud's theories have a very solid basis of fact. but also as indicating that he is so far ahead of the physiology of his time that he and the physiologist have lost sight of one another.

---

[1] See THE I

Yet, after all. Sir, my incursions into psychology form possibly about one-fiftieth part of the whole. How much psychology then does one require to know to be able to understand how it can be that what should be a calm judicial review of the facts actually leaves the facts severely alone. and considers chiefly instead the believed muddier ways of the psychologists? I am, Sir, yours faithfully,

W. BURRIDGE.

Department of Physiology, King George's Medical College, Lucknow, March 3rd, 1933.

CHILDREN IN THE CURRICULUM

To the Editor of THE LANCET

SIR,—Your weighty leading article (p. 477) on the discussion by the General Medical Council on this subject has been read by me with great interest and, if I may say so, with approval. I see, however, that you have credited the inspectors, of whom I had the honour to be one, with a definite request for "a separate written paper, and a special clinical examination, to be conducted by those engaged in the teaching of pædiatrics." No such request was made by me. In my general report on the final examinations in medicine and in dealing with the subjects of mental diseases and the diseases of children I wrote as follows:—

> "Without expressing any definite opinion as to whether the better plan is to carry out some kind of separation of the two subjects on the lines which have been adopted in some of the centres or not, I feel that in those centres where this does not prevail a healthy tradition should be established that should lead candidates to feel that there is a strong probability that questions may be set in the Written and asked in the Clinical or Oral, or in both."

I am, Sir, yours faithfully,

Leeds, March 13th, 1933. T. WARDROP GRIFFITH.

CONTROL OF INFECTIONS IN CHILDREN'S WARDS

To the Editor of THE LANCET

SIR,—The letter from Dr. Nabarro and Dr. Signy in your last issue prompts me to endorse all they say in regard to the dangers of certain of the simple common infections becoming epidemic in the wards of hospitals and institutions devoted to children. The particular bugbear of the rheumatic child is an acute nasopharyngeal infection. and the danger of this spreading from patient to patient in special hospitals and convalescent homes for children with rheumatic heart disease may become considerable. I have had bitter experience of this but, being firmly convinced of the value of these homes. sought for some means, short of closing down during certain of the winter months, to limit the spread of the apparently inevitable "sore-throat." By putting the beds alternately head to foot, in wards where the number of patients prohibits the spacing of beds beyond the regulation 3 ft., the distance of neighbouring mouths and their attendant droplet infections is increased to nearly double. The expedient appears to have been successful. and throat infections, which in the past would almost certainly have led to minor epidemics, have this year remained sporadic.

I claim no originality in the idea. but made a mental note of the method when listening to a discussion on dormitory infection, which took place last year at the Royal Society of Medicine.

I am, Sir, yours faithfully,

BERNARD SCHLESINGER.

Portland-place, W., March 14th, 1933.

EXPERIMENTAL SHOCK

To the Editor of THE LANCET

SIR,—In your recent annotation of my Arris and Gale lecture on experimental shock, I observe that you state (p. 480) that I consider that primary shock was due to an exhaustion of the vasomotor centre. The use of the term "exhaustion" was a little unfortunate, for I attempted to make it as clear as possible, and gave the evidence, that the centre is not exhausted, although its activity may have been diminished as a result of carbon dioxide or of the receipt of inhibitory impulses. I consider this is rather an important practical point, as it suggests the possibility that during primary shock the activity of the centre may be regained by adequate therapeutic measures.—I am, Sir, yours faithfully,

R. J. S. MCDOWALL.

King's College, Strand, W.C., March 10th, 1933.

INTERNATIONAL CONGRESS OF MILITARY MEDICINE. The seventh International Congress of Military Medicine and Pharmacy will be held in Madrid from May 29th to June 4th. The subjects of discussion include: the general principles affecting the military organisation of a nation in case of war; preventive inoculation in the forces: the treatment of urgent cases under fire; the use of preserved foods as rations; and a comparative study of the different dental and administrative military services. The last day of the congress will be occupied with field demonstrations and a visit to various military hospitals. Members of the congress will also have an opportunity of attending the International Congress of Medical Air Services which is being held in Madrid from June 1st to June 4th. and the third session of the International Office of Military Medical Documentation at Seville. to which a special train is being run. The special train will also visit Granada and Melilla, and an excursion to Morocco is being organised after the congress (June 10th–15th), which members may join. Application should be made before April 1st to the secretary of the congress, Ministero de la Marina, Madrid.

WORK OF CHILDREN'S HOSPITALS.—The jubilee report of the Royal Hospital for Sick Children, Glasgow. emphasises the necessity for a research endowment fund and an orthopædic department. It is pointed out that the latter would form the centre of an organisation for Glasgow, the thickly populated neighbouring districts, and the centre and west of Scotland. Last year there were 5819 in-patients, and more than 25,000 attendances of out-patients. Of the in-patients over 4000 were surgical cases. The country branch in Dumbartonshire treated 993 patients, almost equally divided between medical and surgical cases.—Last year Birmingham Children's Hospital received 3309 in-patients. a substantial increase; new surgical out-patients slightly exceeded 10,000, also a considerable increase. The average stay was 22·5 days, against 25 days. The annual report refers to "the new and important chapter in the hospital's history due to the beneficent action of the president. Mr. C. Kunzle, in placing his château at Davos-Dorf at the disposal of the hospital for the treatment of weakly children, particularly those predisposed to tuberculosis. Fifty-three children were sent up to the end of the year. and the medical staff have been immensely impressed with the results and possibilities of the scheme, which is of great promise" (see THE LANCET, March 11th, p. 538). Mr. Kunzle and his son have arranged for a guarantee fund to ensure the continuance of the work.—At 428 the number of patients admitted to Moseley Hall (Birmingham) Convalescent Hospital for Children last year was an increase of nearly 25 per cent. In his medical report Dr. A. V. Neale says that Moseley Hall's "especial value in the control of rheumatic disease is outstanding."—Pressure upon the new Belfast Hospital for Sick Children is already so great that it was stated at the annual meeting last week that acute surgical cases have to be turned away daily. while it is becoming increasingly difficult to obtain beds for the chronic cases met with in the out-patients' department. There are 63 beds and ten cots, and last year there were 951 admissions and over 16,000 new out-patients. A scholarship is now available every second year for research into children's diseases.

PARLIAMENTARY INTELLIGENCE

NOTES ON CURRENT TOPICS

Shortage of Medical Officers in the Army

IN Committee of the House of Commons on the Army Estimates for 1933,

Sir **FRANCIS FREMANTLE** said he wished to raise once more a matter of considerable importance—namely, the number of officers in the medical service. The number of medical officers in the Army was always very much below establishment, and he had raised this question regularly every year for the last 14 years without getting any satisfaction. Whatever their views might be in regard to war and peace, it was most essential to keep the medical service intact and efficient. The medical service had been working on a deficiency in establishment strength for years, and the position was just as serious as ever this year. The total establishment of medical officers required for the Army on the home establishment was 826, and the actual number on the strength was 669; a deficiency of 154 medical officers, or 35 per cent. That was not made up by temporary commissioned officers who were employed, 48, and by retired officers employed, 54.

The position was more serious than the actual numbers suggested. The work was only kept up by having two-thirds of the officers serving abroad. The percentage of majors, captains, and lieutenants at home was 42, and abroad 58, and the period at home was only about two years. As soon as they came back from service abroad they had only two years at home before having to go abroad again. That was partly the reason why the Government could not get officers into the Army Medical Service. Medical officers knew that when they married they would have to spend a great part of their time abroad, because the War Office was able to fill up the positions at home by temporary commissioned officers, while they could not get temporary commissioned officers to go abroad. That became worse and worse every year. The Army Medical Service was becoming more and more a service of old men. That position was definitely recognised in 1931. At that time a memorandum on the health of the Army stated:—

> "The number of new officer entrants in the Royal Army Medical Corps and its supplementary reserve, which has been most unsatisfactory since the Great War, has fallen still lower during the past year, and the deficiency of regular officers is causing grave concern."

When the matter was discussed in the House of Commons the Financial Secretary to the War Office said that all were agreed that this was a very serious matter. It was admitted that the deficiency in medical officers affected not only the War Office, but also the Admiralty and the Air Force, and two years ago it was stated that an inter-Departmental Committee for the three services was being set up for the purpose of finding some solution for the problem. That Committee had been sitting under Sir Warren Fisher, and now they heard that the Committee was proceeding to consider its report. Evidently no solution of the problem had been found or the report was being delayed, because the Committee could not face the solution that was necessary. He (Sir F. Fremantle) had made several suggestions and so had the British Medical Association. He wanted a statement from the Financial Secretary to the War Office, not simply that he was waiting for the Committee's report, the contents of which he probably knew, but that he would put it to the Government and to the Chancellor of the Exchequer that the health services were essential to the Army and that they could not face the possibility of another war with depleted medical services.

Mr. **DUFF COOPER** (Financial Secretary to the War Office) said the question raised by Sir F. Fremantle was a very serious one and had been under consideration for a long time. The Committee to which the hon. Member had referred was much impressed by the evidence that he had given. He (Mr. Duff Cooper) confessed that the work of the Committee might have slackened about a year ago, when owing to financial conditions there seemed to be very little prospect of obtaining funds for anything, even for so good a cause as this, and it was considered that there was no way of obtaining these recruits except by increased expenditure. He knew that Sir F. Fremantle had his own suggestions; he had studied those suggestions, and he thought that if they could be brought into force, which would mean a good deal of collaboration with local authorities, they might overcome the difficulty. The inter-Departmental Committee on the question, which was never dissolved, but which suspended its activities for a short space of time, partly owing to the financial state of the country, and partly owing to the many responsibilities then resting on Sir Warren Fisher, had now resumed its sittings and was actively pursuing its inquiries with a view to finding a solution to the problem. He could assure Sir F. Fremantle that the matter of the Army Medical Services was really now under close consideration, and that it was hoped that some solution would be arrived at in the very near future.

The War Office were fully alive to the importance of the health of the troops, which was a matter of deep concern at the present moment. With regard to cerebro-spinal meningitis, the figures this year, although still giving cause for great anxiety, were falling off. The number of cases for the past year were 67, out of which 26 proved fatal. That was a remarkably low figure for fatal cases. The authorities were doing all they could to keep in touch with the latest developments of science both in this country and in foreign countries with regard to this disease, and everything they could do in the endeavour to lessen it they would do.

The Air Estimates

On Tuesday, March 14th, Sir **PHILIP SASSOON** (Under Secretary for Air), in introducing the Air Estimates for 1933 in the House of Commons, said that a comprehensive review was proceeding of the whole personnel of the Service. Referring to the work of the Royal Air Force, he said that, for example, settlers in the backblocks of Canada and Australia had had their daily existence immensely eased and improved and the amenities of civilisation brought to their very doors. Countless lives of men, women, and children had been saved by the provision of medical and surgical aid where otherwise accident or illness would have entailed fatal consequences. Reports of the oversea commands of the flying carried out in the last 12 months included accounts of the conveyance of surgical aid to sheiks in the deserts of Iraq and on the shores of the Persian Gulf; the carriage to remote villages of anticholera and antityphoid vaccines; and the supply of food to famine-stricken tribes in Transjordan.

In the course of the debate which followed, hon. Members strongly urged the Government to strengthen the air defences of the country and not to favour a policy of the international control of aviation which it was stated might hamper development in this country.

Mr. **WHITESIDE** said that the danger in the next war would come not from explosives, but from germs and gases. It might be, he said, that war would not even be declared, but that one nation wanting to destroy another nation would infect rats with anthrax and plague, and send them to the country it was desired to destroy. They might send through the post a parcel containing germs so potent that a whole nation might be wiped out. No Peace Pact in the world could prevent that.

Pharmacy and Poisons Bill

On Tuesday, March 14th, the House of Lords considered in Committee the Pharmacy and Poisons Bill. The Earl of ONSLOW, Chairman of Committees, was in the chair.

On Clause 23 (Power of the Secretary of State to make rules),

The Earl of LUCAN, Captain Gentlemen-at-Arms, moved an amendment providing that the Secretary of State might issue to the Poisons Board a direction that the power of the Board to make recommendations as to the making of rules with respect to certain matters specified in the Clause should not be exercised except after consultation with such body of persons as was specified in the direction, being a body which was, in his opinion, representative of persons engaged in the manufacture of poisons, or preparations containing poisons, and the Board should comply with any such direction. The Secretary of State might from time to time revoke or vary any such direction without prejudice to the issue of a new direction.

The amendment was agreed to.

The Bill passed through Committee and was reported to the House.

HOUSE OF COMMONS

THURSDAY, MARCH 9TH

Protection against Floods

Mr. HALL-CAINE asked the Minister of Agriculture whether the floods of the last few weeks had disclosed any remedial work which could be undertaken as a matter of emergency in order to provide employment and to protect the public against loss through inundations in future.—Major ELLIOT replied: I do not think that the recent floods have disclosed any further developments in the general situation with regard to the need for the execution of drainage works. I would remind my hon. friend that the responsibility for carrying out remedial works as suggested is upon local drainage authorities and is, of course, governed by financial and economic conditions. I may add that catchment boards set up under the Land Drainage Act, 1930, following a conference among themselves on Feb. 10th last, have expressed their desire to submit their views to the Government, and it is hoped to fix an early meeting with them for this purpose.

Cost of Public Assistance

Mr. JOHN MORRIS asked the Minister of Health the total public assistance expenditure of all local authorities in England and Wales, including all expenditure on transferred poor-law services, for the last available year.—Sir E. HILTON YOUNG replied: The total expenditure under the Poor-law Acts in the year ending March 31st, 1931, was £38,561,000 on revenue account and £798,000 on capital account.

National Health Insurance Medical Benefit

Mr. LECKIE asked the Minister of Health whether he was aware that many insured persons, probably between 60,000 and 100,000, would cease to be entitled to medical benefit at the end of this year as a result of the passing of the last National Health Insurance Act; and what steps he proposed to take to ensure that these people should receive medical attention when ill.—Sir E. HILTON YOUNG replied: A prolonged extension of insurance was granted under the National Health Insurance Acts to persons who have ceased to be employed and to pay contributions. After the further extension of title to medical benefit during 1933 given under the Act of last year, a number of persons will cease to be entitled to medical benefit on Dec. 31st next. Within the financial resources of the health insurance scheme no further extension of insurance rights is permissible. These persons will, after the end of the present year, be in the same position with regard to medical attention during sickness as all other persons who are not within the scope of National Health Insurance.

Enamel Ware and Antimony Poisoning

Mr. HUTCHISON asked the Minister of Health whether, in view of the cases of antimony poisoning reported from the use of cheap enamel ware in this country, he would lay down a standard of safe manufacture to which all leading British manufacturers should be compelled to conform; and whether he would at the same time prohibit the importation of all foreign enamelled ware which did not fulfil the requirements above mentioned.—Sir E. HILTON YOUNG replied: I have no power to lay down a standard such as is suggested. I am sending my hon. friend a copy of a circular which I have recently issued on the subject.

Children and Road Accidents

Mr. HANNON asked the Parliamentary Secretary to the Board of Education if his attention had been called to the action of the chief constable at Stoke-on-Trent who provided a policewoman lecturer to address children in elementary schools on traffic dangers and how to avoid them; if the result of this educational experiment had been to reduce the number of accidents to school-children; and if education committees generally would be encouraged to provide facilities for instruction of the same kind.—Mr. HERWALD RAMSBOTHAM replied: My noble friend the President of the Board is aware of the arrangements in question. He understands that the authority are satisfied that the talks have been effective, and that there are grounds for thinking that they have resulted in some reduction in the number of street accidents to children of school age. As regards the last part of the question, memoranda on traffic dangers have been issued by the Board to local education authorities from time to time, and my noble friend has every reason to believe that authorities are alive to the importance of warning children in their schools, either by notice or by the provision of special instruction, on the subject of traffic dangers generally.

Narcotic Drugs Convention

Mr. MANDER asked the Home Secretary when the Government proposed to ratify the Convention for Limiting the Manufacture and Regulating the Distribution of Narcotic Drugs, 1931.—Sir JOHN GILMOUR replied: It is the intention of H.M. Government to ratify the Convention before the date contemplated in the Convention—namely, April 13th, 1933.

MONDAY, MARCH 13TH

Panel Practitioners and Treatment of War Pensioners

Mr. HICKS asked the Minister of Pensions the number of men suffering from war disabilities who had been referred to their panel doctor for treatment; and what was the attitude of his department to the representations made by the British Medical Association protesting against the practice of referring men suffering from disabilities other than wounds to their panel doctors for treatment.—Major TRYON replied: I have no record of the number of men for whom no special treatment by the Ministry, or treatment other than such as their own medical attendant can give them, is found to be necessary. No representations have been received from the British Medical Association on this matter in regard to which there has been no change of policy.

Ministry of Pensions Hospitals

Mr. MCENTEE asked the Minister of Pensions what hospitals were now maintained by the Ministry of Pensions and where they were situated; and whether any hospitals maintained by the Ministry had been closed since Jan. 1st, 1932.—Major TRYON replied: The following hospitals are now maintained entirely by the Ministry of Pensions: Edenhall, at Musselburgh; Dunston Hill, at Newcastle; Chapel Allerton, at Leeds; Mossley Hill, at Liverpool; Maghull, at Liverpool; Cosham, at Portsmouth; Orpington, at Orpington, Kent; Latchmere, at Kingston, Surrey; Leopardstown Park, at Dublin; Rookwood, at Cardiff; and Chepstow Hospital, at Monmouth.

One hospital, Highbury, Birmingham, was closed on Jan. 9th, 1932, and Maghull Hospital, Liverpool, will be given up by the Ministry on March 31st, when the Chepstow Hospital, now undergoing alterations, will be reopened for the reception of patients of the class formerly dealt with at Maghull. In addition to the hospitals above enumerated there are 19 hospitals not under the control of the Ministry in which either the entire accommodation or some part of it is reserved for Ministry patients who are maintained by a capitation rate at the cost of the Ministry.

Prevention of Distemper in Dogs

Mr. HERBERT WILLIAMS asked the Lord President of the Council what steps were being taken to give publicity to the successful inoculation treatment for the prevention of distemper in dogs which had been discovered as the result of the investigations of the Medical Research Council.—Mr. BALDWIN replied: A statement signed by the Duke of Portland and other members of the "Field Distemper Council," which supported the researches, has been very widely published in the press, and I am advised that full accounts of the work and its results have been communicated to the veterinary profession through the medium of the technical journals. The preparations used are now available commercially and are advertised.

Mr. HERBERT WILLIAMS asked if this research work would have been impossible if the Protection of Dogs Bill had been passed into law.

Mr. BALDWIN said he believed it would have been quite impossible.

MEDICAL NEWS

University of Cambridge

On March 11th the following degrees were conferred :—

M.D.—N. M. Goodman and R. Pearce.
M.Chir.—R. Marnham and T. K. S. Lyle.
M.B. and B.Chir.—L. C. Cook.
M.B.—W. H. G. Jessop and M. A. Rushton.
B.Chir.—S. E. Birdsall.

Royal College of Surgeons of England

A meeting of the council was held on March 9th, with Sir Holburt Waring, the president, in the chair. Mr. Cecil P. G. Wakeley, surgeon to King's College Hospital, was elected a member of the court of examiners in the vacancy occasioned by the death of Mr. H. S. Clogg. Prof. Ernest W. Hey Groves was elected a member of the court of the University of Bristol in place of the late Sir Percy Sargent.

Membership of the College was granted to G. P. Goodwin (Camb. & St. Mary's) and E. R. James (Bengal & St. Mary's).

Licences in dental surgery were granted to the following :—

Arnold Barkin, F. J. Bloor, H. A. M. Ching, L. F. Ferguson, A. C. Fuller, F. C. Hampson, W. L. Haworth, J. R. C. Hindle, Margaret D. Hooper, O. E. Howell, J. F. Hunt, Owen Jacob, Harold Kanaar, G. D. Lloyd, U. S. Malik, L. E. Marshall, L. A. Mills, P. K. Robinson, W. F. Rose, W. G. Scoble, B. St. J. Steadman, H. R. Stubbs, R. B. Sumerling, A. W. Turner, W. C. F. Whaley, Millicent Williams.

Diplomas in ophthalmic medicine and surgery were granted jointly with the Royal College of Physicians to the following :—

A. J. Boase, A. J. Cameron, J. L. Connacher, K. G. Das, L. P. J. Evans, F. S. Flynn, G. S. Forrester, N. C. Ghosh, A. L. Kiow, Lu Djung-Lin, C. A. Pittar, V. B. Purvis, S. V. Rao, O. L. F. Senaratne, S. P. Srivastava.

It was decided to hold a reception for the Société Internationale d'Urologie on July 11th, and for the congress of the International Society of Orthopædic Surgery on July 20th.

University of London

At a meeting of the university court on March 8th it was announced that the Armourers and Braisers' Company and the Carpenters' Company had decided to make grants to the university of £2000 and £1000 respectively in the shape of annual payments extending over ten years; and that the Ironmongers' Company had granted £500 and the Dyers' Company £105. These benefactions will be applied towards meeting the cost of the new ceremonial hall to be erected on the university's site in Bloomsbury. An expression of the court's appreciation and cordial thanks has been conveyed to the companies.

A bequest to the university by the late Mr. Arthur L. Leon has been accepted with great appreciation. The bequest, amounting to some £20,000, is for the promotion and encouragement of post-graduate or advanced research work.

Prof. Geoffrey Hadfield has been appointed a staff examiner in pathology.

Funds for research.—Grants are made annually from the Dixon fund for the purpose of assisting scientific investigations, and the Thomas Smythe Hughes and Beaverbrook medical research funds for original medical research. Application for grants in 1933 should be made not earlier than April 1st and not later than May 15th, and should be accompanied by the names and addresses of not more than two persons to whom reference may be made. Further particulars may be had from the academic registrar.

Institute for the Scientific Treatment of Delinquency

To-day, Friday, March 17th, at 8.30 P.M., at University College, Gower-street, London, W.C., Dr. R. G. Gordon will give a lecture on the Relationship of Delinquency to the Broken Home. Admission is free.

Fellowship of Medicine and Post-Graduate Medical Association

Arrangements for this week will be found in our Medical Diary. At the Royal Albert Dock Hospital, on April 1st and 2nd, there will be a week-end course on clinical surgery, with special reference to the relation of technique and end-result. Demonstrations of medical ophthalmology, primarily intended for M.R.C.P. candidates, have been arranged as follows: Tuesday, March 21st, at 8.30 P.M., at the in-patient department of the West End Hospital for Nervous Diseases, Mr. Lindsay Rea, on the Fundus Oculi; Wednesday, March 22nd, at 5 P.M., at the Royal Westminster Ophthalmic Hospital, Broad-street, Mr. G. G. Penman, Fundi of Medical Interest; on Thursday, March 30th, at 8.30 P.M., also at the Royal Westminster Ophthalmic Hospital, Mr. C. L. Gimblett, on Some Points in Medical Ophthalmology. Further particulars of the courses may be had from the secretary of the Fellowship, 1, Wimpole-street, London, W. 1.

Royal Sanitary Institute

The last London meeting for this session will be held at the institute, 90, Buckingham Palace-road, S.W., on Wednesday, March 29th, at 5 P.M., when Lieut.-Colonel C. Waley Cohen will open a discussion entitled Standards in the Milk Industry: a joint responsibility of medical officers of health, producers, distributors, and the veterinary services. Lord Astor will take the chair.

Beit Memorial Fellowships for Medical Research

An election of junior Fellows will take place in July, and application should be made before May 18th, though late entries will be accepted up to June 1st. The Fellows elected in July will be required to begin work on Oct. 1st. Junior Fellowships are of the annual value of £400, and are usually held for three years. Forms of application and all information may be had from the hon. secretary of the fund, Prof. T. R. Elliott, F.R.S., University College Hospital Medical School, University-street, London, W.C.1.

International Congress on Cancer

An international congress on scientific and social aspects of the campaign against cancer is being held in Madrid from Oct. 25th to 30th, when it is hoped to form a permanent international body. It is organised by the Spanish League against Cancer, and will be divided into a social section and a scientific section. Further particulars may be had from the hon. secretary-general, Dr. Julio Bejarano, Facultad de Medicina (Decanato), Atocha 104, Madrid.

Memorial to Dr. Eichholz

An appeal to raise a sum of money to be used as an endowment for the benefit of the blind and deaf, as a fitting memorial to the late Dr. Alfred Eichholz, has been sent out by the presidents of the national institutes. Contributions may be sent to Mr. W. McG. Eagar, National Institute for the Blind, 224, Great Portland-street, W.1, or to Mr. A. J. Story, National Institute for the Deaf, 2, Bloomsbury-street, London, W.C.1.

Pay Beds

Lord Horder recently opened a new wing of Finchley Memorial Hospital which has cost £26,000. There are 26 private wards for people of moderate means, and accommodation for the nursing staff. In his speech Lord Horder recalled that 15 years ago he gave it as a dictum that no lay-out of a hospital should be passed by the responsible authorities unless it provided for pay beds.

Contraceptive Methods

Lectures and demonstrations are given to medical students at the headquarters of the Society for the Provision of Birth Control Clinics, at 153A, East-street, Walworth-road, S.E.17. Further particulars will be given by the secretary, Mrs. Evelyn Fuller.

Research into Rheumatic Diseases

The annual report of the Red Cross Rheumatism Clinic in Peto-place, London, presented last week, shows 78,580 attendances (plus 8040 in the private patients' department), as compared with 77,892 in 1931. Out of a total of 3154 cases discharged during the year, 36 per cent. of the men and 43 per cent. of the women were able to take treatment without interrupting their work, and a further 22 per cent. of the men and 6 per cent. of the women were hoping to return to their work at the end of their treatment. In moving the adoption of the report, Sir Arthur Stanley said that the results obtained at the clinic, both in the way of treatment and in the way of research, were gratifying. "More important than anything else," he added, "is, I believe, the need for additional research. But research costs money, and we have not the funds at our disposal to allow our highly qualified medical staff to indulge in an expansion of this research work which both we and they would like."

At the recent annual meeting of the Royal Bath Hospital at Harrogate the Earl of Harewood announced the initiation, in conjunction with the University of Leeds and the British Red Cross Society, of a scheme of research into the causes and treatment of rheumatoid arthritis. The research worker to be appointed would, he said, have an official position at Leeds University with the title of fellow in rheumatism research. The cost is estimated at £1000 a year, of which the British Red Cross is contributing one-fifth; this, said Lord Harewood, was a small beginning, but researches of this kind had a happy knack of developing into bigger things. Harrogate is well situated for the purpose: its Bath Hospital specialises in the treatment of rheumatic affections, and the Rawson convalescent home is available for controlled after-care.

Society of Medical Officers of Health

A meeting of this society will be held at 1, Upper Montague-street, Russell-square, London, W.C.. on Friday, March 24th, at 5 P.M. Dr. E. H. T. Nash (medical officer of health for Heston and Isleworth), Dr. J. Graham Forbes (senior medical officer of the London County Council), and Dr. Guy Bousfield (medical officer of the diphtheria immunisation clinics at Isleworth and elsewhere), will open a discussion on Diphtheria Immunisation, its Possibilities and Difficulties.

Maternity and Child Welfare Group.—At 8.30 P.M. on Friday, March 24th, at the same address, Mr. Sydney Owen will give a lecture on Neonatal Abnormalities.

General Nursing Council

Nine members of the General Nursing Council, to hold office for a term of five years, have been appointed in accordance with the schedule to the Nurses' Registration Act by the following bodies :—*Privy Council:* Lady Limerick and Lady Erleigh ; *Board of Education :* Miss E. R. Gwatkin, headmistress of Streatham Girls' High School, and Mrs. J. S. Courtauld ; *Ministry of Health:* Dr. M. A. Collins, medical superintendent of the Kent County Mental Hospital, Mr. H. L. Eason, medical superintendent of Guy's Hospital, Mr. M. H. Harper, house governor and secretary of the Royal Wolverhampton Hospital, Dr. M. H. Kettle, an assistant editor of THE LANCET, and Dr. Charles Porter, medical officer of health for Marylebone. These nominated members are additional to the 16 members elected by vote of State-registered nurses.

Brighton Hospitals

By the end of February the five large hospitals in Brighton had held their annual meetings. The work done in each institution during 1932 showed large increases in every department, but the hospitals' ordinary expenditure exceeded the ordinary income by £11.040.—The Royal Sussex County Hospital, which finished the year with a deficit of £5556, showed a record number of in-patients (3812). The out-patients numbered 16,617—a drop of 550 from the previous year—but the out-patient attendances (121,793) were more. Contributions from patients amounted to £8241, an increase of £545.—At the Royal Alexandra Hospital for Sick Children there were, during 1932, 1060 in-patients and 23,600 attendances in the out-patients' department.—At the Sussex Maternity and Women's Hospital income fell short of expenditure by £1880, and the deficit had to be made good by appropriating legacies instead of paying them to the capital account. The hospital has joined the Federated Superannuation Scheme.—The meeting of the Sussex Throat and Ear Hospital was marked by outspoken comments on sweepstakes for hospitals. The chairman said he had sufficient confidence in the people of Sussex to believe that so long as the hospital carried on its work efficiently and well, so long would it receive the support which was necessary to maintain it.—The Sussex Eye Hospital meeting received the 100th report of the governors. The special appeal for £25.000 to build a new hospital in connexion with the scheme of coördination with the Royal Sussex County Hospital had been completed. The cost had, however, greatly exceeded the estimated £25,000, and an appeal will be made for a further £5000, so that the new hospital may be opened free of debt.

London Clinic and Institute of Physical Medicine

At the annual general meeting of the British Humane Association, on March 1st. Lord Scarorough, the chairman, reported that the total loss on the year's working of this clinic was £354, compared with £1761 in 1931. The number of treatments given was 107,000, of which over 5000 were free of all cost to the patient. Sir Leonard Hill, the general supervisor, said that the activities of the institution were adequately indicated by its new name. The honorary medical advisory board had been strengthened by the addition of Sir Henry Gauvain, and the consulting staff by the addition of two new physicians, a gynæcologist, a manipulative surgeon, and an anæsthetist. With the help of the receiving-room officers and the visiting physicians all patients now received thorough examination before treatment, and when necessary they were sent to a general hospital for treatment. The successful treatment of chronic ulcers by light had been continued, and in addition to other skin diseases birth-marks had been found amenable to intense ultra-violet radiation. The department of pelvic diathermy had gained wide recognition, and diseased tonsils had been successfully treated by diathermy in place of excision. A water-cooled mercury-vapour throat lamp was used with success in cases of laryngeal tuberculosis. The inhalation department continued to be useful for catarrhal and asthmatic complaints, and the foam-bath department had been extended. The private ward had developed in usefulness, and application had been made to the London County Council for the use by clinic patients of ten beds at St. Stephen's Hospital. In a bacteriological laboratory autogenous vaccines were now made by irradiation of the culture fluid with ultra-violet light.

Medical Diary

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

SOCIETIES

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

TUESDAY, March 21st.—5.30 P.M., GENERAL MEETING OF FELLOWS. 8.30 P.M., PATHOLOGY. Annual General Meeting. J. A. Murray : A Contribution to the Lymphstasis Hypothesis of the Origin of Cancer. E. H. Kettle and H. E. Archer : The Differential Diagnosis of Tuberculo-silicosis. P. Fildes and B. C. J. G. Knight : Auxin a Growth Factor. R. T. Brain : The Relationship Between the Viruses of Zoster and Varicella.

WEDNESDAY.—5 P.M., COMPARATIVE MEDICINE. Discussion : Deficiency Diseases. Openers : Sir Arnold Theiler and Prof. S. J. Cowell, followed by Dr. H. N. Green, Mr. M. C. Franklin, Dr. H. H. Green, Mr. W. R. Wooldridge, and others.

THURSDAY.—8.30 P.M., UROLOGY. Papers : Mr. A. E. Roche : Growths of the Testicle. Mr. Ralph Thompson: Some of the Rarer Types of Enlarged Prostate. Mr. V. W. Dix : Some Observations on Temporary Drainage of the Kidney.

FRIDAY.—5 P.M., DISEASE IN CHILDREN. (Cases at 4.30 P.M.) Paper : Mr. G. G. Penman : Concomitant Squint in Children, and Modern Methods of Treatment. 8 P.M., EPIDEMIOLOGY AND STATE MEDICINE. Paper : Dr. J. C. Bridge : The Influence of Industry upon Public Health.

MEDICO-LEGAL SOCIETY.

THURSDAY, March 23rd.—8.30 P.M. (at 11, Chandos-street, Cavendish-square, W.), Pathological Exhibition of Specimens and Demonstrations by Sir Bernard Spilsbury, Dr. W. S. O'Donovan, M.P., Dr. Arthur Davies, Dr. John Taylor, Dr. Gledhill, and Mr. W. G. Barnard.

CHELSEA CLINICAL SOCIETY.

TUESDAY, March 21st.—8.30 P.M. (at the Hotel Rembrandt, Thurloe-place, S.W.), preceded by a dinner at 7.30 P.M., Discussion on Doctors who were also Civilised Men, to be opened by Mr. J. C. Squire.

HUNTERIAN SOCIETY.

MONDAY, March 20th.—7.15 P.M. (at Simpson's Restaurant, Bird-in-Hand-court, Cheapside), Discussion on Practical Dietetics, to be opened by Prof. S. J Cowell.

SOCIETY OF MEDICAL OFFICERS OF HEALTH, 1, Upper Montague-street, W.C.

FRIDAY, March 24th.—5 P.M., Dr. E. H. T. Nash, Dr. J. Graham Forbes, and Dr. Guy Bousfield :Diphtheria Immunisation.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

ROYAL COLLEGE OF PHYSICIANS, Pall Mall East, S.W.

TUESDAY, March 21st, and following THURSDAY.—5 P.M. Dr. Charles R. Box : On Complications of Specific Fevers. (Last Lumleian lecture.)

ROYAL COLLEGE OF SURGEONS, Lincoln's Inn-fields, W.C.,

MONDAY, March 20th, and following FRIDAY.—5 P.M. Demonstrations of Specimens illustrating respectively Diseases of the Kidneys and Testicle. By Mr. C. E. Shattock.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, London.

MONDAY, March 20th, to SATURDAY, March 25th.—MEDICAL SOCIETY OF LONDON, 11, Chandos-street. Cavendish-square, W., Tues., Practical Problems in Medicine and Surgery. Lecture by Dr. A. J. Scott Pinchin on the Effects on the Heart of Disease of other Systems and Indications in Treatment, at 4 P.M. (Free to Members and Associates of the Fellowship.)—ROYAL WATERLOO HOSPITAL, Waterloo-road, S.E. Post-graduate Course in Medicine, Surgery, and Gynæcology. All day.—BRITISH RED CROSS CLINIC FOR RHEUMATISM, Peto-place, N.W. Tues. and Thurs. at 8.30 P.M. Evening Course in Rheumatism.—BETHLEM ROYAL HOSPITAL, Monks' Orchard, Eden Park, Beckenham, Kent. Tues. and Frid., at 11 A.M., Course in Psychological Medicine.—WEST END HOSPITAL FOR NERVOUS DISEASES, 73, Welbeck-street, W. Daily at 5 P.M., Post-graduate Course in Neurology.—GORDON HOSPITAL, Vauxhall Bridge-road, S.W. Post-graduate Course in Proctology. Afternoons only.—HOSPITAL FOR CONSUMPTION, Brompton, S.W. Sat. and Sun., Week-end Course in Diseases of the Chest. All day.—LAMBETH HOSPITAL, Brook-street, S.E. Frid., 2 P.M., Demonstration of Selected Cases of General Interest, by Dr. G. F. Stebbing, assisted by the Staff of the Hospital.—WEST END HOSPITAL FOR NERVOUS DISEASES, Gloucester-gate, N.W. Tues., Demonstration on the Fundus Oculi, by Mr. Lindsay Rea, at 8.30 P.M. (Specially suitable for M.R.C.P. candidates.)—ROYAL WESTMINSTER OPHTHALMIC HOSPITAL, Broad-street, W.C. Wed., Demonstration of Fundi of Medical Interest. By Mr. G. G. Penman, at 5 P.M. (Specially suitable for M.R.C.P. candidates.)—NATIONAL TEMPERANCE HOSPITAL, Hampstead-road, N.W. Tues. and Thurs., 8 P.M., Evening F.R.C.S. (Final) Course.

WEST LONDON HOSPITAL POST-GRADUATE COLLEGE, Hammersmith-road, W.

MONDAY, March 20th.—10 A.M., Medical Wards, Skin Dept., Genito-urinary Operations. 2 P.M., Medical, Surgical, Eye, and Gynæcological Out-patients, Surgical Wards, Operations. 4.15 P.M., Mr. Gibb: Demonstration of Eye Cases.

TUESDAY.—10 A.M., Medical Wards, Surgical Demonstration. 2 P.M., Medical, Surgical, Throat, Nose, and Ear Out-patients, Operations.

WEDNESDAY.—10 A.M., Medical Wards, Children's Out-patients. 2 P.M., Medical, Surgical, and Eye Out-patients.

THURSDAY.—10 A.M., Neurological Department, Fracture Demonstration. 2 P.M., Medical, Surgical, Eye, and Genito-urinary Out-patients. 4.15 P.M., Lecture, Mr. Woodd Walker: Chronic Empyema.

FRIDAY.—10 A.M., Skin Department. 12 noon, Lecture: Therapeutics. 2 P.M., Medical, Surgical, and Throat Out-patients. Operations. 4.15 P.M., Lecture, Dr. Ironside: Diseases of Nervous System.

SATURDAY.—10 A.M., Throat Operations, Medical and Surgical Wards. Surgical and Children's Out-patients. The lectures at 4.15 P.M. are open to all Medical Practitioners without fee.

CENTRAL LONDON THROAT, NOSE, AND EAR HOSPITAL, Gray's Inn-road, W.C.

FRIDAY, March 24th.—4 P.M., Mr. F. W. Watkyn-Thomas: Points in the Acute Mastoid Operation.

ST. PETER'S HOSPITAL FOR STONE, Henrietta-street, W.C.

WEDNESDAY, March 22nd.—3 P.M., Dr. Cuthbert Dukes: Laboratory Tests in Urinary Diseases.

NATIONAL HOSPITAL, Queen-square, W.C.

MONDAY, March 20th.—2 P.M., Dr. Riddoch: Out-patient Clinic. 3.30 P.M., Dr. Symonds: Head Injuries.

TUESDAY.—2 P.M., Dr. Walshe: Out-patient Clinic. 3.30 P.M., Dr. Martin: Abscess of the Brain.

WEDNESDAY.—2 P.M., Dr. Martin: Out-patient Clinic. 3.30 P.M., Dr. James Collier: C

THURSDAY.—2 P.M., Dr. Kinni

Clinic. 3.30 P.M., Dr. R

Nervous Diseases.

FRIDAY.—2 P.M., Dr. Adie: Out-patient Clinic. 3.30 P.M., Mr. Elmquist: Demonstration of Re-educative Exercises. (In Exercise Room.)

ST. MARK'S HOSPITAL, City-road, E.C.

THURSDAY, March 23rd.—4 P.M., Mr. L. E. C. Norbury: Diverticulitis.

KING'S COLLEGE HOSPITAL MEDICAL SCHOOL, Denmark-hill, S.E.

THURSDAY, March 23rd.—9 P.M., Mr. W. Daggett: Treatment of Otorrhœa.

NATIONAL COUNCIL FOR MENTAL HYGIENE.

WEDNESDAY, March 22nd.—5.30 P.M. (at 11, Chandos-street, Cavendish-square, W.), Dr. John Rickman: Ambition.

LONDON JEWISH HOSPITAL, Stepney Green, E.

THURSDAY, March 23rd.—4 P.M., Mr. Maurice Sorsby: Oto-laryngological Lecture Demonstration.

HOSPITAL FOR EPILEPSY AND PARALYSIS, Maida Vale, W.

THURSDAY, March 23rd.—3 P.M., Dr. F. L. Golla will demonstrate.

MANCHESTER ROYAL INFIRMARY.

TUESDAY, March 21st.—4.15 P.M., Mr. John Morley: Abdominal Adhesions and their Symptoms.

FRIDAY.—4.15 P.M., Dr. J. Wharton: Demonstration of Ophthalmological Cases.

ANCOATS HOSPITAL, Manchester.

THURSDAY, March 23rd.—4.15 P.M., Mr. E. E. Hughes: Renal Tumours.

GLASGOW POST-GRADUATE LECTURES.

WEDNESDAY, March 22nd.—4.15 P.M. (at the Victoria Infirmary), Mr. W. A. Sewell: Surgical Cases.

Vacancies

For further information refer to the advertisement columns

Altrincham General Hospital.—Hon. Gynæcologist.

Beit Memorial Fellowships for Medical Research.—Jun. Fellows. Each £100.

Belgrave Hospital for Children, Clapham-road, S.W.—Two H.P.'s and H.S. Each at rate of £100.

Birkenhead General Hospital.—Hon. Asst. Orthopædic Surgeon.

Blackburn, Queen's Park Institution and Infirmary.—Res. Jun. Asst. M.O. At rate of £150.

Bootle General Hospital.—Cas. O. At rate of £150.

Bristol University.—Sen. Pathologist for Dept. of Preventive Medicine. £700. Also Chair of Pathology.

Burden Mental Research Trust, B.M.A. House, Tavistock-square, W.C.—Principal Investigator. £750.

Burnley Municipal Hospital.—Jun. Res. M.O. £150.

H.S. to Special Depts. At rate of £175.

’s and H.S.’s. Also Cas. Surg. O.

Cardiff, Welsh National School of Medicine.—Independent Lecturer in Materia Medica and Pharmacology. £750.

Croydon, Mayday Hospital.—Part-time Visiting Radiologist. At rate of £200.

Doncaster Royal Infirmary.—Cas. H.S. £175.

Durham County Council.—H.S. £150.

Evelina Hospital for Sick Children, Southwark, S.E.—Hon. Physician to the Skin Dept. Also H.S. At rate of £120.

Finchley Memorial Hospital, Granville-road, N.—Res. M.O. At rate of £150.

Grimsby and District Hospital.—H.S. £200.

Guildford, Royal Surrey County Hospital.—Res. Med. and Surg. Officer and Registrar. £250. Also H.S. £150.

Halifax, St. Luke's Hospital.—Sen. Res. M.O. £350.

Harrogate, Royal Bath Hospital.—Res. M.O. At rate of £156.

Hospital for Epilepsy and Paralysis, Maida Vale, W.—Res. M.O. and H.P. At rate of £150 and £100 respectively.

Hospital of St. John and St. Elizabeth, 60, Grove End-road, N.W. Res. H.S. At rate of £75.

Ilford, King George Hospital.—Hon. Surgeon.

Infants Hospital, Vincent-square, Westminster.—Clin. Asst. to Out-patient Dept.

Ipswich, East Suffolk and Ipswich Hospital.—H.S. £120.

Leeds, Herzl Moser Hospital, Leopold-street.—R.M.O. £200.

Leeds General Infirmary.—Hon. Physician.

L.C. —Neurologists £2 12*s.* 6*d.* Radiologists £900.

Lond Reg. to Ear, Nose and Throat Dept. £150. Also Hon. Asst. Surgeon.

London Lock Hospital, 283, Harrow-road, W.—Surg. Reg. £100.

Liverpool, St. Paul's Eye Hospital, Oldhall-street.—H.S. At rate of £145.

Manchester, Ancoats Hospital.—H.S. At rate of £100.

Manchester Ear Hospital, Grosvenor-square, All Saints.—Res. H.S. £120.

Metropolitan Hospital, Kingsland-road, E.—Sen. and Jun. H.P.'s and H.S.'s. Also Two Cas. O.'s. Each at rate of £100.

Ministry of Health, Whitehall, S.W.—Vacancy on Medical Staff. £833.

Newcastle-upon-Tyne, Hospital for Sick Children.—H.P. Also Sen. and Jun. H.S. Each at rate of £100.

Paddington Hospital, Harrow-road, W.—M.O. £350.

Plymouth, S. Devon and E. Cornwall Hospital.—Hon. Joint M.O. for Massage and Electro-therapeutic Dept.

Princess Elizabeth of York Hospital for Children, Shadwell, E.—H.P. and Cas. O. Each £125.

Princess Louise Kensington Hospital for Children, St. Quintin-avenue, N. Kensington, W.—Clin. Asst. for Out-patient Dept. Also Hon. Anæsthetist.

Reading, Royal Berkshire Hospital.—Res. Anæsthetist. £150.

Royal College of Surgeons of England.—Two Leverhulme Research Scholarships. Each £100.

Royal Free Hospital, Gray's Inn-road, W.C.—Res. Cas. O. At rate of £150.

Royal London Ophthalmic Hospital, City-road, E.C.—Sen. Res. O. At rate of £150.

Royal Waterloo Hospital for Children and Women, Waterloo-road, 25 gns. Also Hon. Physician. At rate of £100.

—Cas. O., H.P., and Two H.S.'s. Each at rate of £100. Also Second H.S. At rate of £100.

South London Hospital for Women, Clapham Common, S.W.—Asst. Surgeon. Also Anæsthetist. 10*s* 6*d.* per attendance.

South Shields, Ing H.S. £150.

Sutton and Cheam M.O. £150.

Swansea General a At rate of £150.

West Bromwich and District General Hospital.—H.P. and Two Cas. H.S.'s. Each at rate of £200.

Westminster Hospital, Broad Sanctuary, S.W.—Jun. Asst. P H.S. At rate of £150 and £52.

Wigan At rate of £150.

Wolve —H.S. for Orthopædic Dept. and E Nose Dept. Each at rate of £100. Also Surg. Reg. and Res. Asst. Surg. At rate of £250.

Births, Marriages, and Deaths

BIRTHS

DULAKE.—On March 3rd, at Reigate, to Nina Dulake, M.B., D.O.M.S., wife of Lawrence Dulake, M.B., B.S.—a son.

FRYER.—On March 5th, at the Cottage Hospital, the wife of Dr. D. W. Fryer, of Abergavenny, of a son.

MCCARTAN.—On March 2nd, to the wife of William McCartan M.D., Bleak House, Epsom, Surrey—a daughter.

MCCULLAGH.—On March 2nd, at Harley House, the wife of W. McK. H. McCullagh, F.R.C.S., of a daughter.

MARRIAGES

WHITE—WALKER.—On March 4th, Ernest White, M.R.C.S., L.D.S. Eng., to Dorothea Walker, of Almsmead, Harrogate.

DEATHS

CREERY.—On March 7th, at Riverton, Coleraine, John Tate Creery, M.B., B.Ch., T.C.D., in his 76th year.

O'FERRALL.—On March 13th at Coldharbour-lane, S.W., Edward French O'Ferrall, L.R.C.P.

REYNOLDS.—On March 10th, in London, Major Douglas Reynolds, M.C., R.A.M.C., aged 49.

SOWRY.—On March 12th, at King-street, Newcastle, Staffs, George Herbert Sowry, M.D., F.R.C.S., M.R.C.P., aged 62 years.

WHITTAKER.—On March 8th, at First Avenue, Westcliff-on-Sea, Essex, William Mark Whittaker, M.A., M.B., T.C.D., L.R.C.S.I.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

NOTES, COMMENTS, AND ABSTRACTS

THE HEALTH OF MERCHANT SEAMEN IN 1931

BY FLEET-SURGEON W. E. HOME, O.B.E.

THE return of deaths reported to the Board of Trade in 1931 of men employed in the mercantile marine is more interesting than its predecessors, for it tabulates the deaths of British seamen by ages in the same groups in which they were enumerated at the census of seamen in April of that year. As a result we can now calculate the death-rates for the different ages for 1931 with some degree of confidence. Unless otherwise stated, we are dealing here with British seamen only. They were enumerated at 108,882 (amongst them 1635 women, stewardesses, &c.), their deaths from disease were 315 (2·9 per 1000), from violence 280 (2·5); in all 595 (5·5). It was in 1930 that for the first time the deaths from disease were more numerous than those from violence (accidents, homicide, suicide, and heat stroke), formerly in great excess; the earliest known figures are those for 1901–02, showing by disease 596 but by violence 1067 (about half of these were in sailing ships, of which there then were 897 in the foreign trade, but in 1931 only one).

Ages.	Census of seamen, 1931.		British merchant seamen's deaths, 1931.					England and Wales, all occupied and retired civilian males, 1921–23. (Reg.-Gen., 1927.)			
	No.	Proportion.	Disease.		Violence.		Total rate.	Proportion.	Death-rates.		
			No.	Rate.	No	Rate.			Disease.	Violence.	Total.
–20	10,994	101	11	1·00	40	3·6	4·6	105	2·1	0·4	2·5

55–64	5,782	53	67	11·6	21	3·6	15·2	113	24·5	1·2	25·7
65–	561	5	12	21·4	2	3·6	25·0	72	90·8	2·1	92·9
Not stated	164	—	—	—	—	—	—	—	—	—	—
—	108,882	1000	315	2·9	280	2·6	5·5	1000	7·8	0·6	8·4
									ages 16–65 only.		

In the Table I have compiled are shown, in the first column, the grouping of the ages; in the second, the numbers enumerated; in the third, the proportion in the merchant service per 1000 at the various ages; then by ages the deaths from disease and the death-rate; the deaths by violence and the death-rate; and next, the total death-rate. For comparison, in succeeding columns are given the age proportions and the death-rates by disease, violence, and total of the largest group in the Registrar-General's Occupational Mortality Supplement for 1921, the five millions of "All Occupied and Retired Civilian Males" in 1921–23. Inspection shows the death-rate from disease increasing with age among seamen much as it does ashore, slowly, that is up to 45, and thereafter more rapidly, the employed seamen's rate always remaining about half that ashore; but the rates from violence are at most ages about four times higher at sea, and under age 20 when boys and young seamen are beginning to know and have not yet learned how to avoid the risks of their trade, it is nine times as much.

The death-rate for seamen at all ages to 65 (5·5) is much less than the civilian rate (8·4), as there are so many more seamen, proportionally, in the lower ages with the lower death-rates. Of individual diseases the most deadly were pneumonia 45 (0·4) and phthisis 34 (0·3); they caused, proportionally, more deaths among the 49,215 lascars, pneumonia 35 (0·7), and phthisis 28 (0·6). The nosological list has been extended this year, indeed perhaps too much has been attempted. Thus a line is now given to syphilis with its six deaths, while another line is wasted on the two deaths from general paralysis and locomotor ataxia. One wonders how men with diseases so chronic and well known, obviously too so advanced, managed to pass the medical examination when they joined their last ships.

THE HOUSING OF THE POOR

ON March 9th Dr. C. Killick Millard, medical officer of health for Leicester, gave a Chadwick lecture in London in which he pointed out that the housing problem to-day is the problem of providing decent healthy housing for the poor. Those who are not of the poor can now be catered for by private enterprise subject to the laws of supply and demand. In the past, he said, the poor never really have been decently housed, and there is no prospect that they ever will be in the future unless the State, in one way or other, is prepared to pay part of the cost. In other words, the housing problem, which of course includes the slum problem, cannot be solved without the expenditure of public money. But it is to the interest of the State that all its citizens should be decently housed. Money spent in achieving this end will be wise expenditure, and will incidentally relieve unemployment, and thus help the country back to true prosperity.

In striving to secure decent healthy housing for the poor, Dr. Millard continued, we must not stickle too much about "standards." A small loaf is generally better than no bread. It is better for all to have reasonably good houses than for some favoured ones to have very good houses and the rest to have very bad houses, or no houses at all. If he were given plenary powers his policy would be as follows:—

1. As municipal houses have largely got into the hands of people who are not the ones most in need of housing assistance, their rents should be raised, after due notice, to the full economic level.
2. Many tenants would be glad to stay on and would pay the increased rent, so that these houses would cease to be a charge on the community. The money so saved, and it would be a very substantial amount, should be used for giving assistance to others who really needed help.
3. Tenants able, but unwilling, to pay the increased rent should be given a reasonable time in which to find other accommodation. They could well be catered for by private enterprise.
4. Tenants claiming to be unable to pay the increased rent should be required to submit to an investigation into their circumstances, and if their claim is substantiated they should be granted assistance in the form of temporary rebates from the rent according to scale, such scale to be devised to give special consideration for dependent children. All rebates would be subject to periodical revision and would be regarded and administered as a special form of public assistance.
5. Tenants without children, and not likely to have any, who are occupying a larger house than they require, and who are not able to pay the economic rent, should be transferred to a smaller house.
6. Persons living in privately owned houses, but unable to pay the rent, or requiring a larger or better house, should be entitled to similar assistance, provided their circumstances justify it.
7. Overcrowding, being one of the worst features of slum life, must be relieved before the slum problem can be effectually dealt with. The 1930 Housing Act should be amended to enable overcrowding to be dealt with under Part II. as well as under Part I. This is urgently necessary.
8. *Reconditioning.*—In view of the urgent need of houses to let at a rental within reach of the poor.

reconditioning of old houses, as far as is practicable, ought to be encouraged as a national policy. Where owners are unable to undertake reconditioning the community (local authority or public utility society) should do so; something was to be said for a national housing trust, with a national outlook and national support, but with local branches. Reconditioning need not entail much expense on the community. Necessary repairs to all houses, new or old, should be enforced more vigorously, and landlords in default should be penalised.

9. *Demolition.*—For the present and so long as the shortage of houses continues acute, a "massed attack on the slums"—i.e., schemes of wholesale demolition on a large scale—will be difficult if not impracticable, however much we may wish to see old and inferior houses swept away. The urgent need in most places is for more houses and for cheaper houses. When these are available demolition will be an easy task. In the meanwhile, only the worst houses to be demolished (under Part II. of the 1930 Act), but there will be enough of these to keep the building trade busy with replacement houses for a long time to come.

10. *Subsidies.*—Subsidies under the 1924 Housing Act should cease, but in place thereof the community ought to spend a substantial amount annually in giving temporary help towards rent to those who really need it, and who would not be able to secure decent healthy housing without it. The national exchequer should share with local authorities the cost of this as a set-off against what will be saved by the cessation of building subsidies.

Dr. Millard calculates that the saving to the community by stopping the 1924 Act subsidy will be about £400,000 per annum, and this will be *cumulative*, going on automatically for 40 years. Thus at the end of ten years it will be £4,000,000 per annum, and so on. The amount to be spent on rent assistance, on the other hand, will *not* be cumulative. Moreover, as prosperity returns the need will rapidly diminish.

PUBLICITY AND CRIME

THE scientific study of crime is handicapped more severely than the scientific study of most other human ills. The reason for this, as Mr. Kingsley Martin, the editor of the *New Statesman*, explained in a lecture to the Institute for the Scientific Treatment of Delinquency on March 3rd, is that both press and public are vitally interested in maintaining a different attitude to crime altogether—one based on the most primitive motives and entirely opposed to any attempt to regard crime from a reasonable point of view. To the inhabitants of an industrial civilisation, whose lives are for the most part extremely uninteresting, it is a source of joy to experience vicariously the satisfaction of their basic instincts in identifying themselves either with the hunter, in the form of the skilful and merciless detective, or with the hunted, in the form of the villainous criminal or the hapless victim. To render the satisfaction complete it is necessary that the crime shall have a considerable sexual content. Those responsible for the policy of many of our newspapers make full use of the tremendous opportunities of profit which lie in exploiting this instinctive hunger for horror.

It is permissible to ask "Why not?" It might seem at first sight that to read of lust and violence affords a harmless outlet for passions that would otherwise find their expression in deeds. Mr. Martin, however, brought forward evidence that the deliberate cultivation by the press of this attitude towards the crime increases crime itself, and tends to defeat the efforts of society to prevent and to punish it. Unfortunately, the adequate defence of a murderer rests, he said, on the facts of the crime being sensational enough to justify a newspaper in paying a sufficient sum for the accused man's life story to enable him to employ expensive counsel, while at other times publicity may prejudice the prisoner's case. In a debate in the House of Lords it was suggested that murder reports could be restricted, as divorce reports have been; but Mr. Martin believes that it would be against public policy to prevent the fullest reporting of the trial itself; the matter which needs strict censorship is the preliminary hearing before the magistrate.

The survival of the human race depends on whether man as a species can master his instincts by means of reason. In the case of crime, which is a disease of civilised communities, man is not only making little attempt to master his instincts, but is deliberately using a great part of his reasoning faculty to amplify a wasteful and disastrous concession to them. Those few who see the necessity for studying crime objectively have to face the vast struggle of persuading many millions of their fellows and several dozen powerful and determined corporations to give up a practice which is very dear to their hearts—that of regarding it sentimentally and dramatically.

THE HYGIENE OF MENSTRUATION

THE hygiene of menstruation has made great strides in the last decade. The tradition that bathing is dangerous has been discarded in all educated households, where now the doctrine prevails that comfort depends as much on an ample hot water supply as on the frequent replacement of soiled absorbent pads. The pads now most popular are those intended to be destroyed by burning or by solution in water after use, and girls are taught to avoid discomfort by changing them freely. Facilities such as a slot machine and a tin for used pads are being increasingly provided in the pavilions of school playgrounds, while at some hostels for adults, notably the Nurses' Home at the Middlesex Hospital, a special gas incinerator is installed for this purpose. When frequent changes can be made the ordinary untreated gauze and wool pad on the market has no serious drawbacks; when, however, conditions are inopportune for such changes, the use of a pad impregnated with a substance which inhibits the growth of bacteria doubtless has advantages. The manufacturers of Sterisan sanitary towels claim that the gauze and outer absorbent wool of their product are specially treated to inhibit bacterial growth. The attachment of a pad by means of a soft rubber belt, such as that made by Kleinert Rubber Co. in various sizes, instead of a rigid belt or a piece of knotted tape, and the elimination of all sources of irritation or local soreness, is likely to reduce greatly the number of women who complain of menstrual pain. Unfortunately, the answers received in connexion with most statistical inquiries do not differentiate between deep pain attributable to the period and superficial soreness or dragging, which can be eliminated by careful selection and adjustment of belts and pads, and, most important, frequent renewal of the latter.

Appointments

Certifying Surgeons under the Factory and Workshop Acts: GREEN, H. J., M.B., Ch.B. Aberd. (Banff); JAMIESON, ELIZABETH G., M.B., Ch.B. Glasg. (Kilbride, Bute); LALONDE, T. P., M.B., Ch.B. Bristol (Romsey); and MEIKLE, W., M.B., Ch.B. Glasg. (Whittlesey).

London County Council: WEST, H. O., M.D., B.S., D.P.H., Medical Superintendent, promoted from Medical Superintendent, Archway Hospital, to St. Giles Hospital; AGASSIZ, C. D. S., M.D., M.R.C.P., Ch.B., D.P.H., promoted from Medical Superintendent, High Wood Hospital for Children, to Archway Hospital; READE, A. G. L., M.R.C.S., L.R.C.P., transferred from Senior Medical Officer in the Public Health Department to High Wood Hospital for Children.

WEST SUSSEX ASSOCIATED HOSPITALS CONTRIBUTORY FUND.—On March 4th, at the annual meeting at Chichester, it was reported that the membership during 1932 had increased by 1200, bringing the total membership to 10,900. The available income amounted to £5,502, of which £1845 had been paid to various hospitals for treatment of members.

ADDRESSES AND ORIGINAL ARTICLES

PNEUMOCOCCAL INFECTIONS

BY ROBERT CRUICKSHANK, M.D. ABERD., D.P.H.
LECTURER IN BACTERIOLOGY, THE UNIVERSITY AND ROYAL INFIRMARY, GLASGOW; BACTERIOLOGIST TO GLASGOW ROYAL INFIRMARY

II.—LOBAR PNEUMONIA IN THE COMMUNITY *

IN the previous lecture certain clinical features of lobar pneumonia were considered. I propose now to discuss this affection in its public health aspects; reviewing, in particular, bacteriological and epidemiological evidence relating to the seasonal incidence and mode of spread of lobar pneumonia, and the factors which influence its mortality-rate in an infected community. I shall consider first the case-mortality of the infection which depends primarily on the inter-relationship between the virulence of the infecting organism and the resistance of the exposed persons in the community.

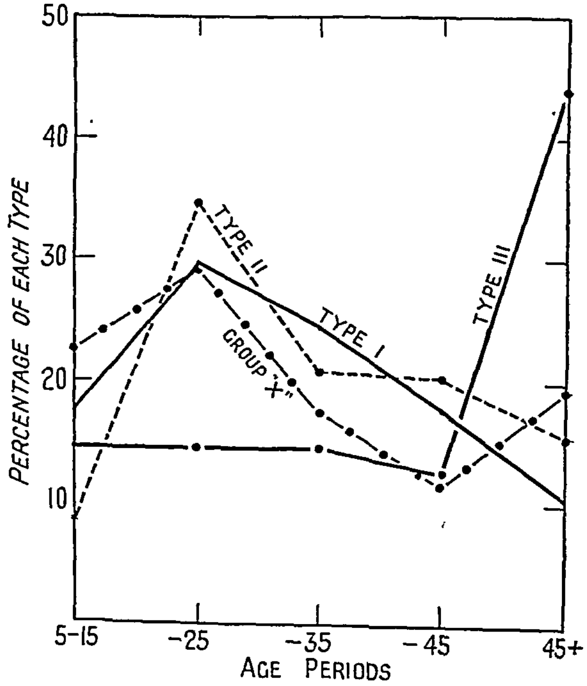
The Infecting Organism

It is customary to ascribe the variations which occur in the severity and mortality of a particular infection from time to time to changing degrees of virulence of the infecting organism rather than to altered resistance of the host. This doctrine has been accepted perhaps too readily as a sufficient explanation of the epidemiological facts, and there is evidence that this theory may have to be modified or even discarded. For instance, the experimental observations of Webster show that the virulence of such organisms as those concerned in mouse typhoid or in pasteurellosis of rabbits is the same at the beginning as at the end of an epidemic and from one epidemic to another, is the same whether the animals die of an acute or of a chronic infection, is unaltered in healthy contacts, and is not increased by animal passage. This view, as applied to infections generally, may seem heterodox, but it is quite possible in spite of criticism that it is fundamentally correct. It has, at any rate, the asset of being based on results obtained from naturally occurring infections in animals. Unfortunately for its application to lobar pneumonia, there is presented in this disease the problem of an infection caused by a series of organisms, each of the members of which seems to possess its own degree of virulence. It is necessary, therefore, to study the behaviour of each type of organism as a separate epidemiological problem, and for this purpose to ascertain the relative incidence of the different pneumococcal types as infecting organisms in a particular community. When the part which the infecting organism plays in the mortality-rate of lobar pneumonia is to be assessed, therefore, the questions which arise are: (1) Is the proportion of the different types the same in different countries or in different parts of the same country—e.g., in Britain and America, in London and Glasgow? (2) Is the proportion constant from one year to another in the same community? (3) Since age is an important factor in the mortality from pneumonia, do the several types attack the same or different age-groups?

(1) It will be seen at once (Table I.) that the incidence of Types I., II., III., and Group "X" pneumonia varies in different countries. If only America and Britain are compared, in the former country Types I. and II. account for 50–65 per cent., Type III. 10–15 per cent., and Group "X" 25–35 per cent. of the infections, whereas in Glasgow the corresponding figures are 70–75 per cent., 3–4 per cent., and 20–25 per cent. A possible explanation of the difference in incidence will be discussed later, but it is obvious that comparison of the crude mortality-rates from lobar pneumonia in the two countries would be unfair unless the differing incidence of the pneumococcal types are taken into account.

(2) The case-mortality from lobar pneumonia may vary considerably from year to year. This variation might be the result of an alteration in the incidence of the infecting types apart from a change in the virulence of any individual type or a variation in the quality of the exposed community. There is some evidence that the relative incidence of the infecting types varies in the same community in different seasons—e.g., Griffith (1928) found in the Smethwick district of London that Type II. pneumonia diminished from 32·6 in 1920–22 to 7·4 per cent. in 1924–27, while there was a corresponding increase in Group "X" infections from 30 to 53·7 per cent. Cecil, Baldwin, and Larsen (1927) in a five-years' survey also reported variations from year to year. Our own figures—based on 875 cases—in three successive winters for Types I., II., III., and Group "X" pneumonia are February–September, 1930, 32, 45, 2, and 19 per cent., September, 1930–August, 1931, 37, 32, 5, and 24, and September, 1931–August, 1932, 37, 30, 4, and 29 per cent., an increase during the three years in Type I. and Group "X" infections, and a corresponding decrease in those of Type II. These figures are open to the criticism that they are not representative of all the cases of lobar pneumonia in the infected community. Nevertheless, in order to contrast the severity of lobar pneumonia in the same community in different years, an accurate

PERCENTAGE DISTRIBUTION IN AGE-GROUPS
of Types I., II., III., and Group "X" pneumonia (1115 cases)



---

* The second Milroy lecture for 1933 delivered before the Royal College of Physicians of London on Feb. 28th. Lect. I. appeared in our last issue.

knowledge of the incidence of the infecting types in each year would seem to be essential.

(3) An investigation of the age-incidence of Types I., II., III., and Group "X" pneumonia might be undertaken to discover what difference exists in the age-distribution of the different types, and to compare the age-incidence of the same types in different countries and localities. There are not many available figures relating to these points. Our results indicate that Type III. infections are most common in older individuals, while Group "X" pneumonia, although sharing in the general increase during the third and fourth decades, has a predilection for the young and the old, say under 10 and over 50. Cecil and Plummer (1932) have made an analysis of the age-incidence of Types I. and II. pneumonia, and a comparison of their figures with those of Glasgow shows that in both groups Type I. pneumonia is rather more common in the "teens," while Type II. pneumonia has its greatest incidence in the third decade of life (see Figure). This is in itself an interesting and unexplained phenomenon. Perhaps the apparently greater invasiveness of Type I. pneumococcus (see Lecture I.) may be concerned in the greater incidence of this infection in the more resistant adolescent.

The Infected Community

With regard to the resistance of the community exposed to infection, there are three or four obvious factors which influence the mortality-rate from lobar pneumonia.

(1) *Age.*—In typhus and typhoid fever the influence of age on prognosis is well known. In the case death-rate from lobar pneumonia also age is of paramount importance (see Lect. I., Fig. 2), although in statistical statements of mortality the influence of age of attack is often overlooked, particularly in estimating the value of remedial measures, such as antipneumococcal serum, or in contrasting mortality-rates in different institutions on the basis of small numbers.

(2) *Constitution.*—This may be interpreted rather vaguely as the inherited resistance of a community. If the incidence and death-rates from Types I., II., III., and Group "X" pneumonia in America and Glasgow are compared (Table I.), two differences are apparent—(*a*) a greater incidence in America of Type III. and Group "X" pneumonia; (*b*) a higher mortality-rate for all pneumococcal types in that country. Type III. and Group "X" pneumococci are apparently much less infective or invasive organisms than Types I. and II., being found frequently in the throats of normal people tending to infect older and debilitated perso The frequency of these types as a cause of lo pneumonia in America suggests a lessened resista of the community to pneumococcal infections general, a suggestion borne out by the high mortality from lobar pneumonia in America tha in Britain. Support for this contention is al gained by comparing the mortality-rate from lob pneumonia in the Bellevue and the Rockefell Institute Hospitals, which admit different classes patients (Cecil, 1932, see Table I.). The Souther races, among whom pneumonia is not so common, ar apparently less resistant to the infection when the migrate to districts where this affection is mor prevalent (see also Lister, 1913).

TABLE I

The Incidence of and Mortality from Pneumococcal Types in Lobar Pneumonia in Various Countries.

Country.	Year.	No. of cases.	Percentage incidence of types.			
			I.	II.	III.	X.
U.S.A. (Rockefeller Institute).	1913–17	454	33·3 (11·6)*	29 3 (28·5)	13·0 (43·0)	24·6 (12·8)
U.S.A. (Bellevue Hospital).	1920–30	4310	32·1 (28·2)	23·0 (48·9)	11·1 (42·7)	33·8 (31·3)
Denmark (Christensen and Jurgens).	1923–25	298	28	28	10	34
Britain (collected; Dible).	1921–31	766	34·4	31·4	3·7	30·6
Glasgow.	1930–32	1215	36·2 (10·8)	35·5 (21·5)	3·6 (40 9)	24·7 (8·6)

Figures in parentheses represent case-mortality rate.
* Mostly serum-treated.

(3) *Climate.*—Meteorological conditions may influence the incidence and possibly also the mortalit of lobar pneumonia in two ways. The greater severity of this affection during the spring months may be associated with a general lowering of resistance, owing to such factors as the absence of sunlight and lower respiratory exchange (Madsen, 1930). For example, Macgregor (1933), in an analysis of the deaths from lobar pneumonia in the isolation hospitals in Glasgow during 1930–31, found that the death-rate was highest in the first four months of the year (20–21 per cent.), lowest in the four summer months (12 per cent.), and intermediate in the last four months (15–16 per cent.). From January to April, 1932, following an exceptionally mild winter, the death-rate was only 13·6 per cent. Again, in a city like Glasgow, where meteorological conditions predispose to recurring minor respiratory infections, the relationship of these to the incidence of lobar pneumonia is quite unknown and well worth investigation. It is possible that some of these infections may increase the general resistance to the pneumococcus. On the other hand, resistance may be weakened, as undoubtedly happens when influenza is present in the population. One may conclude by saying that the factors affecting the general mortality from pneumonia are so complex that very great caution has to be exercised when comparing the death-rate in different countries, or even in different towns in the same country. The principal factors for which allowance must be made are the incidence of the different pneumococcal types, the prevailing age of attack, the constitution of the individuals exposed to infection, and the climatic conditions.

The Seasonal Incidence of Lobar Pneumonia

Pneumonia in Britain is notifiable as "acute primary pneumonia" or "acute influenzal pneumonia," which means that no opportunity is afforded of determining separately the incidence of pneumococcal lobar and broncho-pneumonia. In January, 1931, the International Classification of Causes of Death made provision for discarding the use of the term "pneumonia," and the practitioner is asked to state, if possible, whether the case was one of lobar or broncho-pneumonia. Although it is impossible therefore to estimate completely the seasonal incidence of lobar pneumonia, Macgregor (1933) has recorded separately for Glasgow (January, 1930–June, 1932) the weekly deaths from lobar and broncho-pneumonia in the age-group 10–55, when confusion between the two infections is least likely to occur. There is every winter a regular and sustained increase in the deaths from lobar pneumonia during the first four months of the year, and even allowing for a slightly higher case-mortality rate during this period it seems obvious that the greatest incidence of lobar pneumonia in Glasgow occurs in January to April. When this spring incidence of lobar pneumonia was compared with the annual mass movement of the pneumonias in the city as indicated by the notified cases, it was found that there was no correlation—e.g., "in 1929–30 the winter prevalence (of 'pneumonia') took the form of a sustained fluctuating curve; in 1930–31 an abrupt ascent took place in the middle of November reaching epidemic proportions during the first three weeks of December; in 1931–32 the salient feature was the onset of a sudden explosive incidence lasting for ten weeks from the end of February to the middle of April"—I quote from Macgregor's paper. Support for Macgregor's analysis is obtained from Denmark where lobar pneumonia, broncho-pneumonia, and tracheo-bronchitis are separately notified. Madsen (1930) has compared the seasonal incidence and death-rate from these three infections, and his charts show that whereas broncho-pneumonia and tracheo-bronchitis have superimposed curves, lobar pneumonia has an independent curve occurring later in the winter.

The Spread of Lobar Pneumonia in the Community

Consideration may now be given to lobar pneumonia as a specific infectious disease and the mode of spread of the infection. What are the accepted facts? That the known infectivity of lobar pneumonia is of a low order is attested by the rarity of the occurrence of more than one case in a family, the comparative absence of the disease among nurses and others attendant upon patients, and the infrequency of epidemic outbreaks. As regards seasonal incidence, lobar pneumonia conforms to the behaviour of an infectious disease, although possibly this may be dependent upon changes in the resistance of the community. Again, there is the evidence of the bacteriological facts. Although 70–75 per cent. of cases of lobar pneumonia are due to Types I. and II. pneumococci, these types are rarely found in the throats of healthy persons, whereas those of Type III. and of the heterogeneous Group "X" pneumococci are carried either constantly or intermittently by 30–90 per cent. of the community. These bacteriological facts would in themselves point to the likelihood that lobar pneumonia is, in the main, caused by an exogenous infecting organism. However, Griffith (1928) has demonstrated that one type of pneumococcus may be changed into another by injecting a live "rough" culture of pneumococcus A along with a killed "smooth" emulsion of pneumococcus B into mice from which were recovered a living smooth B type. A similar change of type has since been accomplished in vitro (Dawson and Sia, 1931), and it may be added that Goebel and Avery (1931) have succeeded in linking a derivative of Type III. S.S.S. to horse serum globulin, thus producing a synthetic Type III. pneumococcus which behaves antigenically exactly like the natural organism. Griffith further observed that after an attack of lobar pneumonia the infecting pneumococcal type might quickly disappear from the patient's respiratory tract and be replaced by Group "X" pneumococcus. The important practical question is, Does change of type occur under natural conditions?

As regards the phenomena of infection, therefore, two possibilities present themselves. Lobar pneumonia may be presumed to result from either a biological change in the saprophytic group "X" pneumococci to the more infective Types I. and II., or, on the other hand, infection with an exogenous Type I. or II. pneumococcus derived from an acute clinical case, a convalescent carrier, or a healthy contact carrier, provided these are shown to exist, and provided this chain of events can be demonstrated. It seems somewhat paradoxical that there should exist in nature some 30 fixed immutable types of pneumococcus, of which only two or three should constantly act as infecting strains. It is more natural to assume that the several strains are capable of mutation under certain circumstances in response to changing environment. On the other hand, multiplicity of serological types of a particular species is not exceptional in the bacteriological world. For instance, the hæmolytic streptococcus group comprises many serological types, as do also the dysentery and paradysentery bacilli, or even the coli-typhoid group. Further, in the typhoid-salmonella family there are close affinities in the "rough" state, but it is not suggested that *B. typhosus* may under natural conditions assume the characters of Gaertner's bacillus. As an indication of the stability of the pneumococcus, Neufeld reminds us that his original Type I. has maintained its specificity in artificial culture for almost a quarter of a century. A further fact of importance is that before change of type can occur in the pneumococcus under the experimental conditions mentioned, the original type must be denuded of its capsule; it is rare to find a wholly "rough" strain of pneumococcus in the throat by cultural methods (Webster and Hughes, 1931). Thus the occurrence of biological change in the pneumococcus under natural conditions is a phenomenon which there is little chance at present of either proving or disproving, while there are several considerations in favour of the other view which should be closely examined.

The evidence in support of the argument that lobar pneumonia is infectious may be advanced along the following lines: the occurrence of epidemics due to a particular type of pneumococcus, the infectivity of the acute case, and since this is apparently low, the occurrence of convalescent and contact carriers and the infectivity of these carriers.

Epidemicity of lobar pneumonia.—Although lobar pneumonia in epidemic form has been frequently reported—e.g., in Italy during the eighteenth century—it is only within recent years that bacteriological proof of its "epidemicity" has been available. Stillman (1917) reported two small epidemics caused by Type I. pneumococcus, while Nichols' account (1917) of an outbreak of lobar pneumonia among American recruits in a camp of 43,000 men at El Paso in 1916–17, beginning on Nov. 1st and reaching its peak in February, has the features of a true epidemic. Among the typed cases 78 per cent. were due to Types I. and II. pneumococcus, and there was direct evidence of tent, company, and regimental contagion. Perhaps the best record of the kind is that of Strom[†] (1932) who in an isolated orphanage reported 12 cases of lobar pneumonia and 2 cases of otitis media among 87 boys, aged 5–20, between Feb. 10th and June 15th, 1931. Type I. pneumococcus was recovered in all the cases examined in the acute stage. It is noteworthy that the attack-rate was greatest and the infection most severe among the boys who had been longest in the orphanage. Numerous other epidemiological data could be given—the localised outbreaks noted by Baerman (1914) among the labourers on a Java plantation, the greater incidence of pneumonia at public boarding schools among boys who have common dormitories than among girls who sleep in cubicles (Glover, 1932), and Macgregor's evidence locality in different years, can only be made if due attention is given to such factors as the percentage incidence of the several pneumococcal types, the age-distribution and constitution of the exposed community, and the climatic conditions. No accurate data are available about the relative incidence of lobar pneumonia in this country, and a plea is made for the separate notification of lobar and broncho-pneumonia. Evidence is adduced in favour of the view that lobar pneumonia is an infectious disease endemic in large cities, with an annual winter epidemic, reaching maximum prevalence in the spring. The reservoirs of infection may be the contact and convalescent carriers, both of whom have been shown to occur in considerable proportion. Further investigation is required to clarify the mode of spread of the infection.

THE RELATIONSHIP OF THE ALBUMINURIA OF PREGNANCY TO CHRONIC NEPHRITIS

BY G. W. THEOBALD, M.D. CAMB., M.R.C.P. LOND., F.R.C.S. EDIN., F.C.O.G.

CONSULTANT OBSTETRICIAN TO THE HAMMERSMITH HOSPITAL; LATE PROFESSOR OF OBSTETRICS AND GYNÆCOLOGY, BANGKOK; FORMERLY ASSISTANT MASTER, THE ROTUNDA HOSPITAL, DUBLIN

(From the Department of Pharmacology, University College, London)

UNTIL the second decade of the present century it was believed that almost the only risk attaching to the albuminuria of pregnancy was that it might develop into eclampsia, and the only dangers associated with eclampsia were the immediate maternal and fœtal mortality. In 1921, however, Caldwell and Lyle [1] reported that 2 out of 22 patients who had recovered from eclampsia were found at a later date to suffer from chronic nephritis. In the same year Gibson [2] took a much more gloomy view of the sequelæ and late results of the toxæmic albuminuria of pregnancy, and suggested that such women should not be allowed to place their lives in jeopardy by again becoming pregnant. Six years later Young [3] reported that several of his patients had had eclampsia more than once, and that the subsequent obstetric histories of a considerable proportion of his patients who had suffered from the toxæmias of pregnancy were anything but satisfactory. In a more recent paper [4] he estimates that in England and Wales between 7000 and 10,000 women annually acquire a more or less persisting disability as a result of the pregnancy toxæmias. In 1931 Peckham and Stout [5] opined that one out of every three women who suffer from a toxæmia of pregnancy (excluding vomiting and eclampsia) will ultimately be found to have nephritis. Stander and Peckham [6] in the same year stated that nephritis associated with pregnancy occurred more frequently in women between the ages of 30 and 40, and assumed that multiparity per se was an important predisposing factor. Of 236 patients diagnosed as nephritics only 135 were traced. Of these 46 had died, 37 from nephritis, while the average duration of life after the condition had been diagnosed was only 3·37 years.

Other papers expressing similar views could be quoted, but that by Gibberd [7] is the only one concerned with results in England. After giving valuable figures from the practice of Guy's Hospital he asserts, that, if the standards of treatment which in the past have been considered adequate be adopted, at least 10 per cent. of previously healthy women who suffer from albuminuria during pregnancy will develop chronic nephritis. Not only must a woman who wishes to have a baby accept a 0·4 per cent. risk of death during pregnancy, childbirth, or the puerperium, but also a 0·5 per cent. risk of acquiring chronic nephritis over and above a much higher risk of subsequent ill-health. In other words, the remote mortality from childbirth is greater than the immediate.

This alarming contention is based on the results of the subsequent investigation of 89 out of 300 cases of albuminuria. Of these 89 women, 79 were stated to be healthy before pregnancy, although when examined at a later date 9, or 11·4 per cent., were found to be suffering from chronic nephritis. The following objections to such a contention offer themselves :

(1) Only 89 out of 300, or 30 per cent. of the cases, were subsequently investigated.
(2) It was assumed that because the specimen of urine examined when the patient first came under observation did not contain albumin, she did not suffer from nephritis.
(3) The criteria on which a diagnosis of nephritis is made are not specified.
(4) The ages of the patients are not mentioned.
(5) The numbers are far too small to allow of such an important conclusion being reached.
(6) No control observations have been made on comparable numbers of unmarried women.

As similar objections could be offered to the conclusions arrived at by the other authors, it occurred to me that the national data available at the General Register Office might throw light on the subject. Through the courtesy of the Registrar-General for England and Wales, to whom I express my sincere thanks, I have been able to study the Decennial Report for 1911–1920, prior to its publication, and other relevant statistics at Somerset House, and I have much pleasure in acknowledging the very great help and friendly interest which were offered by his staff.

The Registrar-General's Figures

The report deals with an estimated mean population of 19,239,700 females. The average annual number of births was 809,622, and it may be assumed that the number of twins was more than offset by the number of stillbirths which were not registered during the period under review. The number of multiple births is given in the annual report for Scotland, but not in that for England and Wales. In 1930 2557 out of 94,549 births were multiple, or 2·704 per cent. In the same year 4·007 per cent. of the births in England and Wales were stillborn. If it be taken that 4 per cent. of the mothers suffered from the albuminuria of pregnancy and that 5 per cent. of all births were illegitimate, we are left with some 30,800 cases occurring in married women. Of this number it is postulated that 3080 should have subsequently suffered from chronic nephritis, and that in each year* over 2700 previously healthy women should have acquired nephritis simply and solely because they gave birth to children. Yet the average annual number of deaths in females of all ages from that disease during the period under review was only 5637. Moreover, it is fair to point out that antenatal clinics were not widely established during this period. In the Rotunda Hospital reports for the last two years the incidence of albuminuria has been about 30 per cent., and R. E. Tottenham supplies similar figures for Hong-Kong, another centre where antenatal clinics have not been developed. Had the incidence of the albuminuria of pregnancy between the years 1911–1920 been 20 per cent., as it probably was, then 13,500 previously healthy women should have acquired chronic nephritis in each year!

The first important point which emerged from the figures was that the mortality curves from Bright's disease in females have shown the same upward or downward tendencies as those for males in every year except three since they were first recorded in 1861. It is clear from Table I. that the mortality-rates for both males and females rose sharply in every succeeding decennium until the one under review, in which a fall occurred in those for both sexes. Although part, or all, of this apparent increase may be due to increasing care in death certification and changes in medical opinion as to the importance of kidney lesions, leading to transference from other groups such as "old age," the significant point is that the operation of these factors affected the rates for both sexes in a similar direction.

TABLE I

Mean Annual Mortality, per 1,000,000 *Living (Standardised), from Acute and Chronic Nephritis, Bright's Disease*

	Males.	Females.
1861–70	153	95
1871–80	269	179
1881–90	364	265
1891–1900	418	308
1901–10	435	325
1911–20	406	302

Secondly, the mortality-rates for Bright's disease vary in different parts of the country, and, as a rule, where they are high for men they are high for women, and conversely where they are low for men they are low for women. It is seen from Table II. and Fig. 1 that if the deaths for the whole country be taken as 100, the deaths in the midlands (an area having a population of nearly one-third of that of the whole country) both for males and females, are represented as 85. London has the highest incidence for males, closely followed by the north, while the figures for females are practically the same in both these areas. It is also clear that, generally speaking, the incidence of Bright's disease is highest in the cities and county boroughs and by far the lowest in the rural districts, where the incidence of puerperal convulsions and albuminuria is highest. Part of the latter contrast may, however, be due to the fact that death certification in country districts is less precise than in towns.

TABLE II

Relative Mortality (Standardised), 1911–1920

BRIGHT'S DISEASE

—	England and Wales.	North.	Midlands.	South.	Wales.	London
Males ..	100	112	85	104	97	121
Females ..	100	116 (121)	85 (85)	97 (70)	104 (197)	115 (55)
COUNTY BOROUGHS						
Males ..	110	123	93	99	108	—
Females ..	107 (97)	122 (109)	91 (79)	87 (85)	98 (148)	—
OTHER URBAN DISTRICTS						
Males ..	99	101	88	98	92	—
Females ..	98 (109)	119 (136)	86 (76)	87 (79)	100 (212)	—
RURAL DISTRICTS						
Males ..	78	76	72	82	95	—
Females ..	83 (118)	89 (145)	76 (103)	81 (83)	109 (197)	—

The death-rates for the whole country are taken as 100. The numbers in parentheses are for puerperal albuminuria and convulsions.

The annual mortality from Bright's disease among females per 1,000,000 living according to their civil state is shown in Table III. It is evident that the differences between the figures for married and single women are very small, and in the age-group 30–35 the mortality-rate is actually higher in single than in married women, as it is in every age-group after 55. This Table includes a certain number of deaths from chronic nephritis associated with the puerperal state, classified to this cause by the operation of the rules for the selection of one from two or more jointly stated causes of death. The total annual number of deaths in females (the average for the ten years) did not exceed 5640. Even if it be conceded that 10 per cent. of the single women gave birth to children, it is clear that the actual annual number of deaths amongst married women between the ages of 15 and 45 did not greatly exceed the calculated number if they had remained single. While it is possible that

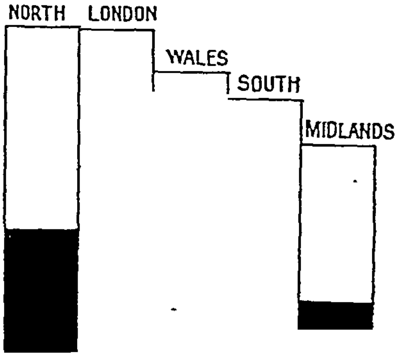

FIG. 1 shows relative mortality (standardised) in women from Bright's disease in different areas. The shaded areas represent (on half the same scale) the relative mortality in the same areas from puerperal albuminuria and convulsions.

---

* This figure is arrived at in the following way: 809,622 less 5 per cent. or 40,481 = 769,141 : 4 per cent. of this number = 30,766 = the number who had albuminuria, of which 10 per cent. or 3077 had chronic nephritis. 79/89 × 3077 or 2731 represents the number of previously healthy women who acquired chronic nephritis.

significance. It is true that mortality-rates are used as a measure of nephritis incidence, but if "puerperal nephritis" is merely a disability that does not end in death from renal or associated causes, it differs from any other form of nephritis and should be called by a different name.

It can be confidently asserted that the risks of marriage and childbirth are less than those of being a spinster at any age after 30 years, and it would be difficult to maintain that the selection accorded by marriage has much causal relation to this fact. So far as Bright's disease is concerned it causes a considerably higher mortality-rate in single than in married women after the age of 55 years, when the greater number of deaths occurs. Indeed, the marked association of the mortality from this disease with advanced age supports the hypothesis that the associated kidney lesions are more often degenerative than *inflammatory*.

In Table VII. are shown the standardised rates for chronic nephritis alone in each year from 1921 to 1930 for females. Although the sudden rise from 1926 to 1928 may be accounted for by the introduction of a new form of death certificate in July, 1927, there is at any rate no suggestion, either that the marked fall in the birth-rate,‡ or the recent growth of antenatal clinics has been accompanied by any lessening of the mortality from chronic nephritis in women.

TABLE VII

The Standardised Death-rates, per 1,000,000 *Living, for Bright's Disease among Females,* 1921–1930. (*Chronic Nephritis only.*†)

1921	197	1926	195
1922	208	1927	213
1923	205	1928	230
1924	195	1929	237
1925	200	1930	234

It is, however, necessary to refute the increasingly expansive and almost competitive estimates of the frequency with which chronic nephritis is caused by the so-called toxæmias of pregnancy, both because such views will cause unnecessary anxiety and will inevitably lead to an increase in the number of abortions, and because they will tend to obscure the ætiology both of the "toxæmias of pregnancy" and of Bright's disease.

In conclusion I wish to thank Dr. Percy Stocks, of University College, reader in medical statistics in the University of London, for valuable suggestions embodied in this paper.

† Table I. includes acute and chronic nephritis under the heading of Bright's disease, whereas Table VII. excludes acute nephritis. Using the same grouping as in Table VII., the standardised figures for 1911–20 would be (according to Reg.-Gen.'s Stat. Review, 1926, p. 99) males 316, females 246.

‡ The average annual number of live births in England and Wales during the decade 1921–30 was 712,907. On the above estimates some 300 less women should have contracted nephritis annually as the result of pregnancy than in the previous decade. Further, in the second half of the decade the average annual number of live births fell to 660,297, so that from 1926 onwards the annual number of women who contracted nephritis as the result of pregnancy should have dropped by over 500 from the calculated figure for the decade 1911–20.

THE GRASS-POLLEN ANTIGEN FOR HAY-FEVER DESENSITISATION

By JOHN FREEMAN, D.M. OXF.
LECTURER IN BACTERIOLOGY AND DIRECTOR OF THE DEPARTMENT OF CLINICAL BACTERIOLOGY, ST. MARY'S HOSPITAL, LONDON

II.*—DOSAGE

IN discussing the valency of pollen antigens for hay-fever it was cited that really heavy dosing with any grass-pollen would cause the dwindling and disappearance of the diagnostic skin reactions. It was further stated that, when these skin reactions could no longer be produced in a patient, he also lost all trace of his usual hay-fever symptoms at the midsummer hay-fever season.

To take an extreme example: when dealing with an exigent case last year, egged on by the patient, I gradually worked up to a dose of 100,000 units of pollen vaccine—that one final dose representing as much of the yellow pollen grains as will handsomely cover one side of a sixpenny-bit. He got his cure, which was duly signalled by the abolition of his skin reactions; but few patients would go to that degree of trouble—and I may add that with such heroic doses there would hardly be enough pollen extract for all cases.

I wish to show first how this heavy desensitisation can best be carried out; we can then take a side glance at the question of gauging the minimum of such treatment which will give adequate relief—or which will be thought worth while by the average case.

THE COURSE OF TREATMENT

Preliminary cutaneo-reactions.—As with all desensitisation work (whether for grass-pollen, for horse-dandruff, for food-proteins, &c.), we need cutaneo-reactions both to clinch diagnosis and to assess the initial inoculation; but, if diminution or obliteration of the skin reaction is to serve as any test or guarantee of success, we need a reaction base-line to start from.

Any skin or eye reaction that is familiar to the inoculator will serve. I am now using a prick (the minimum prick into the skin of the patient that can be felt as a *distinct* prick) made with a sharp clean needle through neighbouring drops of (1) saline, (2) 5000 units grass-pollen extract, and (3) 50,000 units respectively. The weals (which develop in seven to twelve minutes) can conveniently be traced on to a glass microscope slide the surface of which has been prepared with white-of-egg to take the ink without running. The weals vary from the size of a split pea or less to the size of a shilling or over (see Figure). They are often very irregular in outline with long "pseudopodia." The surrounding erythema is also very characteristic of sensitisation and disappears with treatment, but the rash differs very much on different patients' skins, and is sometimes absent or doubtful even with a well-marked weal; if traced for reference it will of course need a larger piece of glass—say a lantern-slide at the least.

Initial doses.—To save time the initial dose is naturally the highest that can be given without undue reaction in the patient. This must be gauged from the diagnostic weal, from the patient's story of hay-fever symptoms, and from any inoculation treatment in previous years. Initial doses range perhaps from 20 to 100 units, but I have not hesitated to start with as much as 200 units on occasion, and with much more than that for cases that have been inoculated previously. If the inoculator is nervous of constitutional reaction, a small quantity of adrenaline mixed with the pollen extract in the syringe serves as a safeguard.

---

* Part I. on Polyvalency appeared in our last week's issue.

Increase of dose by 15 per cent.—Each dose prepares the patient for a larger one to follow, the optimum being the largest that can be taken with comfort. If the initial dose has been under 100 units then it is usual to increase by 20 units at a time up to 200 units, and then to settle down to a 15 per cent. rise at each reinoculation. Thus 200 units would be followed by 230, then 264, 300, 345, 400, 460, 530, &c., right up to say 20,000 units or to a point at which we guess the patient has had enough treatment. If the patient is less sensitive and the initial dose has been 100 or over, then the successive increases on this may be proportionately bolder till the routine 15 per cent. increase is adopted at a dose of 300 or 400 units. The occurrence of reactions after any dose may slow down this increase from time to time, and the absence of any reaction may prompt a bolder increase of dose—say up to 20 per cent.; but it is found that the 15 per cent. rule is convenient in the long run.

Reactions from doses.—If an inoculation is too large the patient may show symptoms such as nettle-rash (either locally, generally, or as angioneurotic œdema), migraine headaches, perhaps asthma, or any of the toxic idiopathies; but unless the dose has been badly over-estimated there will be nothing but a little transient urticaria, which is easily controlled by doses of adrenaline. Even a small urticarial reaction should prompt the inoculator to be cautious for the future, perhaps to repeat the same dose again before increasing, or even, if the reaction was very severe, to go back to a smaller dose.

The sticking-point.—Often, with a stereotyped set of doses as given above, one can completely desensitise a patient without any reaction at all; but sometimes in the course of treatment a "sticking-point" is reached where the patient will not tolerate the usual rate of increase, which has therefore to be slowed down, or possibly even stopped entirely for a dose or two, after which the patient will probably tolerate the inoculations just as readily as previously. As these sticking-points may occur at any place in the gradual ascent of doses, and are in fact just as likely to occur (let us say) at the 200 unit dose as at the 20,000 unit dose, it seems probable that the temporary difficulty lies in the inoculated person; there is, one must suppose, some temporary derangement of metabolism which makes the desensitisation process difficult at that particular time.

Frequency of reinoculation.—The intervals between the doses can be adapted to suit the circumstances of the case within fairly wide limits—e.g., they are preferably not longer than a week nor shorter than four hours. Doses are conveniently given once a day to get through the bulk of the work, but this interval can be stretched out or contracted as convenient. If the inoculation is taking place more rapidly than three times daily it probably saves time to put the patient in a nursing-home or similar institution, and give a regular "rush" course of inoculation.[1]

Number of doses.—It will be readily calculated that if we allow six inoculations for reaching the 200 unit dose, granted there is no hitch, we shall need 19 inoculations to reach the 1000 units, 30 inoculations to reach the 5000 units, 35 inoculations to reach the 10,000 units, and so on. A formidable amount of treatment.

SELF-INOCULATION

For the past three summers for heavy immunisation I have been teaching the more intelligent and busy patients to inoculate themselves, otherwise it is often impracticable to get them completely protected. The actual technique for inoculation is easy enough to teach to almost anyone, but the calculation and measuring out of a string of suitable doses is sometimes more than the patient can compass; thus the student type is suitably repaid for its greater intelligence and capacity. Besides being taught what to do, they must be instructed to keep careful records of dates, doses, and any reactions that may occur. If the doctor in charge frequently reviews their "home work," as shown in these reports, he will soon see if patients are fit to inoculate themselves.

AMELIORATION OR CURE?

How much of this is practicable as a routine?—The extent of treatment very much depends upon the temperament, determination, and circumstances of the patient. We have the paradox that it is more easy to give satisfaction to the serious cases than to the slight ones; and the patient who demands treatment just because his nose occasionally tickles is very difficult to cure—or convince that he is cured.

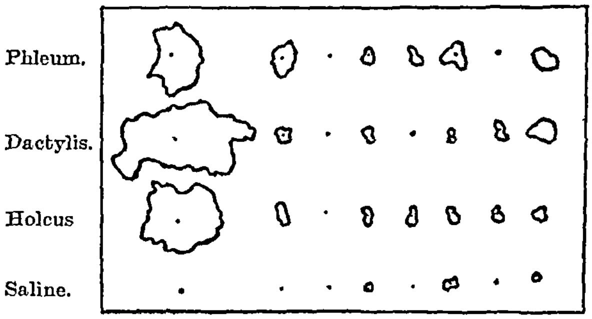
Patients differ very much in the amount of improvement they will get from small amounts of treatment. Probably treatment up to 500 units, or even only up to 300 units, will give noticeable amelioration in some cases, and will give what they claim to be a "cure" to a few. There will be increasing amelioration as the dose gets larger. Where the severity of the symptoms really justifies such a course I shall try to get my patients this year up to 10,000 units, with higher desensitisation for special cases—unless the diminishing skin reactions justify the reduction of treatment.

Cutaneo-reactions as a guide to successful desensitisation.—The skin reactions will usually be diminishing at about the 2000 to the 5000 unit dose, and may begin to go much sooner than this; there seem to be great differences between patients here. Reactions will probably disappear between the 5000 and the 20,000 dose; more rarely, however, the reactions do not completely go until a dose of 50,000 or even 100,000 has been given. So far as is known, complete obliteration of the reactions guarantees a complete cure from hay-fever symptoms—for that season at any rate. It seems to be the rule that a patient is noticeably desensitised when the skin reactions begin to wilt under treatment, and this may happen long before they vanish completely. Unless special guarantee of a cure is demanded I would suggest that treatment might be concluded or merely "maintained" when the skin reactions have been noticeably lessened. Even this does not necessarily give sure guidance to the minimum of treatment which will be deemed adequate by the patient; many cases report complete or almost complete relief with very few doses, and, it must be presumed, with little or no diminution of the wealing of the skin; but as these people do not come for subsequent skin testing it is peculiarly difficult to give statistics. I propose to devote this year's cases to investigating that one point.

The bogy of artificial sensitisation.—Frequently in the past, writers have speculated on the dangers of sensitisation following inoculation treatment. Arguing, as I think wrongly, by analogy from anaphylaxy, it has been suggested or even stated that though inoculations may make a man better for that season perhaps, his last state will be the worse for it because he may subsequently become more sensitive. The facts seem to be dead against this theory. Patients are not more sensitive in subsequent years but very much less so, and we have now had over 20 years of experience of this. Also inoculation treatment, in addition to being less necessary, is subsequently much easier: not only the initial doses but also the subsequent increases can be bolder—much bigger with impunity. Thus the patient needs less and less treatment in succeeding years; this is true over a long period of years with the smaller doses which were previously given, and it is more conspicuously true with the heavy desensitisations I have given in recent years. *In fact, judging by the skin reactions, very heavy desensitisations may render unnecessary* any treatment in the next spring at any rate. For example, if E. F. (see Figure) does not show increasing reactions by the beginning of May she will be advised to go without treatment this year.

---

[1] THE LANCET, 1930, i., 744.



E. F. commenced her treatment with 40 units of dactylis pollen on May 3rd (reactions in first column); by May 25th she had reached a 20,000 unit dose of dactylis and her skin reactions (second column) had almost gone. On July 8th, with 50,000 units of dactylis, the reactions had quite disappeared (third column). Treatment was then stopped. The next four columns show the reactions only slightly returning on successive dates in July, September, November, and December, 1932, while the last column was traced on March 14th, 1933. Five other pollens to which she equally lost her reactions have been omitted from this diagram to save space.

Lastly, I may quote the experience of a normal—i.e., non-hay-fever—subject. For experimental purposes—e.g., when demonstrating a Prausnitz reaction —I have frequently injected into myself either subcutaneously or intravenously doses of pollen extract from a minute dose up to 30,000 units, and I can detect no subsequent sensitisation in myself when tested by cutaneo-reactions, or when injecting the next massive dose, or from the atmospheric pollen cloud at midsummer. I have remained normal, and so have my colleagues who have suffered similar treatment. Yet there must be some slight trace of true anaphylaxy from pollen—even in man one must suppose; and it can be readily demonstrated in the guinea-pig which does not experience any trace of true hay-fever so far as we can find out. Therefore in this respect, as in several others, anaphylaxy and hay-fever are in different categories. In practice there is no danger of artificial sensitisation.

CONCLUSION

(1) The practitioner may justifiably tell his hay-fever patient that he *can* be cured for certain; but should add in the next breath that unless symptoms are really exceptionally severe such complete treatment may be hardly worth while. Far less treatment than this usually gives satisfactory or even complete relief, but it is impossible at present to guarantee how much less will do sufficiently well. (2) Some, but at present not enough, evidence as to the successful progress of the desensitisation can be gained from the diminishing skin reactions. (3) There is apparently no danger that the patient may have to pay for present desensitisation by subsequent increased sensitisation.

THE NUTRITION OF THE HEART
IN RELATION TO THE ELECTROCARDIOGRAM AND ANGINAL PAIN

BY K. SHIRLEY SMITH, M.D., B.SC., M.R.C.P. LOND.

ASSISTANT PHYSICIAN AND PHYSICIAN IN CHARGE OF THE CARDIOGRAPHIC DEPARTMENT, CHARING CROSS HOSPITAL; PHYSICIAN TO OUT-PATIENTS, CITY OF LONDON HOSPITAL FOR DISEASES OF THE HEART AND LUNGS

IT is the purpose of this paper to consider the influence of some nutritional disorders on the heart and the electrocardiogram. The results of an electrocardiographic study of anæmia will be recorded and assessed in the light of the findings I have already published [1] concerning the diabetic heart. It is further intended here to elucidate the principles underlying abnormalities of nutritional type in the electrocardiogram, and to consider how these influence our conceptions of the production of anginal pain.

The problems of general malnutrition of the heart have hitherto received relatively little attention. Advances in cardiological knowledge during the past twenty years have been concerned mainly with the pathology of coronary artery disease and consequent focal myocardial damage, and with the clinical and electrocardiographic counterparts of these morbid processes. Such researches *have yielded results of so great importance that they mark an outstanding epoch in the develop*ment of cardiological knowledge. But the mechanism of coronary blood-supply and the myocardial lesions due to coronary obstruction constitute only one aspect of the picture. Abnormalities of the irrigating blood in its content of nutritional substances—oxygen, internal secretions, and vitamins—must exert an immense influence, the nature and extent of which still remain problematic. It is true that certain outstanding contributions have already been made to our knowledge of the operation of these factors. The work of Wenckebach [2] on beri-beri heart, and the more recent researches of Harris [3] and others on the arterial changes in experimental hypervitaminosis D, have demonstrated the important influence exerted upon the cardiovascular system by accessory food factors. The control of the heart and circulation by the hormones of the thyroid, adrenal, and pancreas, and the *relation of these regulating* agents to the vitamins and the nutrition of the heart presents a vast field of research hitherto relatively unexplored.

It was believed in the early days of electrocardiography that for any given subject free from cardiovascular disease the electrocardiogram was constant. While it is now generally appreciated that this is not so, the fact that rapid and gross changes occur in various circumstances in such individuals is not sufficiently recognised. The conditions in which such electrocardiographic abnormalities supervene are, in general, those associated with disturbances of nutrition or with the development of toxæmia. It has long been observed that in such conditions as uræmia and pneumonia, alterations that might simulate those of cardiac infarction could be seen in the electrocardiogram. Again, to take a nutritional example, it has been shown by McCullough [4] that gross changes in the electrocardiogram occur in the course of malnutrition in infants. Electrocardiographic anomalies belonging to these categories involve, essentially, the T-deflection and the S–T or R–T interval.

Much obscurity still surrounds many of the problems of cardiac nutrition. It has been known for years that glucose administration is sometimes valuable in the treatment of heart disease. Certain observers have recorded the beneficial effects of oral and intravenous administration,[5-7] while Lasch [8] and others have reported negative results. The experiments of MacLean and de Wesselow [9] and Foster [10] have shown that hyperglycæmia following ingestion or injection of glucose may be succeeded by hypoglycæmia, and that repeated doses may produce even more paradoxical results. It may be that these processes underlie the conflicting reports on the value of glucose in the treatment of heart disease and failure. In the sphere of electrocardiography the mechanism of T-wave production is still imperfectly understood. Conditions of local myocardial ischæmia are known to produce certain modifications in the R–T or S–T intervals, and in the T-waves. It has been established that coronary lesions, if they affect the electrocardiogram, produce opposite results in leads I. and III. Thus R–T elevation in lead I. is accompanied by corresponding depression in lead III. if there is any change at all in this lead. The same principle holds, in general, for inversion of the T-wave from a coronary cause. On the other hand, electrocardiographic changes due to parenchymatous damage from toxæmia or nutritional disturbances have sometimes passed unrecognised or have been misunderstood.

NORMAL GLYCOGEN METABOLISM IN THE HEART

Before considering the metabolic basis of malnutrition in the heart, it is necessary to recapitulate briefly present-day knowledge of normal metabolism in the heart. It must be remembered that modern conceptions of these processes are derived very largely by inference from animal experimentation, and from the knowledge that has been gained of skeletal muscle through the work of Fletcher and Hopkins [11] and Hill [12] and others.

It is generally believed that the heart obtains a large part of its energy from the combustion of glycogen. This substance is present in the heart muscle in amounts inversely proportional to its utilisation, as has been shown by Cruickshank and Patterson.[13] The energy of cardiac contractions is provided largely by the breakdown of glycogen into sugar, and sugar into lactic acid. It is believed that about one-fifth of such lactic acid is oxidised to form carbonic acid and water, while the remaining four-fifths are reconverted to glycogen. It is obvious that under all conditions of rest and exercise a balance must eventually be struck between lactic acid formation and disposal. This implies continuous fresh supplies of glycogen, presumably mobilised from the body, and sufficient oxygen to combust a fraction of the lactic acid produced in the course of cardiac contractions. As in every sphere of carbohydrate utilisation, these processes must be under the control of insulin. Hepburn and Latchford [14] have shown that in the isolated perfused heart of the rabbit, addition of insulin to the perfusate produces threefold increase in the glycogen utilisation. Further, it has been demonstrated [13] that glycogen utilisation in the human diabetic heart is only one-half that of the normal heart. It seems probable that insulin also promotes the reconversion of lactic acid into glycogen.

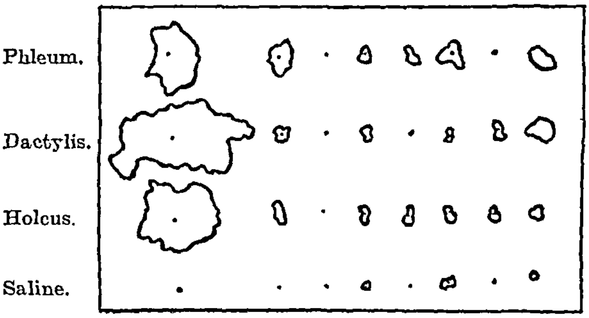
While it has been held in the past that the presence of lactic acid was necessary for the contraction of muscle to take place, it has been proved by Lundsgaard [15] that this is not so, and that muscular contractions may occur in the absence of lactic acid. Lundsgaard's researches were based upon the use of the substance mon-iod-acetic acid which inhibits the production of lactic acid in muscle. The use of this substance has been extended to a study of the mammalian electrocardiogram by Siegel,[16] who has shown that if the production of lactic acid in the heart is inhibited by the use of mon-iod-acetic acid, the T-wave disappears from the electrocardiogram.

THE ELECTROCARDIOGRAM IN DERANGEMENTS OF GLYCOGEN METABOLISM

In a previous publication [1] I have recorded, in collaboration with R. A. Hickling, the results of an electrocardiographic study of the heart in diabetes. Gross abnormalities were observed, ranging from slight depression of the T-waves in lead II. or III. to inversion of the T-waves in all leads. These changes always disappeared in the course of treatment. Reasons were given for believing these electrical phenomena to be due to parenchymatous myocardial damage consequent upon defective nutrition of the heart muscle. Studies by Taterka [17] of patients in diabetic coma yielded corresponding results. Support for the view that nutritional deficiency underlies these electrocardiographic abnormalities is gained from a consideration of the hypoglycæmic state. In this condition also there is a deficiency in the utilisation of glycogen, not, as in hyperglycæmia, because the tissues are unable to use their supplies, but because supplies are not forthcoming. It has been shown by Stepp and Parade,[18] Weichmann,[19] and Middleton and Oatway [20] that depression of the T-waves is commonly found in hypoglycæmia.

It is convenient here to mention some other phases of glycogen metabolism which bear upon this question. Examples of conditions in which enhanced glycogen-utilisation occurs in the body are: (1) exercise, (2) thyrotoxicosis, and (3) excitation of the sympathetic by administration of adrenaline. All of these conditions are found to be associated with well-developed T-waves in the electrocardiogram. It has been shown by Müller and Nicolai,[21] and it is generally agreed, that exercise increases the amplitude of the T-waves. It is still debated how far thyrotoxicosis produces any specific effect upon the electrocardiogram, but White and Aub [22] found a very limited parallelism between the basal metabolic rate and the amplitude of the T-wave in thyroid disease. Siegel [16] states that very steep and high T-waves occur with great regularity in hyperthyroidism. The increased amplitude of the T-wave produced by adrenaline administration has been frequently demonstrated.[23 18]

Reverting to the carbohydrate metabolism of the normal heart already discussed, it is clear that enhanced utilisation of glycogen implies rapid formation of lactic acid, and it has been seen that in such circumstances T-waves of increased amplitude are found. Conversely, both in diabetes and hypoglycæmia, the defective utilisation of glycogen must result in a slowing of the rate of lactic acid formation, while flattened or inverted T-waves are the electrical counterparts of these states. Mention might also be made here of the myocardial disturbances in myxœdema and cretinism, demonstrated by Thacher has been suggested or even stated that though inoculations may make a man better for that season perhaps, his last state will be the worse for it because he may subsequently become more sensitive. The facts seem to be dead against this theory. Patients are not more sensitive in subsequent years but very much less so, and we have now had over 20 years of experience of this. Also inoculation treatment, in addition to being less necessary, is subsequently much easier: not only the initial doses but also the subsequent increases can be bolder—much bigger with impunity. Thus the patient needs less and less treatment in succeeding years; this is true over a long period of years with the smaller doses which were previously given, and it is more conspicuously true with the heavy desensitisations I have given in recent years. In fact, judging by the skin reactions, *very* heavy desensitisations may render unnecessary any treatment in the next spring at any rate. For example, if E. F. (see Figure) does not show increasing reactions by the beginning of May she will be advised to go without treatment this year.



E. F. commenced her treatment with 40 units of dactylis pollen on May 3rd (reactions in first column); by May 25th she had reached a *20,000 unit dose of dactylis and her skin reactions* (second column) had almost gone. On July 8th, with 50,000 units of dactylis, the reactions had quite disappeared (third column). Treatment was then stopped. The next four columns show the reactions only slightly returning on successive dates in July, September, November, and December, 1932, while the last column was traced on March 14th, 1933. Five other pollens to which she equally lost her reactions have been omitted from this diagram to save space.

Lastly, I may quote the experience of a normal—i.e., non-hay-fever—subject. For experimental purposes—e.g., when demonstrating a Prausnitz reaction—I have frequently injected into myself either subcutaneously or intravenously doses of pollen extract from a minute dose up to 30,000 units, and I can detect no subsequent sensitisation in myself when tested by cutaneo-reactions, or when injecting the next massive dose, or from the atmospheric pollen cloud at midsummer. I have remained normal, and so have my colleagues who have suffered similar treatment. Yet there must be some slight trace of true anaphylaxy from pollen—even in man one must suppose; and it can be readily demonstrated in the guinea-pig which does not experience any trace of true hay-fever so far as we can find out. Therefore in this respect, as in several others, anaphylaxy and hay-fever are in different categories. In practice there is no danger of artificial sensitisation.

CONCLUSION

(1) The practitioner may justifiably tell his hay-fever patient that he *can* be cured for certain; but should add in the next breath that unless symptoms are really exceptionally severe such complete treatment may be hardly worth while. Far less treatment than this usually gives satisfactory or even complete relief, but it is impossible at present to guarantee how much less will do sufficiently well. (2) Some, but at present not enough, evidence as to the successful progress of the desensitisation can be gained from the diminishing skin reactions. (3) There is apparently no danger that the patient may have to pay for present desensitisation by subsequent increased sensitisation.

THE NUTRITION OF THE HEART
IN RELATION TO THE ELECTROCARDIOGRAM AND ANGINAL PAIN

By K. Shirley Smith, M.D., B.Sc., M.R.C.P. Lond.
ASSISTANT PHYSICIAN AND PHYSICIAN IN CHARGE OF THE CARDIOGRAPHIC DEPARTMENT, CHARING CROSS HOSPITAL; PHYSICIAN TO OUT-PATIENTS, CITY OF LONDON HOSPITAL FOR DISEASES OF THE HEART AND LUNGS

It is the purpose of this paper to consider the influence of some nutritional disorders on the heart and the electrocardiogram. The results of an electrocardiographic study of anæmia will be recorded and assessed in the light of the findings I have already published[1] concerning the diabetic heart. It is further intended here to elucidate the principles underlying abnormalities of nutritional type in the electrocardiogram, and to consider how these influence our conceptions of the production of anginal pain.

The problems of general malnutrition of the heart have hitherto received relatively little attention. Advances in cardiological knowledge during the past twenty years have been concerned mainly with the pathology of coronary artery disease and consequent focal myocardial damage, and with the clinical and electrocardiographic counterparts of these morbid processes. Such researches have yielded results of so great importance that they mark an outstanding epoch in the development of cardiological knowledge. But the mechanism of coronary blood-supply and the myocardial lesions due to coronary obstruction constitute only one aspect of the picture. Abnormalities of the irrigating blood in its content of nutritional substances—oxygen, internal secretions, and vitamins—must exert an immense influence, the nature and extent of which still remain problematic. It is true that certain outstanding contributions have already been made to our knowledge of the operation of these factors. The work of Wenckebach[2] on beri-beri heart, and the more recent researches of Harris[3] and others on the arterial changes in experimental hypervitaminosis D, have demonstrated the important influence exerted upon the cardiovascular system by accessory food factors. The control of the heart and circulation by the hormones of the thyroid, adrenal, and pancreas, and the relation of these regulating agents to the vitamins and the nutrition of the heart presents a vast field of research hitherto relatively unexplored.

It was believed in the early days of electrocardiography that for any given subject free from cardiovascular disease the electrocardiogram was constant. While it is now generally appreciated that this is not so, the fact that rapid and gross changes occur in various circumstances in such individuals is not sufficiently recognised. The conditions in which such electrocardiographic abnormalities supervene are, in general, those associated with disturbances of nutrition or with the development of toxæmia. It has long been observed that in such conditions as uræmia and pneumonia, alterations that might simulate those of cardiac infarction could be seen in the electrocardiogram. Again, to take a nutritional example, it has been shown by McCullough[4] that gross changes in the electrocardiogram occur in the course of malnutrition in infants. Electrocardiographic anomalies belonging to these categories involve, essentially, the T-deflection and the S–T or R–T interval.

Much obscurity still surrounds many of the problems of cardiac nutrition. It has been known for years that glucose administration is sometimes valuable in the treatment of heart disease. Certain observers have recorded the beneficial effects of oral and intravenous administration,[5–7] while Lasch[8] and others have reported negative results. The experiments of MacLean and de Wesselow[9] and Foster[10] have shown that hyperglycæmia following ingestion or injection of glucose may be succeeded by hypoglycæmia, and that repeated doses may produce even more paradoxical results. It may be that these processes underlie the conflicting reports on the value of glucose in the treatment of heart disease and failure. In the sphere of electrocardiography the mechanism of T-wave production is still imperfectly understood. Conditions of local myocardial ischæmia are known to produce certain modifications in the R–T or S–T intervals, and in the T-waves. It has been established that coronary lesions, if they affect the electrocardiogram, produce opposite results in leads I. and III. Thus R–T elevation in lead I. is accompanied by corresponding depression in lead III. if there is any change at all in this lead. The same principle holds, in general, for inversion of the T-wave from a coronary cause. On the other hand, electrocardiographic changes due to parenchymatous damage from toxæmia or nutritional disturbances have sometimes passed unrecognised or have been misunderstood.

NORMAL GLYCOGEN METABOLISM IN THE HEART

Before considering the metabolic basis of malnutrition in the heart, it is necessary to recapitulate briefly present-day knowledge of normal metabolism in the heart. It must be remembered that modern conceptions of these processes are derived very largely by inference from animal experimentation, and from the knowledge that has been gained of skeletal muscle through the work of Fletcher and Hopkins[11] and Hill[12] and others.

It is generally believed that the heart obtains a large part of its energy from the combustion of glycogen. This substance is present in the heart muscle in amounts inversely proportional to its utilisation, as has been shown by Cruickshank and Patterson.[13] The energy of cardiac contractions is provided largely by the breakdown of glycogen into sugar, and sugar into lactic acid. It is believed that about one-fifth of such lactic acid is oxidised to form carbonic acid and water, while the remaining four-fifths are reconverted to glycogen. It is obvious that under all conditions of rest and exercise a balance must eventually be struck between lactic acid formation and disposal. This implies continuous fresh supplies of glycogen, presumably mobilised from the body, and sufficient oxygen to combust a fraction of the lactic acid produced in the course of cardiac contractions. As in every sphere of carbohydrate utilisation, these processes must be under the control of insulin. Hepburn and Latchford[14] have shown that in the isolated perfused heart of the rabbit, addition of insulin to the perfusate produces threefold increase in the glycogen utilisation. Further, it has been demonstrated[13] that glycogen utilisation in the human diabetic heart is only one-half that of the normal heart. It seems probable that insulin also promotes the reconversion of lactic acid into glycogen.

While it has been held in the past that the presence of lactic acid was necessary for the contraction of muscle to take place, it has been proved by Lundsgaard[15] that this is not so, and that muscular contractions may occur in the absence of lactic acid. Lundsgaard's researches were based upon the use of the substance mon-iod-acetic acid which inhibits the production of lactic acid in muscle. The use of this substance has been extended to a study of the mammalian electrocardiogram by Siegel,[16] who has shown that if the production of lactic acid in the heart is inhibited by the use of mon-iod-acetic acid, the T-wave disappears from the electrocardiogram.

THE ELECTROCARDIOGRAM IN DERANGEMENTS OF GLYCOGEN METABOLISM

In a previous publication[1] I have recorded, in collaboration with R. A. Hickling, the results of an electrocardiographic study of the heart in diabetes. Gross abnormalities were observed, ranging from slight depression of the T-waves in lead II. or III. to inversion of the T-waves in all leads. These changes always disappeared in the course of treatment. Reasons were given for believing these electrical phenomena to be due to parenchymatous myocardial damage consequent upon defective nutrition of the heart muscle. Studies by Taterka[17] of patients in diabetic coma yielded corresponding results. Support for the view that nutritional deficiency underlies these electrocardiographic abnormalities is gained from a consideration of the hypoglycæmic state. In this condition also there is a deficiency in the utilisation of glycogen, not, as in hyperglycæmia, because the tissues are unable to use their supplies, but because supplies are not forthcoming. It has been shown by Stepp and Parade,[18] Weichmann,[19] and Middleton and Oatway[20] that depression of the T-waves is commonly found in hypoglycæmia.

It is convenient here to mention some other phases of glycogen metabolism which bear upon this question. Examples of conditions in which enhanced glycogen-utilisation occurs in the body are: (1) exercise, (2) thyrotoxicosis, and (3) excitation of the sympathetic by administration of adrenaline. All of these conditions are found to be associated with well-developed T-waves in the electrocardiogram. It has been shown by Müller and Nicolai,[21] and it is generally agreed, that exercise increases the amplitude of the T-waves. It is still debated how far thyrotoxicosis produces any specific effect upon the electrocardiogram, but White and Aub[22] found a very limited parallelism between the basal metabolic rate and the amplitude of the T-wave in thyroid disease. Siegel[16] states that very steep and high T-waves occur with great regularity in hyperthyroidism. The increased amplitude of the T-wave produced by adrenaline administration has been frequently demonstrated.[23 18]

Reverting to the carbohydrate metabolism of the normal heart already discussed, it is clear that enhanced utilisation of glycogen implies rapid formation of lactic acid, and it has been seen that in such circumstances T-waves of increased amplitude are found. Conversely, both in diabetes and hypoglycæmia, the defective utilisation *of glycogen* must result in a slowing of the rate of lactic acid formation, while flattened or inverted T-waves are the electrical counterparts of these states. Mention might also be made here of the myocardial disturbances in myxœdema and cretinism, demonstrated by Thacher of defective glycogen metabolism. Although coronary lesions not infrequently complicate the states of hyperglycæmia and hypoglycæmia, there appears to be no doubt that pure metabolic derangements of this type may induce anginal pain.

To my medical colleagues of the staff of Charing Cross Hospital, who have allowed me to investigate patients under their care, and specially to Dr. Hickling, who has given also valuable criticism, I tender my thanks. Towards the expenses of this research a grant was made by the British Medical Association.

Clinical and Laboratory Notes

AIR EMBOLISM DURING ARTIFICIAL PNEUMOTHORAX INSUFFLATION

By V. R. Walker, M.B. Glasg., D.P.H.

ASSISTANT MEDICAL OFFICER, CHESHIRE JOINT SANATORIUM, MARKET DRAYTON

THE following case is of interest in view of the fairly definite nature of the accident, the dramatic sequence of clinical symptoms, and the rapid and uneventful recovery.

A man, aged 20 years, was admitted to the Cheshire Joint Sanatorium on Dec 12th, 1932, with a history of recent onset of morning cough and sputum. He had had one slight hæmoptysis and some loss of weight. The sputum contained tubercle bacilli, and physical and radiological examination showed an active exudative lesion of upper half of right lung, with an appearance of recent cavity in right infra-clavicular area and some lesser deposits at the left apex

Right artificial pneumothorax was performed on Jan 11th, 1933, and successive refills were :—

Date.	Manometer readings—		Amount of air given.
	Initial.	Final.	
Jan. 11th, 1933	− 7 −5	+1 +14	300 c cm.
,, 12th, ,,	−11 −5	+5 +11	300 ,,
,, 14th, ,,	− 5 −2	+1 +14	350 ,,
,, 17th, ,,	− 8 −3	−2 + 6	300 ,,
,, 21st, ,,	−10 −5	−3 + 1	300 ,,

The readings, though not very satisfactory, appeared to show the possibility of an increasingly efficient collapse.

On Jan. 26th fluoroscopy showed a narrow vertical collapse of the lower two-thirds of the right lung with flattening of the diaphragm. Three attempts at pleural puncture gave equivocal manometer readings, and the case was referred to Dr. Peter W. Edwards, the medical superintendent, who made a final attempt. A free manometer swing (about −3 + 2) was found, and a small experimental insufflation was attempted. Within a few moments the patient became extremely restless, and the needle was at once withdrawn The patient's colour then became poor and the expression anxious, followed quickly by partial loss of consciousness, convulsive movements, clonic spasms of limbs, and conjugate deviation of eyes to the right. There was no loss of sphincter control, and no respiratory signs.

A few moments' later multiple circular areas of blanching, with bright circumferential injection, each 1 in. to 2 in in diameter, were noticed over two areas of skin—(1) the radial aspect of the right forearm from elbow to fingers, and (2) the submammary region of the right chest wall

Consciousness was quickly regained and speech recovered, the conjugate deviation persisting somewhat longer. There was then noted definite laxity of the left arm and left leg with loss of voluntary movement, exaggeration of deep reflexes on affected side, and ankle-clonus with extensor plantar response. The skin areas quickly changed to an ashy grey colour with surrounding dusky injection, and finally to a diffuse dusky marbling. The paretic signs passed off within about 20 minutes, and the plantar response became flexor. The skin marbling persisted for about an hour, and there was some residual pallor, general weakness, and diffuse headache, passing off within 24 hours.

This case was clearly one of multiple air emboli affecting the terminal distribution of the right internal carotid, right brachial, and (probably) right internal mammary arteries. The left hemiparesis indicated interruption of conduction probably in the region of the internal capsule, and the irritative symptoms probably showed some additional cortical distribution of air. The amount of air passing from the pulmonary venous system to the systematic circulation must have been several cubic centimetres, and its distribution being confined to the terminal circulation of the innominate artery had a clear physical explanation through the patient being in the left lateral position for insufflation. The entry of the air into the pulmonary venous system despite the manometer swing, which must have been alveolar, was probably due to the positive water pressure of the apparatus causing air to enter an injured vein from the alveoli. The happy termination of the accident indicated non-involvement of the blood-supply of the vital centres of the medulla, and the *rapid subsidence of* symptoms showed the quick absorption of the embolic air by the circulation—presumably more rapid in the freer cerebral circulation than the skin—while the rapidity of progress demonstrated the uselessness of any active treatment.

Cases of air embolism both cerebral and cutaneous are freely described in the literature of pneumothorax therapy, but this case is of considerable interest in the combination of symptoms. This case was the first suggestion of air embolism occurring among a long series of artificial pneumothorax cases in the records of the sanatorium. Such cases are stated to "truly belong to the historical period of pneumothorax therapy"[1] which may account for their non-publication in more recent years.

I have to thank Dr. Edwards for permission to publish the above case.

SPONTANEOUS SUBARACHNOID HÆMORRHAGE

By John A. Page, M.B. Dub.

SENIOR HOUSE SURGEON, GENERAL INFIRMARY, MACCLESFIELD

A MAN, aged 46, was admitted to the Macclesfield General Infirmary on Jan. 2nd, 1933, in a semi-comatose condition suffering from intense occipital headache and nuchal rigidity.

History.—The patient suffered from a "nervous breakdown" nine years ago, characterised by the gradual onset of severe occipital headache. with pain in the back of the neck and general weakness. On this occasion he remained in bed at home for two weeks, recovery was slow, and he did not resume work for two months. Since then he has been subject to attacks of severe bilateral, frontal, and occipital headache, "neuritis of the neck," and vomiting, suggesting a "cerebral" type of migraine.

On Dec. 31st, 1932, whilst working in the garden, he suddenly complained of intense pain in the head, vomited, and collapsed, and remained in an unconscious condition for several hours. The next day he was confined to bed, and was admitted on the following day.

On *admission* he was in a very drowsy condition, with a hand clasped to the forehead, and complained of intense headache. Questions evoked a response only after some delay. Pulse-rate 60, temperature 99° F. There was definite rigidity of the neck muscles, but Kernig's sign was negative, tendon reflexes normal. The pupils were small and gave a transient contraction to light. Fields of vision normal, and no papillœdema or ocular paresis was present. Nothing abnormal was found in the chest or abdomen.

Special investigations.—Urine normal. A lumbar puncture was performed on Jan. 4th, and two specimens were taken, which were uniformly blood-stained, and on centrifugalisation gave a clear yellow supernatant fluid with a heavy deposit of red blood-cells. No other investigations on the fluid were made. Wassermann reaction negative. Blood pressure 150 systolic, 95 diastolic.

Course of illness.—With symptomatic treatment the patient remained in much the same condition for two weeks. The lumbar puncture relieved the symptoms for some hours. Gradual improvement then took place, the ocular symptoms clearing up after some days, the headache became less intense, but the nuchal rigidity persisted. A second lumbar puncture performed on Jan. 18th showed transparent fluid of a brownish-pink colour, containing no coagula, 190 red cells, and 80 leucocytes per c.mm. The supernatant fluid retained its pink colour, and the deposit showed many erythrocytes showing crenation and other evidence of disintegration. Polymorphonuclears and mononuclears were present in equal numbers. Globulin tests were strongly positive. A culture remained sterile.

The patient was discharged free from symptoms on Feb. 4th, 1933.

This case is of interest owing to its close similarity to the case reported by Dr. Maurice E. Shaw in THE LANCET of Jan. 21st (p. 138), where the patient, having improved steadily after a severe hæmorrhage, eventually became suddenly unconscious and died after another hæmorrhage. At the post-mortem examination a ruptured congenital intracranial aneurysm was found in close relation to the circle of Willis. A similar diagnosis can be made with certainty in this case. The "neuritis" of the neck and occipital headache which were present before admission may possibly be explained by leaking of the aneurysm, causing clots about the nerve-roots of the medulla and cervical cord, with an eventual severe hæmorrhage producing coma.

The ocular symptoms suggest irritation of the third cranial nerve, rather than paralysis. The cerebro-spinal fluid taken at the second lumbar puncture showing absence of any undegenerated blood-cells made it clear that the hæmorrhage had ceased, and that complete recovery would ensue if there was no further hæmorrhage.

MEDICAL SOCIETIES

ROYAL SOCIETY OF MEDICINE

SECTIONS OF NEUROLOGY AND PHYSICAL MEDICINE

AT a joint meeting of these sections on March 16th, with Dr. RISIEN RUSSELL, president of the section of neurology, in the chair, a discussion on the causation and treatment of

Interstitial Neuritis

was opened by Dr. WILFRED HARRIS. The term was used, he said, to describe an acute or chronic inflammation of the supporting connective tissue binding together the separate nerve-fibres. The nerve-fibres were liable to be compressed and damaged by such inflammation. Neuritis might have a toxic origin from alcohol or diabetes—in which case both interstitial and parenchymatous nerve degeneration might occur—or it might follow certain fevers, such as paratyphoid, or the more chronic infection of dental sepsis or other distant suppuration. Another group of cases were due to the local spread of neighbouring inflammation, as in tuberculous caries, or the more chronic condition of fibrositis of the shoulder and back muscles, involving the finer nerves and nerve-endings and causing the pains of so-called muscular rheumatism and lumbago. Spread of such a chronic inflammatory process might involve the sheath of the sciatic nerve at the notch, producing sciatica; and fibrositis of the neck muscles might give rise to brachial neuritis by affecting the brachial plexus. A rheumatic or osteo-arthritic process involving the spinal nerves at the intervertebral foramina gave rise to an obstinate form of sciatica with contralateral scoliosis, the trunk being flexed laterally away from the painful side. Osteo-arthritis of the hip-joint might also cause some sciatica by direct spread of a chronic inflammation to the sheath of the nerve, which passed close behind the joint. Chill might be a predisposing factor in neuritis, for example in facial palsy; and direct injury from contusion and bruising might produce the same result.

Treatment differed in the acute and the chronic stages and might be medicinal or physical. Rest was important in the acute stage, and opiates might be necessary to relieve pain. Strychnine and other tonics were valuable in the convalescent stage of acute neuritis when pain and tenderness had disappeared, but arsenic and alcohol should be avoided since both could cause neuritis. Iodine was of value in the chronic conditions, and massage was usually borne before either electrical treatment or strychnine. Antiphlogistine, mud packs, hot saline baths, and radiant heat had a place in treatment, but he had obtained little success with diathermy; liniments alternating with poultices were often useful. In long-standing sciatica the nerve was shrunken and cord-like; longitudinal stretching was useless, except in a few cases, but lateral stretching could be produced whether a connective tissue with lowered metabolism and reduced blood-supply should become the site of calcification.

DISCUSSION

Mr. **Duncan Fitzwilliams** referred with appreciation to the work of D. M. Greig, of Edinburgh, on the subject under discussion and said that the views expressed seemed to be a development of those sketched out by Greig.

The **President** said that it was common to find that patients who had to remain in bed for a long time because of accident had renal calculi; a number of patients with spinal caries had developed calculi. Reference had been made to calcification following injections of lead; he had seen calcification take place following deep X ray therapy, no injections having been given.

Dr. J. F. **Brailsford** said that in cases of injury to the wrist-joint a radiogram taken immediately after the accident sometimes revealed not even slight evidence of a lesion. He had such a case under his care at present; but a month afterwards X rays showed a cyst inside the scaphoid, and a few weeks later still there was evidence of a fracture. In osteochondritis the first phenomenon seen was an increased density of bone; then there was a gradual crumbling and islands of condensation became apparent. If the patient was watched carefully evidence could be detected that areas of new bone were being laid down, of equal density to contiguous bone.

Dr. C. **Thurstan Holland** said that during the war he had seen many cases among severely wounded soldiers of stones in the kidneys due to lack of movement and exercise; but as soon as the men were able to get about again and resume their activities the stones disappeared in a few weeks.

Prof. J. M. **Woodburn Morison** said he had not been studying in Edinburgh many weeks before Greig showed him that his ideas on bone pathology must be revised; one thing on which Greig insisted was that the term myositis ossificans should not be used, and he had also written on the formation of intracranial osteophytes. Prof. Woodburn Morison regretted that in so many quarters the old bone pathology was still being taught.

Dr. W. H. **Coldwell** said a common site of calcification was the pineal gland, and another the costal cartilages; he would like to know the reason for the early disposition of lime salts in costal cartilages, and also why the age-incidence of calcification was so varied in different people. If patients with linear cracks in bone were followed up it would be found that these cracks were later filled with new bone.

Dr. H. B. **Scargill** (Leeds) described his sensations and experiences while suffering from supraspinatus tendinitis. The pain, he said, was like a toothache round the shoulder-joint; the time of greatest intensity was at night, and it was difficult to get the arm into a comfortable posture. Movements of arm and scapula did not seem to influence the pain. At one time he suddenly got agonising pain and the shoulder-joint was more or less locked. When the pain eased somewhat, on the second day, a radiogram was taken, and a shadow was seen just above the head of the humerus. Operation was to have been done to remove what appeared to be a piece of bone, but a bad cold postponed the procedure, absorption took place, and he had no more pain. He attributed the onset to the exertion of daily cranking his car.

Mr. **Watson Jones**, in reply, said there was no more vascular tissue in the body than fibro-cartilage, and the question of age did not necessarily come into the calcification problem. Possibly trauma of the scaphoid could cause traumatic hyperæmia and decalcification with the formation of a cyst, but that he regarded as quite rare. It was common to meet with a fracture of the scaphoid of so slight degree that it was not detected on the first day of the injury. Nowadays many surgeons examined radiograms of the wrist with a lens to detect any cracks before passing a wrist as sound.

HUNTERIAN SOCIETY

A MEETING of this society was held at Simpson's Restaurant, Cheapside, on March 20th, with Dr. **Nathan Raw** in the chair, when a discussion took place on

Practical Dietetics

Prof. S. J. **Cowell** said that a first requirement of one starting to practise dietetics was a knowledge of the composition of normal diet—that is to say, of a diet capable of promoting nutrition. During the last few years the attention of people who had been working on the subject of nutrition had been focused largely on the importance of certain constituents of diet which, 20 years ago, were quite unrecognised. He referred, of course, to the vitamins and also to the mineral salts, the significance of which was only now being appreciated. Eventually it should be possible not only to name the essential components of a diet, but to determine the quantities of all constituents needed under varying conditions.

The next point was to discover in what foods these constituents were present. The constituents of foods varied considerably according to the conditions under which the foods were produced. The nutritive properties of milk varied according to the way in which the cow was fed, of vegetables according to the soil. It was said that the type of manure applied to the soil in which a plant was grown affected its content of vitamin B. It was not always appreciated how varied might be the mineral content of green vegetables. The outermost leaf of the cabbage might contain 30 times as much calcium as the inner part, and four or five times as much calcium even as the leaf next to it.

A third point to be considered was the physiological or pathological effects of excess or deficiency of food factors. It was known that a deficiency in the diet of a particular vitamin led to certain ill-effects, but in the present state of knowledge the signs of each deficiency could not always be distinguished. Probably small degrees of deficiency in vitamins and in mineral salts produced certain symptoms not at present recognised which it would be possible to distinguish in the future. A Swedish investigator had found that in slight deficiencies vitamin C led to a certain weakening of the capillaries, and so caused liability to unusual bleeding under slight stress. The susceptibility to hæmorrhage had been found to vary according to the amount of vitamin C. There was now a tendency, Prof. Cowell continued, to regard some diseases which a few years ago were considered purely deficiency diseases as being more complicated in their origin. Beri-beri used to be definitely ascribed to the eating of polished rice; the tendency now was to regard it as not due purely to a deficiency of one factor, because in many cases a supply of the missing factor did not definitely cure the disease. It had been suggested it might be associated with a combined deficiency of vitamin B_1 and some other food factor, or some constituent in the diet which actually created damage in the absence of the protective antineuritic vitamin. The same argument was gaining ground with regard to pellagra, which a few years ago was regarded as due to a deficiency of vitamin B_2. It could be argued that rickets was not a pure food deficiency disease, for though it would not develop in the presence of an ample supply of vitamin D, it would be quite possible to arrange to keep individuals on the same diet and to allow rickets to develop in one and not in another, because exposure to sunlight or ultra-violet radiation could compensate for the absence of vitamin D in the diet.

Dietetic factors were used for the cure of diseases not in the ordinary way produced as a result of dietetic deficiency, as for example liver in pernicious anæmia. Dr. Cramer had shown that a definite nephritis could be produced in animals if the diet was constructed in such a way that it contained a smaller quantity of magnesia than normal. In the treatment of bone diseases there was scope for the application of modern principles of dietetics, and an enormous field lay open to the pædiatrician in this respect. The growing child was particularly sensitive to deficiencies in his diet. In this country probably the elements most likely to be lacking in the diets of infants and young children were vitamins A, which played an important part in the normal development of tissues, and vitamin D. Mrs. May Mellanby had found that young dogs fed on a deficiency diet showed a pronounced tendency to pyorrhœa alveolaris, and that the condition could not be cured—or could only occasionally be cured—by supplying vitamin A to the adult animal; whereas animals fed with a proper supply of this vitamin early in life did not develop pyorrhœa. There was no doubt great scope for the application of modern principles of dietetics in antenatal treatment. A woman during pregnancy should be supplied with a diet particularly rich in protective elements. The possibility that the size of the child at birth could be influenced by restricting the diet of the mother had, he believed, led a certain accoucheur deliberately in cases to restrict the quantity of the diet of a mother with a small pelvis. Various dietary restrictions, particularly of protein intake, might lessen the tendency to toxæmia during and immediately after delivery.

Dr. W. CRAMER said that in view of the large number of different constituents necessary to diet it seemed in theory impossible to construct a diet which was adequate; but, of course, long before anything was known of modern dietetics millions of people had lived long and healthy lives on diets dictated by experience. The right diet was a very mixed diet if one could afford it. The problem of applied dietetics was not a question so much of vitamins and salts as of cost. The only way in which to construct a sound dietary was to build around the basis of cereals and milk. A diet of cereals and milk in itself was not adequate, but it avoided most of the mistakes, and it furnished in the cheapest possible way proteins, fats, carbohydrates, and most of the important salts except iron, and most of the vitamins except vitamin C. Yet the consumption of milk in this country was probably lower than anywhere else in the civilised world, and at the same time the dairying industry was crying out that it was ruined. The addition to cereals and milk of a small amount of fresh fruit, vegetables, and a little meat would provide as good a diet as could be obtained on a limited income. It was interesting to speculate what would have happened if vitamins had not been discovered, because, about 50 years ago, a complete revolution was made in dietary by the introduction of roller mills to produce white flour whereby the cereal on which the population mainly lived—namely, wheat—was deprived of vitamin B. White flour did not contain vitamin B, and the small amount of yeast that went into bread making brought in so little vitamin that it did not count. A second revolution was to substitute margarine for butter. If it had not been for the discovery of vitamins, these revolutions in the production of food would have gone on uncorrected.

Another important lesson learned from the vitamins was a new conception of the pathology of certain diseases. Animals which developed infections spontaneously were just as resistant as any others to infections introduced experimentally. The explanation, he thought, was that the mucous membrane of the respiratory and intestinal tracts was as much dependent on the supply of vitamin A as, for example, the uterus was dependent on the supply of ovarian hormone. It was easiest to think of vitamins as substances very like hormones, but instead of being manufactured in the body they were contained in the material eaten. When an insufficient amount of vitamins was taken certain specific tissues atrophied, with the result that, in the case of the intestinal tract, bacteria which normally inhabited the mucous membrane crept into the crypts and proliferated there, giving rise to a condition of alimentary toxæmia, and this, passing into the blood, set up a metastatic infection. Vitamin A did not seem to protect at all against virulent bacteria. He did not think that appendicitis occurred any more frequently among people on a deficiency diet than among people who had all the vitamins they required; nor did he think that any of the severe enteric infections were the result of deficiency. It appeared to be only the normal inhabitants of the respiratory and intestinal tracts which were kept in check by the normal mucous secretions. Nevertheless, there were probably a great number of conditions which began at any rate with a very indefinite condition of alimentary toxæmia, or whatever it might be called, and on that basis other diseases were implanted, so that the whole picture was very complicated.

Dr. S. MONCKTON COPEMAN referred to the question of possible danger from excess of certain dietetic factors, more particularly vitamins. It was not impossible that an excess of growth-favouring factors, which of course were absolutely essential to the young child, might be detrimental to the adult. He had tested the question first by experiments on animals and later in an experiment on human beings. Mice and rats were inoculated experimentally with cancer and put on a special dietary, and although they had not succeeded in preventing the development of cancer, the resulting tumours were more than three-quarters less in size than in the controlled animals. Certain patients suffering from cancer were found who were willing to adopt the dietaries suggested—namely, dietaries from which animal fat, eggs, cream, suet and the like had been eliminated. It was suggested that such a deprivation of food would have a detrimental effect in a depressing disease like cancer, but actually it was found that the patients so treated—who were hopeless from the operative or any other point of view—showed prolongation of life for months and years, and their painful symptoms were manifestly relieved. Dr. Copeman quoted statistical evidence favouring the theory that the incidence of cancer is affected by diet.

Sir FREDERICK HOBDAY spoke on dietetics as applied to veterinary medicine. A careful adjustment of diet had been successful in eliminating certain bowel diseases of horses. Since the instruction was given in large studs that horses were not to be allowed to drink a large quantity of water immediately after feeding, but to take water before feeding, the amount of colic had greatly decreased. A further factor was that horses, thanks to the eight-hour day for their drivers, were not nearly so overworked as in former years, and the disappearance of excessive fatigue had contributed to the same result. Asthma and allied ailments were quite common among horses and other animals which were fed irregularly, and various illnesses attacked dogs which were pampered and were not given the hard dog biscuits on which others flourished. The work done on calcium deficiency disease in cattle saved the agriculturists in this country a large sum of money every year.

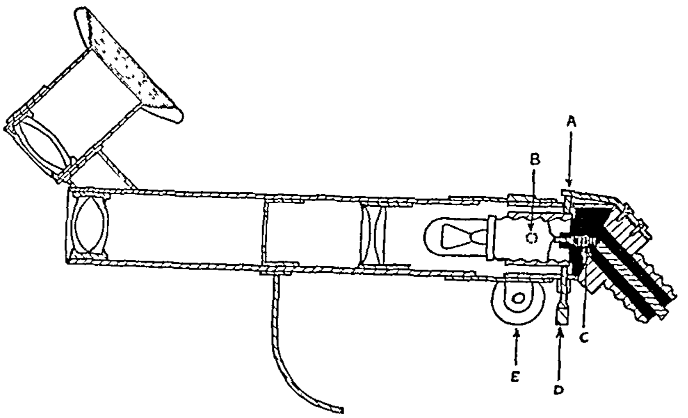
Sir ARNOLD THEILER spoke of mineral deficiency diseases in herbivorous animals as observed in South Africa; and Mr. H. H. GREEN of an acute intoxication found in cattle, which promptly disappeared when the animal was fed with phosphorus.

NEW INVENTIONS

A HAND SLIT-LAMP

THE value of the standard forms of slit-lamps for certain ophthalmic investigations is undoubted. But the immobility of these large instruments limits their use to the consulting-room and clinic.

The hand slit-lamp illustrated has been devised with the intent of securing an instrument that could be used as readily and as easily as an electric ophthalmoscope, so that it can be carried about and used with ease for the examination of children and patients in bed or in their own homes. It cannot by reason of its small size compete with the large instruments in magnification and in resolution of fine detail. Yet it will secure a valuable view of the media of the eye as deep as the anterior part of the vitreous. The small lamp as compared with the large might be said to have something like the relation of the two-thirds inch objective of the microscope to the one-sixth inch objective. But the small lamp gives the same effect of depth as the large lamp, so that its value for localisation is certain.



In the diagram, A represents the spring and D the screw controlling the lamp centre. B indicates the position of the trunnion, C the centre contact of the lamp, and E the clamping screw. Note that in practice the filament and slit are horizontal.

The lamp is fitted to the battery handle of an electric ophthalmoscope, or a small adapter can be supplied with leads to a torch battery or other suitable source of current. At the upper end, set at right-angles to the ophthalmoscope handle, is an eyepiece consisting of a triple achromatic lens giving a linear magnification of × 12. The lens holder is so made that other powered lenses can be substituted. The case of the eyepiece is graven with a scale, so that the focus of the lens, once found, can always be recovered.

Below the eyepiece, and at an angle of 45° to it, is the projection combination, forming a horizontal slit of light at a distance of one inch. It comprises a gas-filled lamp with a single-strand filament, made for two-cell or three-cell dry batteries. The centre pole of the lamp abuts on to a spring contact, so that all lamps can be set with the filament horizontal. A powerful condensing system produces an image of the filament upon a slit fixed in the tube, so that the projection lens, an achromatic lens of some 60 dioptres, can form a clear image of this slit, free from disturbing haze or filament irregularities.

In use, the instrument must be kept steady in relation to the eye of the patient, and yet allow focusing for depth. This can be obtained by the following manœuvre. The lamp is held by the main tube with the battery handle or adapter hanging down. There is a trigger-like spur projecting below the main tube, and this lies conveniently between the second and third fingers. The thumb rests on the top of the tube, with its end in the angle between the tube and eyepiece; the forefinger lies along the side, so that the projecting tip of the finger can rest against the patient's cheek at the lower border of the orbit. This contact gives steady support. Alternate crooking and straightening the forefinger brings the lamp nearer or further from the eye and gives focusing for depth.

Adjustments of the instrument are of the fewest, normally the eyepiece alone is likely to require setting. But the setting of the lamp bulb, in case of replacement, needs attention. The filament must be horizontal and in the axis of the system. Whether or no this adjustment is correct can be seen by looking at the face of the projection lens. The bright line of light should cut the lens horizontally into two equal parts. If this line is not true the position of the filament must be altered. The lamp mount is pivoted at its front end on a horizontal axis on trunnions. At the back there are a screw and a spring on a vertical axis, the one lifting the back, the other allowing it to fall. As the back rises, so the filament is lowered and vice versa, the movement being made by releasing or screwing in the lower screw. The distance between the lamp and the condenser system can be varied by loosening the large-headed screw under the lamp end of the tube and allowing the tube to slide over the lamp stem a little. This large-headed screw should be turned firmly when the adjustment has been made. Once the adjustment is obtained it need not be altered until a new lamp is required.

It is better not to wear spectacles when using the lamp so that one's eye can be well within the shield of the ocular. It is well not to over-run the electric bulb, so when a new battery is used the switch to the rheostat should be turned on no more than two-thirds until the battery weakens.

The hand slit-lamp is made by Messrs. Rayner of New Bond-street, London.

N. BISHOP HARMAN, F.R.C.S.

WORK OF WOMEN'S HOSPITALS.—The report for 1932 of the Royal Waterloo Hospital for Women and Children states that there were 2300 in-patients and 14,740 new out-patients; the latter made over 76,000 attendances. There is an accumulated deficit of £5000.—The Birmingham and Midlands Hospital for Women (the Women's Hospital, Sparkhill, and the Maternity Hospital) and the district midwives last year dealt with 6162 patients. The pressure on the beds at Sparkhill was "greater than ever"—there were 2066 patients. The average cost per in-patient was 10*s*. 8*d*. per day. There were 1734 in-patients at the Maternity Hospital.

REVIEWS AND NOTICES OF BOOKS

Significance of Phosphoric Esters in Metabolism

By ROBERT ROBISON, Ph.D., D.Sc., F.R.S., Professor of Biochemistry, University of London; Head of the Department of Biochemistry, Lister Institute of Preventive Medicine. New York: University Press. 1932. Pp. 104. 11s. 6d.

THERE have been of recent years many publications on the rôle of phosphorus in the body, and the whole question of phosphorus metabolism has become one of the utmost importance, and not only from the point of view of the human biochemist, since phosphorus has a bearing on many fermentation processes. This volume is based upon the three Christian A. Herter lectures given by Prof. Robison in New York in 1931. It is always a source of pride for English workers to look through the list of Herter lecturers and to see the relatively large number of British investigators. The original lectures have been expanded, and a very full review of the literature up to 1932 is here provided; the major contributions in this particular field have been made by Prof. Robison himself.

The first lecture deals with the distribution of phosphoric esters in nature and gives an up-to-date account of the very loosely defined group of substances of the lecithin and phospholipin type. The compounds of phosphoric acid with the carbohydrates are described and particular reference is made to the occurrence of the compounds in bone. The second lecture deals with the method of calcification occurring naturally in cartilage and bone, and here is to be found a very readable account of the researches which have been conducted during the last ten years at the Lister Institute. The final lecture is concerned with calcification in vitro and establishes with precision the conditions which govern this complicated process.

The work is essentially a summary of what is known about phosphorus in connexion with metabolism, and is a very valuable contribution to the literature of this subject.

L'angine de poitrine

Formes cliniques traitement médical et chirurgical. By CAMILLE LIAN, Professeur agrégé à la Faculté de Médecine de Paris; Médecin de l'Hôpital Tenon. Paris: Masson et Cie. 1932. Pp. 430. Fr.55.

Prof. Lian and his pupils, after detailed and exhaustive study, have come to the conclusion that angina pectoris is a syndrome, encountered in diseases of the arteries or of the heart of most diverse kinds and found even where no cardiac lesion exists. They point out that to give this name to one particular category is as valueless as to say that hæmoptysis shall be the name given only to those cases where pulmonary tuberculosis is the cause of the coughing up of blood. Nevertheless, they admit that the fundamental though not unique cause is coronary stenosis. The clinical manifestations are divided into three big ætiological groups: (1) angina cardio-arterial, coming on generally after the age of 40 years in cases showing hypertension or vascular sclerosis; these cases constitute four-fifths of all cases of angina pectoris; (2) angina of cardiac origin appearing at about 30 years of age in subjects suffering from rheumatic valvular disease or purely functional conditions, such as paroxysmal tachycardia; (3) functional angina attacking subjects with normal cardiovascular systems. These three groups are subjected to minute clinical, electrocardiographic, and anatomical examination, and a further subdivision is made of the cardiovascular anginas into the common form accompanying muscular effort or effort and repose; the so-called "Angor aigu coronarien fébrile," the name given by Lian to the condition we know as coronary thrombosis; and finally the abdominal anginas. The functional anginas are divided into reflex, nervous, and toxic. The section on treatment is exceptional in being sufficiently long and detailed to be really useful. All the usual methods are discussed, and in addition three less well-known treatments are described in detail—namely, the intravenous injection of iodides, subcutaneous injections of carbonic acid gas, and application of X rays; these measures are said to have given particularly good results. According to Prof. Lian certain cases have rapidly and definitely improved under radiotherapy, even when all medical treatment has failed; in some cases, on the other hand, it has no effect. Diathermy is discussed both as a form of treatment in coronary thrombosis, where it is said to alleviate the pain, relieve the spasms, and improve the circulation, and in angina pectoris of whatever ætiology; Prof. Lian has abandoned diathermy except in cases of coronary thrombosis and in a few cases of reflex angina. The use of muscle extract is dismissed with the statement that the premises on which its use is based are so little credible that it should fall rapidly into well-deserved obscurity.

Prof. Lian's teaching is clearly and methodically set out and is easy to follow, and an extensive bibliography is supplied.

Clinical Gynecology

By C. JEFF MILLER, M.D., Professor of Gynecology, Tulane University School of Medicine. London: Henry Kimpton. 1932. Pp. 560. 50s.

ONE of the most important contributions to gynæcology in recent years was Prof. Jeff Miller's "Introduction to Gynecology," which provided, in delightful style, a short summary of gynæcological diagnosis and pathology. This was a good basis upon which students could build a study of gynæcology. A companion volume has now been prepared in order that students already well grounded in diagnosis and pathology should learn therapeutics from the same reliable teacher. The work is, however, not quite so satisfactory as its predecessor, though it contains much useful information, and the opinions expressed are for the most part sound. The section dealing with the treatment of salpingitis is an excellent contribution, full of wise judgment, which deserves careful study. Similarly the treatment of carcinoma of the cervix is admirably dealt with from all points of view. But some of the minor gynæcological ailments receive scant attention, and it is doubtful whether practitioners will be satisfied by the paragraphs on pruritus vulvæ. Trichomona vaginitis is considered in detail; it is extraordinary how many different treatments are in use. Operations are described separately at the end of the book; illustrations are plentiful, but some of the drawings might be clearer. There is some repetition, for treatment, which is often operative, is described in the first part of the book, and later on the operation is detailed again. Moreover, in certain places, after-treatment is described before technique has been considered. Despite these disadvantages, the book is a worthy contribution illustrating the practice of the modern school of American gynæcology, and should be of particular service to resident medical officers.

Walter Bradford Cannon

Exercises Celebrating Twenty-five Years as George Higginson Professor of Physiology October 15, 1931. Harvard University Press. 1932. Pp. 94. 10*s.* 6*d.*

Prof. Cannon has been for many years a leading physiologist, and in America one of the relatively few who have followed the outlook and technique of what may be called classical British physiology. For these and for personal reasons many people in this country will be interested to read this account of the ceremonies at Harvard surrounding the presentation of his portrait: a reproduction of the picture and a charming speech by the late Prof. Graham Lusk should reconcile them to the rather excessive price. Prof. Cannon's implacable faith in the righteousness of investigation has led him into many fruitful inquiries, still, we hope, far from finished. Much of his work was admirably summarised in his recent book "The Wisdom of the Body," and his explanations of shock, of how we get into a temper, why we are thirsty, and so on, have made his name familiar to many who are not professional physiologists.

Epidemiology in Relation to Air Travel

By ARTHUR MASSEY, M.D., D.P.H., Medical Officer of Health for the City of Coventry. London: H. K. Lewis and Co., Ltd. 1933. Pp. 68, and five maps. 7*s.* 6*d.*

THIS little book is an elaboration of the speculations which Dr. Massey has previously made [1] on the possible risks to the public health arising from the introduction of regular long-distance flying, together with a summary of the views of others on the same subject. By means of excellent maps he shows that journeys by air from distant countries can now commonly occur within the incubation period of the major infectious diseases. He also discusses the possibility of insect vectors being transported alive by air into uninfected areas, and various subsidiary questions, such as the disposal of sewage from aircraft and the general difficulties of sanitary control. It is a pity that the text of the proposed International Convention for the Sanitary Control of Aircraft is not given. The diseases considered are yellow fever, cholera, plague, malaria, typhus fever and relapsing fever, and small-pox.

Materia Medica, Pharmacology and Therapeutics

Third edition. Reset. By WALTER A. BASTEDO, Ph.G., M.D., Sc.D. (Hon.), F.A.C.P., Assistant Clinical Professor of Medicine, Columbia University. London: W. B. Saunders Co., Ltd. 1932. Pp. 739. 32*s.* 6*d.*

THERE is nothing strikingly original in the arrangement of matter in this book, which in the main follows the lines of some of the better known works on pharmacology and therapeutics in this country. But it is written by a physician of experience who is also a pharmacologist, and therefore most stress is laid upon that aspect of pharmacology which is of immediate practical interest and importance. The first part of the book consists of a succinct description of the constituents of organic drugs, pharmaceutical preparations, and methods of administration, and of dosage; while it closes with a brief but adequate discussion of the rapidly decaying art of prescription writing. By far the greatest part of the book is taken up with the discussion of individual remedies. These are classified in some instances according to their action on different parts of the body, the circulation, the central nervous system, the peripheral nervous system; in others according to their therapeutic uses as cathartics, diaphoretics, emetics, and so forth. The section on the pharmacological action of drugs is up to date and adequate, and the discussion on their therapeutic uses is in many cases excellent though occasionally a little uncritical.

The book can be cordially recommended to students and practitioners of medicine.

Basic German for Science Students

By MARIE L. BARKER, Ph.D., lecturer in German in the University of Edinburgh. Cambridge: W. Heffer and Sons. 1933. Pp. 164. 6*s.*

"IN the beginning God created heaven and earth" is an unusual sentence to find at the beginning of a scientific book, yet in the introduction to this book the author has successfully used the first chapter of Genesis as the reading matter on which she has based her outline of German grammar, and from which she has drawn many of the important basic words which must be learnt at an early stage in every language. In the next section of the book (Part I.), which is devoted to general passages, the author proceeds further to enlarge the student's vocabulary with passages describing the more advanced version of the same phenomena supplied by science, and also the development of man and his civilisation. Two extracts from general scientific works precede Part II., which is made up of a variety of technical passages typical of the vocabularies of the different branches of science; chemistry, botany, physics, mathematics, and medicine are all represented. The medical extracts include samples on therapeutics, pathology, histology, physiology, anatomy, and embryology, and the book is arranged so that it may be used by the student who is teaching himself. Sufficient grammar for a reading knowledge of German is given clearly and concisely in the introduction, the English version of each prose passage is printed opposite the German, and basic words are printed at the foot of each page as they occur. The author hopes, perhaps optimistically, that having reached the end of the book the student should be familiar with over 1000 basic German words. The work includes also some specimen examination papers for chemistry students and a complete vocabulary where basic words are printed in heavy type. Some sensible phonological hints are given at the beginning, and there is a short list of useful abbreviations and chemical terms at the end of Part II. This book should give the student an adequate general foundation for the reading of scientific German, and after mastering its contents he should have no difficulty in getting up the technicalities of his own specialty.

THE LANCET

LONDON: SATURDAY, MARCH 25, 1933

THE MECHANISM OF PROTEINURIA

Although "albuminuria" is common enough, and has long been the subject of careful clinical observation, the mechanism whereby protein can escape from the blood into the urine has not yet been adequately explained: indeed, relatively little sustained effort has been made of late years to elucidate this problem. It is known, of course, that egg-albumin, if introduced into the circulation of a mammal, will be excreted in the urine, and this effect has usually been explained by the hypothesis that the kidney acts as an eliminator of foreign substances from the blood, but Cushny in his monograph on the excretion of the urine observed that the glomerulus usually appeared to be impermeable to colloid substances, and concluded that the passage into the urine of proteins, such as egg-albumin, was dependent upon glomerular damage. Very little advance has in fact been made in our knowledge of this aspect of renal function since the work of Posner at the end of last century.

In a recent contribution to The Lancet[1] Mrs. Phyllis Kerridge, Ph.D., and Dr. L. E. Bayliss attacked the view that the excretion of proteins by the normal kidney depends on whether they are foreign to the body. And on the basis of a number of perfusion experiments with the pump-lung-kidney and with intact anæsthetised animals they have been able to show that the facility with which any protein passes through the glomerulus depends upon the size of its molecule. Their estimates of the molecular weights of the different proteins used have been taken from Svedberg's figures. Molecules with a weight below 68,000, such as egg-albumin, gelatin, and Bence-Jones's protein are excreted, while those with a weight above 68,000, such as the serum proteins, are retained. As promised in their first communication a full account of the work has now been published elsewhere[2] with the collaboration of Dr. Dorothy S. Russell, who has examined histologically a number of the kidneys used in these experiments. Those interested in the subject should refer to this paper for details. Without losing sight of the fact that alterations in capillary permeability are doubtless responsible for proteinuria in some diseases of the kidney and of the cardiovascular system, it is clear that a good case has been made out for a purely mechanical basis of proteinuria in the normal kidney. Both physiologically and histologically there was no evidence of any glomerular damage associated with the passage of the smaller protein molecules, such as egg-albumin, into the urine. But lest the reactionary-minded should still argue that damage may yet exist that eludes microscopical examination, an interesting observation by these investigators may be quoted which seems to dispose of this objection. It happens that gelatin, in distinction to other proteins, is not precipitated by trichloracetic acid. The passage of gelatin into the urine in these perfusion experiments was detected by means of picric acid, and the addition of trichloracetic acid caused no further precipitate such as would be anticipated if the glomerular capillaries had sustained any injury that caused an increase in their permeability.

The replacement by this newer mechanical hypothesis of the older teleological theory that ascribed an almost uncanny power of discrimination to the renal glomerulus will be welcomed as an advance in our conception of renal function. It will doubtless be asked what light such a theory may throw on the question of clinical albuminuria. It is clearly desirable that the physical properties of the proteins that are excreted in such disorders as cardiac failure, nephritis, and so on should be investigated anew. An encouraging start in this direction has already been made by E. Andrews, W. A. Thomas, and W. F. Welker,[3] who find that nephritic serum, though poorer in proteins than normal serum, has greater hydrophilic properties, while the urinary proteins show an abnormally high degree of dispersion and will readily pass through a collodion membrane. The proteins excreted in nephritis appear therefore to differ from the normal blood proteins. On the basis of their experiments these workers suggest that alterations in the mineral salt balance result in a pathological escape of tissue proteins into the circulation in nephritis, with the formation of protein complexes possessing a smaller molecular aggregation or in a higher state of dispersion than is normally associated with the serum proteins. This, though admittedly pure theory, converges in an interesting way towards a possible common ground with the theory of Kerridge and Bayliss. The investigation of various types of nephritis from this angle may be expected to throw valuable light on the disturbances of metabolism that occur in Bright's disease.

A TEST OF TELEPATHY

Belief or disbelief in the possibilities of telepathy and feats like water-divining seems to be determined by temperamental rather than intellectual influences. To some people belief in them is a clinging to the superstitions of a pre-scientific age: to some they offer a field of research that may ultimately enlarge the scope of science: to some they give a pleasing proof of the impotence of science to understand certain phenomena the existence of which it conveniently denies. Perhaps it is asking too much of mankind to hope for a final decision and cessation of argument, but it is not too much to ask that any serious investigation should take into account all the pitfalls, statistical and psychological, that may lurk beneath the simplest-looking and most convincing observations.

[1] The Lancet, 1932, ii., 785.

[2] Jour. of Physiol., 1933, lxxvii., 386.

[3] Arch. Internal Med., 1929, xliii., 445.

Incidents of "premonition" or of knowledge of events happening beyond the individual's ken, and subsequently found to be true, are, as everyone knows, by no means rare. The difficulty in assessing their value as evidence of telepathy, or of some other psychic power, lies in the absence of any means of measuring the probability that they are not due to coincidence. A common example of premonition in the war period was the feeling of a mother that her son was in danger and calling for her help, and the subsequent news that he was killed at that hour. But it is obvious that innumerable mothers must have had the same feeling at one time or another during the period of the war, and it is only when the thought and the subsequent news coincide that the premonition is remembered and recorded. In such matters the common error of recording the "successes" and ignoring the "failures" is at its highest. Another test of telepathy commonly adopted is that in which one person endeavours to convey to another "telepathically" some object of fact which he has in his mind. Such a test, it will be remembered, was carried out a few years ago under the auspices of the B.B.C. In these tests also we do not know the underlying probabilities, or in other words what proportion of right answers are likely to be due only to coincidence.

It was this suggestive type of test that was employed by the wife of UPTON SINCLAIR whose book on this problem was discussed in our columns three years ago.[1] The general plan of the experiments was that a man agreed to make a drawing of any object he might select at random and then to sit gazing at it and concentrating his entire attention upon it for a period of from 15 to 20 minutes. At the same agreed hour Mrs. SINCLAIR was lying 40 miles away in semi-darkness with her eyes closed, employing a system of mental concentration. "As a result she took pencil and paper and wrote, with the date, in six words exactly what the drawing would be found to be. And so it was." UPTON SINCLAIR gives 65 drawings which he calls successes and about half of 155 which he called partial successes. This number, he says, is too great for coincidence. On the other hand, apart from the probability problems involved, another factor has crept in here—the subjective factor; for *someone* must decide what *is* a success, what is a partial success, and what is a failure. Dr. E. E. FREE argues that while there are many reported experiments of this type, suggestive of the possibility of telepathy, there are none which could be called complete and satisfactory proof. In an article in the *Scientific American* (March, 1933) he proposes a simple test in which he asks readers to participate. The experiment merely consists of two persons making a large number of throws with an ordinary die. The "transmitter" looks at the number thrown each time and concentrates upon it; the "percipient" who is blindfolded states the number. The reply is recorded, without comment, as right or wrong; 500 such throws, it is reckoned, can be made in one hour—though but seven seconds for a shake of the die, a throw, the thought transference and the recording of the reply, seems somewhat too little. If a large number of such sets are obtained it will become clear whether the number and distribution of correct guesses differs from that to be expected from the theory of chances. If it does not, then there will be presumptive evidence that readers of the *Scientific American* (or rather, a "selected" group with time and inclination for such tests) do not as a class possess telepathic ability. At the same time provision is made to get in touch with those, if any, whose results do suggest more than the operation of mere chance. The working out of the chance distribution may, eventually, prove somewhat more difficult than may seem at first sight, owing to the fact that ordinary commercial dice are on the average not true, and tend to record an excess of high numbers.

Such attempts to transfer the tests of telepathy to experiments in which the underlying probabilities are known are not new, as Dr. FREE realises. Tests have been made with playing cards, one person attempting to "send" and another attempting to "receive" the names and suits of cards turned up at random. Many interesting examples of these tests are to be found in the work of JOHN COOVER,[2] who concluded that "no trace of an objective thought-transference is found either as a capacity shared by our normal reagents in general or as a capacity enjoyed in perceptible measure by any of the individual normal reagents." The results of experiments with ten "psychics" (reputed to be specially gifted with a power of telepathy or clairvoyance) seem to differ in no essential respects from the results of the experiments with normal reagents. Some of these results have been discussed from the statistical aspect by the late Prof. EDGEWORTH.[3] The latter found that the number of "successes" in a group of experiments was certainly greater than would be expected by mere chance; yet in a control group in which the agent did not endeavour to "transmit" the card but the recipient guessed it, the number of successes was likewise excessive. "What if the explanation," writes Prof. EDGEWORTH, "should prove to be the same for both phenomena—namely, the impossibility of realising ideal randomness, the tendency of law to recur however much we try to expel it by instruments of chance." The marriage of telepathy and the theory of probability may still be unproductive of the convincing proof Dr. FREE seeks.

THE NATURAL HISTORY OF RHEUMATIC FEVER

NEARLY a hundred years ago Latham wrote of the need for better clinical control of the various methods of treatment advocated for acute rheumatism, and despite other advances since that time the need remains urgent to-day. For this reason a group of workers in New York have been studying [1] a series of cases in which all the usual antirheumatic drugs were withheld in order to see what was the natural course of the untreated disease. Actually every care was taken to prevent pain and discomfort—by placing the patients in special beds, by protecting painful joints with cotton-wool and cradles, and by administration of codeine. It is also stated that a special diet was given, efforts were made to force fluids, and "when infected foci were found every effort was made to eradicate them." Under these conditions the progress of the disorder was investigated very elaborately. A detailed history was obtained upon a special form, members of a patient's family were interviewed, and the home was visited by a special medical social worker. The pulse-rate and rectal temperature were taken every four hours. A complete blood count was done on admission, twice a week during the acute stage, and once a week up to discharge. An electrocardiogram was taken at similar intervals or even daily if there were acute cardiac complications. Blood cultures were made in all cases at frequent intervals, skin tests with streptococcal filtrates were carried out, the heart was radiographed as soon as possible after admission, and X rays were also used to investigate the teeth, nose, throat, and accessory sinuses. Notes were made at least once daily by clinical observers.

During the two years of this comprehensive investigation 162 patients with acute rheumatic fever were studied. Of these 50 were treated with salicylates or vaccine and were not included in the present survey, which comprised 105 who had no form of therapy which might be regarded as specific, and no antipyretic drug. They were considered in three groups, all having active disease: those with polyarthritis with either no heart involvement or old cardiac trouble which was inactive; those with chorea; and those with a history of repeated rheumatic infection and advanced structural heart disease. Actually only 47 patients remained in hospital long enough to fulfil certain conditions laid down as to the cessation of activity, the remainder leaving for various reasons. The age-distribution of these 47 patients was as follows: under 20 years, 18; between 20 and 29 years, 11; between 30 and 39 years, 14; and between 40 and 49 years, 4. They were distributed in the three groups outlined above, with 29 in the polyarthritis group, 6 in the chorea group, and 12 in the carditis group. The actual clinical results in this total of 47 cases are set out in great detail. Comparing these patients with another series described by H. F. Swift, in which drugs were used against the rheumatic process, the present authors conclude that the elimination of such remedies did not prolong the illness. Without antipyretics the temperature appeared to subside spontaneously; as a rule it became, and remained, normal after but a single cycle of fever. In 22 out of the 29 patients with polyarthritis the joint complications subsided, untreated, in a week, and recurrences, which were seen in half the cases, affected fewer joints, were less severe, and were of shorter duration than the initial attacks. Cases were encountered in which spontaneous subsidence of arthritis was as abrupt and complete as when salicylates were used.

Variations in the P–R interval noted on the electrocardiogram were wide and inconstant and did not appear very different from those seen in patients who had had salicylates. Tachycardia, like the fever, in general appeared to subside spontaneously. There were six deaths in the series, five from cardiac failure in association with active carditis, and one with pericarditis and profound toxæmia with a rapid downhill course from the onset. Unfortunately studies of the sedimentation-rate were not made, for the method only became known to the authors after the work had been begun; but their studies seem to have been sufficiently exhaustive to justify the conclusion that "in adolescence and adult life the acute manifestations of rheumatic fever tend to subside spontaneously."

ANNOTATIONS

TWO VIEWS OF PEPTIC ULCER

THE many factors that may promote peptic ulceration can be classified as general or local: under the one heading we have all the circulatory, toxic, chemical, and constitutional variations which are suggested as exciting or predisposing causes, while under the other there are several possible sources of damage to the mucous membrane. The part played by dietary indiscretion in causing such damage has lately been considered by Prof. R. Ehrmann,[1] of Berlin, who has analysed some 7000 cases of peptic ulcer and also about 800 autopsies. He notes that during the years 1917–24 there was a gradually increasing incidence of ulcer, followed by a conspicuous diminution. This rise during and just after the late war Ehrmann attributes to the unsatisfactory diet of those times, which he regards as very favourable to the production of local gastric injury. He points out that at this time the diet was voluminous, coarse, and lacking in fat, so that the stomach was likely to be unduly distended. According to his view, peptic ulcers arise, like wounds of the skin, through injuries, hæmorrhages, or necroses, particularly situated along the *Magenstrasse*—i.e., the lesser curvature—and are primarily due to faulty diet. Gastric ulcer he describes as a disease of the "seven lean years" in contrast to cholelithiasis which he regards as a disease of "fat years."

L. W. Kohn,[2] on the other hand, assumes that various factors are responsible, and emphasises the significance of local thrombosis of gastric arteries, comparing them with the changes seen in thrombo-angiitis obliterans. On these lines he has treated a number of patients with intravenous injections of sodium citrate, in the hope of improving the local blood-supply to the stomach. In his studies, which are not reported in detail, he has noted an increased clotting tendency of the blood in ulcer patients, and he considers that sodium citrate has the ultimate effect of lessening coagulation, in spite of some of mankind to hope for a final decision and cessation of argument, but it is not too much to ask that any serious investigation should take into account all the pitfalls, statistical and psychological, that may lurk beneath the simplest-looking and most convincing observations.

[2] Med. Jour. and Record, Feb. 1st, 1933, p. 103.

The mass of material which these big-eater cells will take up is important in determining their functional nature as compared with monocytes of the milk spots which take up only a small amount of foreign material.

The tuberculo-phosphatide when injected into the peritoneal cavity was found to be taken up by the big-eating clasmatocyte only in small amounts, but was absorbed in such large amounts by the young connective tissue cells and monocytes that the milk spots appeared swollen to the unaided eye. When studied with supravital staining methods the cells which engorged the material were found to break into finer and finer particles in three stages: (1) cells with largest vacuoles filled with phosphatide either intact or slightly changed (a phosphatide cell); (2) cells showing cytoplasm filled with a rosette of many coarse vacuoles, uniform in size, making the cell appear to have a foamy cytoplasm (the coarse vacuolated epithelioid cell); (3) a cell with a rosette of such tiny vacuoles that the cytoplasm appeared dense and nearly uniform in structure (the typical epithelioid cell). This third stage is reached in the second week. With repeated intraperitoneal injections of the phosphatide there was a marked maturation of the monocytes and production of epithelioid cells in such numbers that the outlines of the milk spots became obscured. It seemed clear, therefore, that the epithelioid cell was the characteristic response to tuberculo-phosphatide, and was associated with phagocytosis. Other immediate reactions were minimal and consisted only of a transient emigration of leucocytes from the tissues. The epithelioid cell of the third stage has the same type of rosette in the supravital staining reaction as the Langhans giant cell. It is a multinuclear epithelioid cell, whereas the so-called foreign body giant cell is a reaction to foreign material by fusion of cells, usually monocytes. Caseation and infiltration of lymphocytes forming complete capsules followed as in the ordinary natural infection. Dr. Sabin considers that caseation is the end stage of the epithelioid cell, the infiltration of the leucocytes being secondary to the death of this cell. He regards these changes as the specific reaction to the phosphatide, and such other reactions as migration of leucocytes from the blood-vessels, their phagocytosis and destruction by clasmatocytes, the development of plasma cells, the increase in lymphocytes, in young connective tissue cells, in fibroblasts, and the development of new blood-vessels as non-specific reactions.

An unknown fatty acid of high molecular weight and designated phthioic acid was next used. This was the only substance isolated from the original fatty acid of the bacillary material which produced a response of tubercular tissue. Its empirical formula is $C_{26}H_{52}O_2$. It is a heavy oil and much too irritating to be used undiluted, causing necrosis and complex response. When diluted with mineral oil it gave a diffuse reaction of epithelioid cells of the typical third stage described above. Further researches showed that the specific activity towards the production of epithelioid cells was only produced by a dextrorotatory acid obtained by the fractionation from the phthioic acid. Next an unsaponifiable wax, believed to be a higher alcohol with the formula $C_{94}H_{188}O_4$, was tested. The cellular reaction produced to this unsaponifiable alcohol showed undifferentiated connective tissue cells and leucocytes. Lastly an acetone-soluble fat was used. This produced by far the most complex cellular reaction of the substances tested. There was a diffuse reaction of epithelioid cells as in the case of fatty acids, but in addition there was a general infiltration of the tissues with leucocytes, an increase in undifferentiated connective tissue cells, fibroblasts, lymphocytes, plasma cells, and a marked increase in new blood-vessels with hæmorrhage.

All these tests with tuberculous lipoids therefore suggest that both the tuberculo-lipoids are remarkable stimulants of the cells of connective tissue. Some of them, such as the phosphatide, act as a foreign body and produce effects by phagocytosis; others, such as the unsaponifiable higher alcohol, act as a stimulant without being phagocyted; whilst yet a third, the acetone-soluble fat, is an extremely complex irritant. The explanation of the cellular reactions in tuberculosis are to be found, the author considers, in all these reactions, the epithelioid cell being the result of phagocytosis of a tuberculo-lipoid by monocytes and young tissue cells. Lastly, Dr. Sabin found that polysaccharides obtained from lipoids and from the whole bacillus produced migration of leucocytes from the blood-vessels and damaging of them so that they were quickly phagocyted by clasmatocytes. This was a constant reaction regardless of the number of injections. Although there is no fraction of the tubercle bacillus which does not produce this reaction to a certain extent it was considered to be so consistently found with all the polysaccharides as to raise the issue as to whether the material in the other fractions may not be the content of carbohydrate.

The protein fraction from tubercle bacilli is responsible for the reactions that give the skin test, a reaction common to all other proteins, but a particularly sensitive one in the tuberculous animal. Given in sufficient doses this fraction produces a rise of temperature, then a rapid fall of temperature followed by death. The cellular reaction produced thereby appears to be mainly a proliferation of plasma cells with damage to the endothelium of the blood-vessels causing hæmorrhage.

THE QUANTUM THEORY OF INFECTION

It is now nearly five years since Brevet-Colonel C. A. Gill, I.M.S., brought out his book entitled the "Genesis of Epidemics," based largely on experience as director of public health in the Punjab.[1] The report of the department for 1931, now before us, is the last for which Colonel Gill will be responsible—he has been transferred to Burma on promotion—and it is interesting reading in the light of a theory of epidemicity to which in his book he gave the name of the quantum theory. Nature in general exhibits a remarkable unity of design, and one would not expect to find a separate mechanism of epidemicity in each specific disease. Plague, cholera, small-pox, malaria, influenza, and the rest may display many distinctive clinical and epidemiological features, but they all show a similarity in periodicity and seasonal incidence, in wave form, diffusibility and toxicity, and in their special incidence upon certain age-groups; these are the genetic features of epidemic disease. If, he argued, a unitary mechanism can be postulated for all epidemics, then several important implications follow. (1) The intensive study of any single epidemic disease will throw light on the general law. (2) General laws may be deduced from specific instances. (3) Investigations in connexion with animals and plants may elucidate problems of human epidemiology. (4) The complexity of problems of epidemic causation and investigation is simplified. The basic principle of the quantum theory is that all epidemic manifestations are the outcome of loss of equilibrium between the dose of toxin and the degree of resistance of the subject. Colonel Gill could discover four factors in the mechanism of an epidemic: the reservoir of infection, the parasite factor, the immunity factor, and the transmission factor—the last being of predominant importance. A prolonged interruption of transmission would naturally be followed by a sudden increase, given favouring circumstances in which meteorological and atmospheric conditions play a large part. The Punjab offers exceptional opportunities for the intensive study of epidemics of malaria, and the quantum theory works out thus. Regional epidemics are mainly dependent on unstable climatic conditions. For prolonged periods these may be unfavourable to transmission, with the result that immunity is lowered. Then comes an exceptional monsoon, with a complete change of climatic and atmospheric conditions, and the transmission factor suddenly becomes favourable; conditions are suitable for insect life, a vast increase of anopheles mosquitoes occurs, and the opportunities for transmission are greatly enhanced. High temperature and increased humidity are not only conducive to the metabolic activity and longevity of the insect host; they also favour a rapid completion of the sexual cycle of the parasite in the tissues of the insect, and an acceleration of the intracorporeal phase. There is thus a rapid multiplication of the infective cycle. The intensity of an epidemic is influenced by the number of persons exposed, and since mortality is mainly amongst infants and young children the average age of the population is important. In the Punjab the birth-rate is high (40 to 50 per mille), and the average duration of life low (35 years). The well-being of the population is also important; one of Colonel Gill's main contentions has always been that an under-nourished community is particularly liable to malaria; improved nutrition is accompanied by a lessened susceptibility. A crucial test of the theory would be provided if it were shown that epidemics can be predicted with precision. It was stated in 1928 that six forecasts had up to then been prepared; the data employed in forecasting were the humidity or rainfall factor, the spleen rate, the economic factor (as represented by the average price of food grains), and the coefficient of variability of fever mortality. In each case the intensity and distribution of the disease were accurately predicted.

TUBERCULOUS MENINGITIS

TUBERCULOUS meningitis is so commonly found in association with miliary tuberculosis—especially in childhood—that it has been generally assumed to arise from a blood-borne infection of the meninges. Not every case of miliary tuberculosis, however, shows a coexistent meningitis. It has long been recognised, moreover, that the meningitis is occasionally caused by direct spread of the infection from a caseous focus in some neighbouring structure, such as the brain or one of the bones of the skull; and the meningitis so produced is morphologically identical with that found in most cases of miliary tuberculosis. These facts have led A. R. Rich and H. A. McCordock[1] to study the pathogenesis in more detail, and they have confirmed the observation that, while intravenous and even intracarotid injection of massive doses of tubercle bacilli experimentally will always produce a generalised miliary tuberculosis, it very rarely causes a meningitis. In the few exceptions to this rule the meningitis develops some time after the injection, and it can usually be shown to have spread from an older local caseous focus. On the other hand, injection of tubercle bacilli directly into the meninges was always followed by an intense meningitis with all the characteristics of tuberculous meningitis in man. The next step in Rich and McCordock's inquiry was to examine the brain and spinal cord in 82 cases of tuberculous meningitis. The material was cut into slices 3–5 mm. in thickness and the slices were carefully examined for small caseous foci. In 75 of the cases such foci, which had ruptured and discharged into the cerebro-spinal fluid, were found in the brain or meninges; in a further 2 cases there were discharging foci in the choroid plexus and in the vertebræ; while in the remaining 5 cases the material available for study was incomplete. These investigations indicate that diffuse tuberculous meningitis is not a direct result of a blood-borne infection, but is the result of discharge of tubercle bacilli into the cerebro-spinal fluid from adjacent caseous foci.

HEALTH OF THE NAVY IN 1931

THE statistical report on the Health of the Navy for 1931[1] has just been issued. The total force was 87.075; the new cases and sick daily were more numerous, but there were fewer invalids and deaths. There were invalided: for phthisis 164, for errors of refraction 142, for diseases of the ear 66, for injuries 83, and 14 who refused operations. The largest cause of death was injury, total 83, of which 18 occurred in the loss of the submarine *Poseidon* in China; 19 died of pneumonia, 12 of meningococcal infection, 10 of pulmonary tuberculosis, 2 of other tuberculosis, 6 of suicide, and 7 of malignant disease (5 carcinoma, 1 sarcoma, 1 lymphosarcoma). A case of anthrax from a shaving-brush arose at Hong-Kong, but recovered after excision. One case of dysentery died in the Mediterranean; he had already had bacillary dysentery in 1926 and amœbic in 1929. Two cases of typhoid were seen at Shanghai, one had been inoculated preventively three months before, the other apparently two months after attack (but that is perhaps a misprint). Two cases of paratyphoid were seen in China, one in the Mediterranean; no other cases of the enteric group came to notice. Influenza attacked especially the Atlantic fleet and the Mediterranean station, but was less prevalent at home than in the Army in this year. Malaria is, we are told, treated with plasmoquine by the United Fruit Company in British Honduras and elsewhere, but no reports on the drug from ships are given. Of meningococcal infection 27 cases (12 deaths) occurred, 11 of them in the submarine and general depôts, whence also arose several cases of tubercle. The five cases of small-pox were all in China and all apparently well vaccinated; none died. Fewer men were infected with venereal diseases this year; China is still in this relation a grave danger. Chlorination of drinking water is progressing at Malta and all naval establishments will, it is hoped, soon have a safe supply. Swimming baths are tested daily with starch-iodine to secure just enough chlorination. Some 2000 civil cases of undulant fever occurred in Malta, but only 9 in the Navy; compulsory pasteurisation ashore of all goat's milk is being considered. Dick-testing and active immunisation against scarlet fever have been undertaken in *Britannia* and *St. Vincent;* of the cadets in the former 55 per cent. were found to be susceptible, only 24 per cent. in the latter. Against diphtheria 238 ratings were immunised; there were fewer cases of both diphtheria and scarlet fever this year. A solarium was taken into use on the surgical side of Plymouth Hospital, and another on the medical side will soon be ready. At Chatham Hospital methylated spirit is being used for sterilising the skin, with excellent clinical results and with great economy. Inquiry is proceeding at Chatham into the increase of gastric and duodenal ulcers in the service. Many vaccines for the service are prepared

[1] Statistical Report of the Health of the Navy for 1931. H.M. Stationery Office. Pp. 147. 2s. 6d.

The mass of material which these big-eater cells will take up is important in determining their functional nature as compared with monocytes of the milk spots which take up only a small amount of foreign material.

The tuberculo-phosphatide when injected into the peritoneal cavity was found to be taken up by the big-eating clasmatocyte only in small amounts, but was absorbed in such large amounts by the young connective tissue cells and monocytes that the milk spots appeared swollen to the unaided eye. When studied with supravital staining methods the cells which engorged the material were found to break into finer and finer particles in three stages: (1) cells with largest vacuoles filled with phosphatide either intact or slightly changed (a phosphatide cell); (2) cells showing cytoplasm filled with a rosette of many coarse vacuoles, uniform in size, making the cell appear to have a foamy cytoplasm (the coarse vacuolated epithelioid cell); (3) a cell with a rosette of such tiny vacuoles that the cytoplasm appeared dense and nearly uniform in structure (the typical epithelioid cell). This third stage is reached in the second week. With repeated intraperitoneal injections of the phosphatide there was a marked maturation of the monocytes and production of epithelioid cells in such numbers that the outlines of the milk spots became obscured. It seemed clear, therefore, that the epithelioid cell was the characteristic response to tuberculo-phosphatide, and was associated with phagocytosis. Other immediate reactions were minimal and consisted only of a transient emigration of leucocytes from the tissues. The epithelioid cell of the third stage has the same type of rosette in the supravital staining reaction as the Langhans giant cell. It is a multinuclear epithelioid cell, whereas the so-called foreign body giant cell is a reaction to foreign material by fusion of cells, usually monocytes. Caseation and infiltration of lymphocytes forming complete capsules followed as in the ordinary natural infection. Dr. Sabin considers that caseation is the end stage of the epithelioid cell, the infiltration of the leucocytes being secondary to the death of this cell. He regards these changes as the specific reaction to the phosphatide, and such other reactions as migration of leucocytes from the blood-vessels, their phagocytosis and destruction by clasmatocytes, the development of plasma cells, the increase in lymphocytes, in young connective tissue cells, in fibroblasts, and the development of new blood-vessels as non-specific reactions.

An unknown fatty acid of high molecular weight and designated phthioic acid was next used. This was the only substance isolated from the original fatty acid of the bacillary material which produced a response of tubercular tissue. Its empirical formula is $C_{26}H_{52}O_2$. It is a heavy oil and much too irritating to be used undiluted, causing necrosis and complex response. When diluted with mineral oil it gave a diffuse reaction of epithelioid cells of the typical third stage described above. Further researches showed that the specific activity towards the production of epithelioid cells was only produced by a dextrorotatory acid obtained by the fractionation from the phthioic acid. Next an unsaponifiable wax, believed to be a higher alcohol with the formula $C_{94}H_{183}O_4$, was tested. The cellular reaction produced to this unsaponifiable alcohol showed undifferentiated connective tissue cells and leucocytes. Lastly an acetone-soluble fat was used. This produced by far the most complex cellular reaction of the substances tested. There was a diffuse reaction of epithelioid cells as in the case of fatty acids, but in addition there was a general infiltration of the tissues with leucocytes, an increase in undifferentiated connective tissue cells, fibroblasts, lymphocytes, plasma cells, and a marked increase in new blood-vessels with hæmorrhage.

All these tests with tuberculous lipoids therefore suggest that both the tuberculo-lipoids are remarkable stimulants of the cells of connective tissue. Some of them, such as the phosphatide, act as a foreign body and produce effects by phagocytosis; others, such as the unsaponifiable higher alcohol, act as a stimulant without being phagocyted; whilst yet a third, the acetone-soluble fat, is an extremely complex irritant. The explanation of the cellular reactions in tuberculosis are to be found, the author considers, in all these reactions, the epithelioid cell being the result of phagocytosis of a tuberculo-lipoid by monocytes and young tissue cells. Lastly, Dr. Sabin found that polysaccharides obtained from lipoids and from the whole bacillus produced migration of leucocytes from the blood-vessels and damaging of them so that they were quickly phagocyted by clasmatocytes. This was a constant reaction regardless of the number of injections. Although there is no fraction of the tubercle bacillus which does not produce this reaction to a certain extent it was considered to be so consistently found with all the polysaccharides as to raise the issue as to whether the material in the other fractions may not be the content of carbohydrate.

The protein fraction from tubercle bacilli is responsible for the reactions that give the skin test, a reaction common to all other proteins, but a particularly sensitive one in the tuberculous animal. Given in sufficient doses this fraction produces a rise of temperature, then a rapid fall of temperature followed by death. The cellular reaction produced thereby appears to be mainly a proliferation of plasma cells with damage to the endothelium of the blood-vessels causing hæmorrhage.

THE QUANTUM THEORY OF INFECTION

It is now nearly five years since Brevet-Colonel C. A. Gill, I.M.S., brought out his book entitled the "Genesis of Epidemics," based largely on experience as director of public health in the Punjab.[1] The report of the department for 1931, now before us, is the last for which Colonel Gill will be responsible—he has been transferred to Burma on promotion—and it is interesting reading in the light of a theory of epidemicity to which in his book he gave the name of the quantum theory. Nature in general exhibits a remarkable unity of design, and one would not expect to find a separate mechanism of epidemicity in each specific disease. Plague, cholera, small-pox, malaria, influenza, and the rest may display many distinctive clinical and epidemiological features, but they all show a similarity in periodicity and seasonal incidence, in wave form, diffusibility and toxicity, and in their special incidence upon certain age-groups; these are the genetic features of epidemic disease. If, he argued, a unitary mechanism can be postulated for all epidemics, then several important implications follow. (1) The intensive study of any single epidemic disease will throw light on the general law. (2) General laws may be deduced from specific instances. (3) Investigations in connexion with animals and plants may elucidate problems of human epidemiology. (4) The complexity of problems of epidemic causation and investigation is simplified. The basic principle of the quantum theory is that all epidemic manifestations are the outcome of loss of equilibrium between the dose of toxin and the degree of resistance of the subject. Colonel Gill could discover four factors in the mechanism of an epidemic: the reservoir of infection, the parasite factor, the immunity factor, and the transmission factor—the last being of predominant importance. A prolonged interruption of transmission would naturally be followed by a sudden increase, given favouring circumstances in which meteorological and atmospheric conditions play a large part. The Punjab offers exceptional opportunities for the intensive study of epidemics of malaria, and the quantum theory works out thus. Regional epidemics are mainly dependent on unstable climatic conditions. For prolonged periods these may be unfavourable to transmission, with the result that immunity is lowered. Then comes an exceptional monsoon. with a complete change of climatic and atmospheric conditions. and the transmission factor suddenly becomes favourable; conditions are suitable for insect life. a vast increase of anopheles mosquitoes occurs, and the opportunities for transmission are greatly enhanced. High temperature and increased humidity are not only conducive to the metabolic activity and longevity of the insect host; they also favour a rapid completion of the sexual cycle of the parasite in the tissues of the insect, and an acceleration of the intracorporeal phase. There is thus a rapid multiplication of the infective cycle. The intensity of an epidemic is influenced by the number of persons exposed. and since mortality is mainly amongst infants and young children the average age of the population is important. In the Punjab the birth-rate is high (40 to 50 per *mille*), and the average duration of life low (35 years). The well-being of the population is also important; one of Colonel Gill's main contentions has always been that an under-nourished community is particularly liable to malaria; improved nutrition is accompanied by a lessened susceptibility. A crucial test of the theory would be provided if it were shown that epidemics can be predicted with precision. It was stated in 1928 that six forecasts had up to then been prepared; the data employed in forecasting were the humidity or rainfall factor. the spleen rate, the economic factor (as represented by the average price of food grains), and the coefficient of variability of fever mortality. In each case the intensity and distribution of the disease were accurately predicted.

The mass of material which these big-eater cells will take up is important in determining their functional nature as compared with monocytes of the milk spots which take up only a small amount of foreign material.

The tuberculo-phosphatide when injected into the peritoneal cavity was found to be taken up by the big-eating clasmatocyte only in small amounts, but was absorbed in such large amounts by the young connective tissue cells and monocytes that the milk spots appeared swollen to the unaided eye. When studied with supravital staining methods the cells which engorged the material were found to break into finer and finer particles in three stages: (1) cells with largest vacuoles filled with phosphatide either intact or slightly changed (a phosphatide cell); (2) cells showing cytoplasm filled with a rosette of many coarse vacuoles, uniform in size, making the cell appear to have a foamy cytoplasm (the coarse vacuolated epithelioid cell); (3) a cell with a rosette of such tiny vacuoles that the cytoplasm appeared dense and nearly uniform in structure (the typical epithelioid cell). This third stage is reached in the second week. With repeated intraperitoneal injections of the phosphatide there was a marked maturation of the monocytes and production of epithelioid cells in such numbers that the outlines of the milk spots became obscured. It seemed clear, therefore, that the epithelioid cell was the characteristic response to tuberculo-phosphatide, and was associated with phagocytosis. Other immediate reactions were minimal and consisted only of a transient emigration of leucocytes from the tissues. The epithelioid cell of the third stage has the same type of rosette in the supravital staining reaction as the Langhans giant cell. It is a multinuclear epithelioid cell, whereas the so-called foreign body giant cell is a reaction to foreign material by fusion of cells, usually monocytes. Caseation and infiltration of lymphocytes forming complete capsules followed as in the ordinary natural infection. Dr. Sabin considers that caseation is the end stage of the epithelioid cell, the infiltration of the leucocytes being secondary to the death of this cell. He regards these changes as the specific reaction to the phosphatide, and such other reactions as migration of leucocytes from the blood-vessels, their phagocytosis and destruction by clasmatocytes, the development of plasma cells, the increase in lymphocytes, in young connective tissue cells, in fibroblasts, and the development of new blood-vessels as non-specific reactions.

An unknown fatty acid of high molecular weight and designated phthioic acid was next used. This was the only substance isolated from the original fatty acid of the bacillary material which produced a response of tubercular tissue. Its empirical formula is $C_{26}H_{52}O_2$. It is a heavy oil and much too irritating to be used undiluted, causing necrosis and complex response. When diluted with mineral oil it gave a diffuse reaction of epithelioid cells of the typical third stage described above. Further researches showed that the specific activity towards the production of epithelioid cells was only produced by a dextrorotatory acid obtained by the fractionation from the phthioic acid. Next an unsaponifiable wax, believed to be a higher alcohol with the formula $C_{94}H_{188}O_4$, was tested. The cellular reaction produced to this unsaponifiable alcohol showed undifferentiated connective tissue cells and leucocytes. Lastly an acetone-soluble fat was used. This produced by far the most complex cellular reaction of the substances tested. There was a diffuse reaction of epithelioid cells as in the case of fatty acids, but in addition there was a general infiltration of the tissues with leucocytes, an increase in undifferentiated connective tissue cells, fibroblasts, lymphocytes, plasma cells, and a marked increase in new blood-vessels with hæmorrhage.

All these tests with tuberculous lipoids therefore suggest that both the tuberculo-lipoids are remarkable stimulants of the cells of connective tissue. Some of them, such as the phosphatide, act as a foreign body and produce effects by phagocytosis; others, such as the unsaponifiable higher alcohol, act as a stimulant without being phagocyted; whilst yet a third, the acetone-soluble fat, is an extremely complex irritant. The explanation of the cellular reactions in tuberculosis are to be found, the author considers, in all these reactions, the epithelioid cell being the result of phagocytosis of a tuberculo-lipoid by monocytes and young tissue cells. Lastly, Dr. Sabin found that polysaccharides obtained from lipoids and from the whole bacillus produced migration of leucocytes from the blood-vessels and damaging of them so that they were quickly phagocyted by clasmatocytes. This was a constant reaction regardless of the number of injections. Although there is no fraction of the tubercle bacillus which does not produce this reaction to a certain extent it was considered to be so consistently found with all the polysaccharides as to raise the issue as to whether the material in the other fractions may not be the content of carbohydrate.

The protein fraction from tubercle bacilli is responsible for the reactions that give the skin test, a reaction common to all other proteins, but a particularly sensitive one in the tuberculous animal. Given in sufficient doses this fraction produces a rise of temperature, then a rapid fall of temperature followed by death. The cellular reaction produced thereby appears to be mainly a proliferation of plasma cells with damage to the endothelium of the blood-vessels causing hæmorrhage.

THE QUANTUM THEORY OF INFECTION

It is now nearly five years since Brevet-Colonel C. A. Gill, I.M.S., brought out his book entitled the "Genesis of Epidemics," based largely on experience as director of public health in the Punjab.[1] The report of the department for 1931, now before us, is the last for which Colonel Gill will be responsible —he has been transferred to Burma on promotion— and it is interesting reading in the light of a theory of epidemicity to which in his book he gave the name of the quantum theory. Nature in general exhibits a remarkable unity of design, and one would not expect to find a separate mechanism of epidemicity in each specific disease. Plague, cholera, small-pox, malaria, influenza, and the rest may display many distinctive clinical and epidemiological features, but they all show a similarity in periodicity and seasonal incidence, in wave form, diffusibility and toxicity, and in their special incidence upon certain age-groups; these are the genetic features of epidemic disease. If, he argued, a unitary mechanism can be postulated for all epidemics, then several important implications follow. (1) The intensive study of any single epidemic disease will throw light on the general law. (2) General laws may be deduced from specific instances. (3) Investigations in connexion with animals and plants may elucidate problems of human epidemiology. (4) The complexity of problems of epidemic causation and investigation is simplified. The basic principle of the quantum theory is that all epidemic manifestations are the outcome of loss of equilibrium between the dose of toxin and the degree of resistance of the subject. Colonel Gill could discover four factors in the mechanism of an epidemic: the reservoir of infection, the parasite factor, the immunity factor, and the transmission factor—the last being of predominant importance. A prolonged interruption of transmission would naturally be followed by a sudden increase, given favouring circumstances in which meteorological and atmospheric conditions play a large part. The Punjab offers exceptional opportunities for the intensive study of epidemics of malaria, and the quantum theory works out thus. Chlorination of drinking water is progressing at Malta and all naval establishments will, it is hoped, soon have a safe supply. Swimming baths are tested daily with starch-iodine to secure just enough chlorination. Some 2000 civil cases of undulant fever occurred in Malta, but only 9 in the Navy; compulsory pasteurisation ashore of all goat's milk is being considered. Dick-testing and active immunisation against scarlet fever have been undertaken in *Britannia* and *St. Vincent*; of the cadets in the former 55 per cent. were found to be susceptible, only 24 per cent. in the latter. Against diphtheria 238 ratings were immunised; there were fewer cases of both diphtheria and scarlet fever this year. A solarium was taken into use on the surgical side of Plymouth Hospital, and another on the medical side will soon be ready. At Chatham Hospital methylated spirit is being used for sterilising the skin, with excellent clinical results and with great economy. Inquiry is proceeding at Chatham into the increase of gastric and duodenal ulcers in the service. Many vaccines for the service are prepared

SCOTLAND

(FROM OUR OWN CORRESPONDENT)

MENTAL DEFECTIVES AND STERILISATION

Dr. J. R. Bailey, medical superintendent of garburn Institution, which is the chief Edinburgh stitution for mental defectives, has lately been scussing deficiency in its relation to heredity. It d been calculated, he said, that if every mental fective in every generation were sterilised, it would ll take 2000 years to stamp out the proportion of ental defect that was due to inherited taint. But heritance was not the only factor concerned: sease and injury to the developing brain in infancy d early childhood was responsible at least as ten, and produced the more severe grade of mental ficiency such as idiocy and imbecility, with epilepsy d paralysis as frequent concomitants. The defect at sprang from inherited causes was usually of the ss severe type; the feeble-minded grade, who, many instances, escaped observation or received supervision after they left the special school. erilisation in these cases would, in his opinion, ad to an increase in sexual promiscuity and a rapid read of venereal infection.

Greater care of the expectant mother, especially the direction of ensuring that she had a well-alanced diet, rich in vitamins; greater attention child life and health, especially in the earliest ears; more intensive research into the cause and pread of disease affecting the nervous system—these ere the methods, Dr. Bailey said, which would, lowly but surely, eliminate mental deficiency. They ere the same as the measures that would build up strong and virile race.

THE ADEQUACY OF MODERN DIET

In a lecture to the Edinburgh Women Citizens' ssociation, Dr. John Boyd Orr, director of the owett Research Institute, Aberdeen, said that an cre in Scotland now grew about five or six times as nuch as it did about a hundred years ago; and where ormerly a cow gave 300 or 400 gallons or less, a good ow now gave over 1000 gallons. Improved transport made it possible for us to draw our food now from lmost every quarter of the world. There was abundance of food, but the kind of food had changed remarkably. Up to the middle of the last century the people of Scotland were eating natural foodstuffs. With the introduction of machinery this had been changed. Instead of getting barley and oats, grinding them, and making them into bread, we now got white flour, polished rice, sugar, dried milk, and tinned foodstuffs. The natural foods had been changed into artificial foods with the very substances purified away that were necessary to perfect health. But a nation that could spend £1,000,000 a week on sweets and chocolate could very well afford the natural materials of good diet—plenty of milk, fresh eggs, fresh meat, fresh vegetables, fruit and sunshine, and whole wheat ground up. These were within the reach of most, especially skim milk, which contained everything except the fat, and yet was not regarded as an important item of diet.

GLASGOW ROYAL HOSPITAL FOR SICK CHILDREN

The Glasgow Royal Hospital for Sick Children celebrates its jubilee this year. The original hospital, projected in 1861, was completed in 1882 at a total cost of £13,000. There were 58 cots, later 74, and the annual cost of maintenance was £2000. To-day there are 300 cots and the annual cost of running them is £43,000. In the first year 300 children were treated; last year 5819 and 936 in the country branch. In 1907 the directors appealed for £100,000 to construct a new building, and raised the sum in a year. It was opened in 1914. This year the hospital closes with a balance on the right side, in spite of the depression.

IRELAND

(FROM OUR OWN CORRESPONDENT)

A CLEAN MILK BILL

The Minister for Local Government and Public Health of the Irish Free State has informed a deputation from the Clean Milk Society that he will use all expedition in introducing a Bill dealing with the milk supply of the country. The Bill has been drafted and its provisions are being studied in detail by the officers of his department. It is nearly four years since the Minister's predecessor announced the provisions of a Milk Bill which was to be introduced as soon as possible, but, in spite of questioning by medical and other deputies interested in health the Bill never saw the light. The provisions, as stated, were somewhat drastic, and no doubt roused the opposition of the agricultural interest, always strong in the Dáil. It is satisfactory that the present Minister recognises the danger to the community from the present almost uncontrolled production of milk, and one may hope that he will not lose time before establishing adequate control.

UNITED STATES OF AMERICA

(FROM AN OCCASIONAL CORRESPONDENT)

MEDICAL STUDENTS ABROAD

The strenuous and successful efforts made by the American medical profession during the present century to raise the standards of medical qualification have had some unforeseen results. One of them has been the uprising of numerous healing cults such as chiropractors and naturopaths with practically no standards at all. Another result has been that with the closing of numerous second-rate medical schools the remaining first-rate schools are not sufficient to meet the demand for medical education. It is widely believed that they are adequate to supply the medical needs of the nation and that there is already an over-supply of doctors. For this reason the medical schools are disinclined either to lower their high requirements in premedical education or to extend the size of their classes. The result has been that many would-be doctors have gone abroad for their medical education and returned with European diplomas claiming the right to practice in their native land. This displeases the State medical boards, who feel that there is a risk that the high standards of medical education achieved in recent times may not be maintained. At the annual meeting of the boards, held in Chicago on Feb. 14th, two resolutions were adopted. As a result all American students graduating from European medical schools after the present academic year must secure from a State medical board or other competent state authority a certificate to be endorsed by the Association of American Medical Colleges in proof of satisfactory premedical education. They must also pass an examination qualifying them to practise in the European country in which they must have studied for at least four academic years. American students in Great Britain should investigate these new conditions with to accept the report in whole or in part." In particular the judge may so refer to a special referee any question as to the nature, extent, and permanence of an injury alleged to have been caused by the negligence of a party to the action. It seems, however, that the use made of this new facility has so far been disappointing. Properly applied, it would promote the early settlement of many cases before trial. It would save much time now spent by medical witnesses in courts of law and it would give cynics less opportunity to point out how doctors can differ.

The Prejudice against Lunatic Asylums

An odd case, noted in the *Law Times*, illustrates the old-fashioned horror of institutional treatment for mental disease. Under a will made in 1925 a man left the residue of his estate to his brother " on condition that my friends keep me out of a lunatic asylum." Under a proviso to Section 10 of the Lunacy (Ireland) Act, 1867, there was at that date in force a power for " any relation or friend " to take " under his own care or protection " (on entering into recognizances for the patient's peaceable behaviour or safe custody) any dangerous lunatic who otherwise would have to be compulsorily detained in the local authority's lunatic asylum under the section. Thus, whether the testator was aware of the fact or not, there was a statutory provision under which his friends could do him the service he desired. " If," added the testator in his will, " they allow me to be put into a lunatic asylum," then £700 of his residuary estate was to go to the British Home and Foreign Bible Society and the balance to the brother. Within two years of making his will the testator was detained for a month in the Londonderry Asylum on the information of a neighbour. Did this deprive the brother of the £700 ? The executors submitted the point to the court in Northern Ireland, the brother contending that the condition was invalid. He had been living in Queensland (as the testator well knew) : he was unaware of the terms of the will and, if he had known of them, was not in a position to avert the detention order made many thousand miles away. The judge, however, upheld the condition. Such a stipulation is not invalid unless it is ineffectual or illegal ; mere eccentricity or difficulty of compliance does not upset it. The court had to assume that the will was the work of a sane man. However absurd it might seem, the bequest was subject to a condition precedent, and the condition had been broken. Thus the Society took its £700.

The 1926 report of the Royal Commission on Lunacy and Mental Disorder dwelt on the atmosphere of suspicion and aversion with which mental treatment was invested. Patients and relatives alike, it declared, hated the idea of resort to an asylum. The 1930 Act, it is hoped, is dissipating that atmosphere. It even abolished by statute the invidious nomenclature of " lunatic " and " asylum," substituting (as the British Medical Association had suggested) euphemisms which avoid any stigma. The Northern Ireland Parliament made similar provision last year.

A Jury's Second Thoughts

The Coroners Act directs that, after hearing the evidence, the jury shall give their verdict and certify it by an inquisition in writing. There seems no reason why the jury should not alter the verdict at any time before they certify it in writing. The inquest is not closed merely because an announcement has been made in open court and members of the public have left the building in the belief that a final decision has been made. It is nevertheless unusual for a jury to change its mind as a Kent jury did at an inquest last week. If it is desirable that the verdict should be delivered publicly (as a decision in the Irish courts suggests), any amendment of it ought to have equal publicity. The Kent proceedings concerned the death of a patient who was being anæsthetised before an operation in hospital. By one of those unfortunate mistakes from which human actions will never be entirely free, a bottle had somehow been wrongly filled, and the bottle labelled " ether " contained chloroform. The original verdict of the jury, announced in open court, was as follows : " We find that the death was due to syncope accelerated by the administration of the wrong anæsthetic. No blame attaches to Dr. X or Dr. Y for believing the patient was fit to undergo the operation. We absolve Dr. Y from any blame for the administration of the wrong anæsthetic. He rightly assumed the contents of the bottle to be correct. We are of the opinion that the mistake in regard to the bottle was due to an error on the part of Nurse Z. The jury consider that in future stricter supervision in regard to anæsthetics should be observed, also that the sister in charge should give more definite instructions to her juniors in regard to the preparation of the vessels containing the drugs." After the announcement of this verdict the nurse whose name had been mentioned protested and collapsed in court. The coroner, when about to write out the record of the verdict, evidently regarded it as unfair to place on the record the name of the nurse : she was regarded as a thoroughly competent nurse, and she had stated at the inquest that she did not touch the ether bottle, which was already filled. He therefore gave the jury, through their foreman, the opportunity of recasting the verdict so as to omit the nurse's name. The jury accepted the suggestion. The coroner is reported to have then said : " What shall we call it ? " Whereto the jury replied, " Misadventure." A verdict of " Death by misadventure " was then recorded. Even in its original form the verdict seems not to have been intended as one of manslaughter, since mere mistake or error of judgment does not amount to criminal negligence. It does not appear, therefore, that the jury's second thoughts affected any question of criminal liability. They merely eliminated words which need never have been inserted. There is, by the way, good authority for the rule that if the jury finds a verdict of manslaughter and gives particulars which show that the case is not one of manslaughter, the verdict will be quashed (R. *v.* Clerk of the Oxford Assize).

Some will think it a pity that coroner's juries do not confine themselves to a plain verdict without trimmings. Every coroner is aware of the tendency to long-winded verdicts even in simple cases, and (perhaps in the supposed interests of surviving relatives or other parties) to multiplicity of comment by way of rider. On the whole a long verdict is a bad verdict ; the shorter it is, the less to revise. Still the jury has some justification. The Act says that their certified inquisition is to set forth, so far as such particulars have been proved to them, " who the deceased was, and how, when and where the deceased came by his death, and, if he came by his death by murder or manslaughter, the persons if any whom the jury find to have been guilty of such murder or manslaughter or of being accessories before the fact to such murder." There is, however, nothing here to necessitate the mention of persons who are not guilty.

THE DOCTOR'S DAY

"Come, tell me how you live," I cried,
"And what it is you do!"

XX.—ON THE URBAN FRINGE

I AM usually awakened by my terrier who deposits my letters on the bed. This morning amongst the circulars of nostrum vendors and company promoters are several that will want filing later: a batch of medical record envelopes for new panel patients and some green cards requesting the return of others who have ceased insurance or moved out of the district; a report on a sputum; a request for a report on a panel patient who has been drawing sick pay for some months. This is opportune as I had thought of referring her to the regional medical officer myself; she does not seem to be unfit for *any* work, but always has a relapse or new symptoms when I suggest that she might "sign off." There is also a letter asking me to judge at a baby show and a notice of a meeting of the hospital managing committee.

Breakfast is interrupted two or three times by the telephone and soon after 9 A.M. I arrive at the surgery to find four or five people waiting, but the room will fill up just before 10 and I shall be there till nearly 11 as usual. An average morning surgery consists of six to eight private and the same number of panel patients. Most of our panel of a thousand is made up of clerks, typists, and domestic servants, with a few factory workers and shop assistants. Statistics kept over the last three years show that we see 66 per cent. of those on our list and this entails an average of 100 visits and 300 attendances per month.

CASES IN THE SURGERY

This morning's cases are fairly typical. The first is a little girl with a bead in her ear. If it had been in the nose I might have tried pepper, remembering a case where this practical measure promptly produced a sneeze and the invisible bead. The little girl is good and the hole in the bead lies propitiously for quick removal. Would half-a-crown have been exorbitant for a sniff of pepper?

Now come two regulars. The first a case of lupus, who has had a new nose grafted on from her arm. The nares of this had become so contracted that she was becoming a mouth-breather, but last year they were enlarged and she now wears a flesh-coloured prop in each. She should be fit for work soon, but the disfigurement is so great and the public so fearful of infection that I am afraid she will find it very difficult to get employment. I will suggest that she starts looking for work and continue to give her certificates in the meantime. The second is a patient with diabetes who attends a clinic in a London hospital, but comes to me for certificates. Legally I could give her a monthly one, but many societies will not pay out money weekly on a monthly certificate and as she cannot afford to wait a month I see her every Tuesday. Next comes a man for a dressing: quite a pleasant change at the surgery from the writing work. His neck shows a clean wound healing over where a carbuncle was excised five days ago at hospital. Another case is that of a woman at the menopause who fears she may be pregnant with her "seventh." She says it is cheap at 3*s.* 6*d.* to learn there is no pregnancy. Her record shows that she came for the same thing six months ago. Next Mrs. X wishes to engage me for her confinement. It is her first and she is two and a half months gone. I examine her to see that things are normal and take her measurements. As she has not engaged a nurse I give her a list of those I can recommend and send her away with instructions when to come again for further antenatal examination. Making a note in the "mid-book" I turn over the pages. There was a forceps case last week: otherwise I have not used forceps for six months and have attended 24 labours. Midwifery in private practice is much more likely to be normal than one expects after a short training in a lying-in hospital. As I look through the book it seems that the percentage of "normals" became higher and higher during the first five years of practice, so I suppose some of my early forceps were due to over-anxiety and the urge to rush in and do something rather than let nature have her way. My last patient is a young mother with a husband out of work and two children under three years—Will I tell her how to avoid further pregnancies? Information on birth-control is increasingly sought and it is high time the profession made up its mind on the subject and that something should be taught in our curriculum.

Before leaving the surgery I file the sputum report and deal with the panel correspondence. In the letter-box I find an envelope with something heavy inside. It is an old-fashioned door-key with a note requesting a visit later to Mrs. A.

COTTAGE HOSPITAL

From the surgery I go to hospital a mile away. There there is no resident medical officer, and the local practitioners attend their own patients and take duty in monthly rotation to be on call for accidents, anæsthetics, and emergencies. My patient who was operated on for fibroids is doing well; her neighbour is for operation this afternoon. I go over her heart and order an injection to be given beforehand. In the X ray department are the films and report of a barium meal and enema both confirming the presence of a suspected growth of the sigmoid colon. I must arrange for this patient to see one of the consulting surgeons or physicians who come down from London to the hospital on regular days to meet local practitioners and discuss with them their interesting or puzzling cases. The patient is saved the expense of train journey and hours of waiting at an out-patient department and appreciates the greater privacy and often less hurried examination given by the specialist. The practitioner has the advantage of discussion over the case and can moreover keep in contact with the patient right through an illness instead of losing sight of him during the most critical and interesting part of it, as so often happens when cases are sent to hospital out-patient departments.

In the children's ward my case of empyema is being dressed and I take the opportunity to go over her chest. A case of tonsillectomy has earache and remembering my own experience of three years ago, I ask sister to wrap warm wool round neck and ear.

It is now past eleven and I hurry home to hot chocolate and an appointment with a well-to-do woman who is suffering from the so-called "nervous breakdown." This is a delicate interview because I want her to consult a psychologist and yet not to feel that I have any doubt about the state of her mind.

A MORNING ROUND

After this comes the morning round, the first visit being to a nursing-home where a patient is recovering from an operation for hæmorrhoids. Here a telephone message reaches me to go at once to a case of asthma. I call for adrenaline as I pass home and the road takes me along a ridge between green fields to a house on the border of the district opposite the last street lamp; beyond this are only country roads unlit at night. The little boy I have to see suffers from asthma and eczema and at last we have tracked down the cause—sensitivity to horse dandruff. He cannot ride without getting eczema behind the knees or go for a drive in a dog-cart without an attack of asthma. He even got an attack after visiting the circus at Olympia. It had been half-term and he could not resist a canter round the grounds on his pony—result, an attack of asthma. He is given an injection of adrenaline and is soon relieved. Next I go to a house where I am always sure of a vociferous welcome and this from a patient who will care unless they are now in their final year of medical school.

IDIOPATHIC PLEURISY AS A RISK IN LIFE ASSURANCE

Louis I. Dublin and Herbert H. Marks have recently made a study for the Metropolitan Life Insurance Company of the risk of insuring applicants who give a history of "idiopathic" pleurisy. They fully recognise that these cases represent true pleurisy of various but unrecognised origins and also some cases that were not true pleurisy at all. Nevertheless their statistical analysis of these cases is full of interest. They found that the excess mortality was for the most part concentrated in the years immediately following issuance of insurance and was more marked among the younger policy-holders. Underweight adds to the bad prognosis in the younger age-groups but is of less importance in those of more mature years. The excess mortality is, as might be expected, largely due to death from tuberculosis. They conclude that no applicant with a reliable history of wet or dry pleurisy should be granted insurance within two years of his illness, nor within three years if he be under 35 years of age. If he is below this age ten years must elapse before the applicant can be accepted as a normal risk. At ages over 35 a few cases may be granted standard insurance after five years have elapsed. The majority of cases reporting pleurisy of unspecified type (neither "wet" nor "dry") lasting only two or three days may be treated with generosity. Such a history is not regarded as of much importance.

DEATH OF MAYOR CERMAK

The death of the mayor of Chicago from an assassin's bullet aimed at President Roosevelt is deeply regretted. Among the reforms established in his administration is to be counted an ordinance passed on May 4th, 1932, creating a board of health of five members. For a number of years before this Chicago had no legally authorised health department. The ordinance of May 4th last reorganised the personnel of the department, eliminating waste and increasing efficiency.

PANEL AND CONTRACT PRACTICE

Medical Benefit and the Unemployed

In the House of Commons last week Mr. Leckie asked the Minister of Health what he proposed to do about medical attention for the 60,000 or more insured persons who would, owing to recent legislation, pass out of benefit at the end of the present year; and the Minister answered that they would then be in the same position with regard to medical attention during sickness as all other persons who are now not within the scope of national health insurance. But is this really so? Most people leaving the ambit of the Insurance Act do so of their own accord. They may exceed the wage limit and so become able to pay for their treatment; or they may marry and again voluntarily pass out of insurance. But here are 60,000 or more people who, through no action of their own, are unable to pay insurance contributions. They belong to the insured group and not to any other; they are not passing out of benefit voluntarily—because of altered circumstances. They were obliged to become insured persons when first employed, and as such they had to choose to look after them a doctor who was willing to serve under the Act. Now when they go out of insurance benefit they will in theory be able to have the doctor of their choice, but it is perfectly clear that they will not in fact be able to do so, because they are not in a position to pay private fees. They will ordinarily receive attendance by those who still are, but are no longer called, parish doctors with the stigma attached to what used to be called poor-law relief. We have referred before to this unfortunate discontinuity of medical benefit, believing it to be a penny-wise policy on the part of the Ministry to treat this class differently from those who are better off. In the meanwhile, surely it is not correct to say they are in the same position as all others without the scope of the Act.

Records Then and Now

In the *St. Bartholomew's Hospital Journal* for March Dr. Philip Gosse has an interesting story to tell of contract work before the Insurance Act came into force. The club doctor was then appointed by the committee, and while it was definitely unwise to neglect any club members, the more especially if they were the friends of the council or of a member of the committee, yet the amount of attendance expected was not nearly s[illegible] what was at the present day. There was less tendency to make much of illness than there is now, for all the members of the club knew each other; the secretary was soon warned, and through him the doctor, that John Smith was not fond of work and it was quite time he ceased to be drawing club funds. The snag of the position medically was that if trouble arose about a particular member, and the committee of management became hostile to their doctor, he was apt to lose the whole club and not, as under present insurance practice, only that member and his family. Nor was the keeping of records included in the capitation fee. While it may be true that the records required under the Act of 1911 have not materially varied since, Dr. Gosse makes good fun of the large folding book containing name, age, sex, address, visits, and medicine supplied, which had to be sent to the insurance committee for periodical inspection. His cheque for the first quarter arrived punctually, but at the end of the second quarter none came; after expostulating he was told that no cheque would be sent until his records for the previous six months had been received for examination. "So after dinner that night," he writes, "I got down to it, and filled in a vast number of sheets with the names of every panel patient I thought I could remember having treated, with suitable crosses or lines to indicate domicilary calls or visits to my surgery. When I had made out what seemed to be enough of these to meet the requirements, I posted them off, and received my cheque by return." That such a feat of imagination was even then not unattended with risk may be seen from the sequel: "Not long afterwards a letter of thanks reached me from the local secretary to say that he had been instructed to write and inform me that at headquarters my meticulous and conscientious care of my insured patients was much appreciated, and that they hoped the example I had set would be followed by the other doctors in my area. It seemed that, according to the statistics, I had visited my patients at a rate of 300 per cent. higher than any of my colleagues." This official approval did not, however, increase his popularity, as a newcomer, with his fellow-practitioners, and afterwards we learn that he "fell into line and gradually brought down my numbers of visits to coincide with the rest." Things are strangely different to-day when the Ministry of Health have worked out areal averages for all kinds of practice, and H.M. Inspector of Taxes knows everything.

CORRESPONDENCE

FOOD AND HEALTH

To the Editor of THE LANCET

SIR,—I trust that all those concerned with the hysical condition of the unemployed, and especially f their children, will read the special article on Food and Health in your last issue. A careful study f this valuable contribution is especially desirable ecause certain reassuring reports have appeared recently. Thus at the meeting of the London County Council on March 8th, a report of the examination of the children in the elementary schools of London during 1932 was submitted. In this it was shown that the percentage of children found with abnormal nutrition, which was 4·8 in 1930 and 1931, ad only risen to 4·9 in 1932.

One cannot feel that conditions are satisfactory even when 4·9 per cent. of the children in the elementary schools of London are reported as suffering from want f the right sort of food, nor can one feel absolutely ssured that the reports of the school medical officers record fully and completely the results of the present period of financial stringency on the health of the school-children. The effects of under-nourishment are by no means always easy to detect by physical xamination. Moreover, they do not become evident at once. Furthermore, the amount of malnutrition that is recognised by an observer must obviously depend on the standard that he has in his mind during examination, and it is very easy for those engaged in this work to *confuse the average with the normal.* Should this confusion continue year by year, and about 5 per cent. of the children be recognised each year as below the *average*, a very considerable divergence from the *normal* may in fact exist after a period of years. That something of this sort is possible is suggested by two considerations: (1) a special report to the L.C.C., and (2) my own observations.

(1) On Jan. 17th last the medical officer of the L.C.C. reported on a special examination of 25 children of nine families attending a school in Poplar. These families were selected because social workers in the district felt uneasy about the children belonging to them. It was reported, however, after medical examination that the nutrition of only 7 of these 25 children was below the average, and in no case greatly so. The weights of 24 of these children were given in the report, and when I compared these with the average weights of children in the elementary schools of London at different ages I found that in 19 of the 24 the weights were below the average. The number of children examined is admittedly small, but it does seem significant that while only 28 per cent. showed signs of malnutrition as many as 76 per cent. were below the average weight of children of the same age in the elementary schools.

(2) During January and February, 1933, the medical examination of 53 children belonging to 21 families of the unemployed in one of the western districts of London was undertaken. The families were selected because we had reason to believe that members, other than those we examined, had shown signs of under-nourishment. There was, however, no selection of cases, and the record of every child examined is included in this report. I was assisted in this work especially by Dr. Margaret Ritchie, who examined with me about 90 per cent. of the children on whom we are reporting. Every child was examined by two of us before any opinion was given as to its physical condition.

In all cases the children were stripped and weighed, and their weights were later compared with the table of average weights of the school-children of London obtained from the education department of the L.C.C. In an explanatory note given with this table of weights, it is stated that the true weights of children under 7 are probably a little higher than those given in the Table. The children were examined in their homes and all were of school age with the exception of five that had not quite reached this age. In several of the families there were children below this age as well as a few above, but these were not examined.

We classified the defects observed under four headings: thin, rickety, flabby, pot-bellied. In not a few cases two defects were observed in the same child. In some cases we found it a very difficult task to determine whether a given child's condition was due to under-feeding or not. We appreciate that none of the above defects is necessarily an indication of under-nourishment; indeed, as will be seen in the Table which follows, with the exception of rickets, each of the defects described was observed in children that we did not regard as being underfed.

We have divided the children, for classification purposes, into those that in our opinion showed signs of under-nourishment and those that did not, and the general results of our observations are as follows:—

Under-nourished

No.	Sex.	Of average weight or over.	Below average weight.	Thin.	Rickety.	Flabby.	Pot-bellied.
15	Boys	2	13	11	4	2	4
8	Girls	7	11	9	11	3	3
23		9	24	20	15	5	7
			Not Under-nourished				
6	Boys	4	2	2	—	1	1
14	Girls	9	5	2	—	—	1
20		13	7	4	—	1	2

We also made inquiries of the parents as to how many of the children were having milk or dinners at school. We were informed that of the children showing signs of under-nourishment none was having dinners at school, but four were having milk which was given free. Of the children not showing signs of under-nourishment four were having school dinners given free, and three were receiving milk for which a charge was made. Several of the parents of the children showing signs of under-nourishment informed us that they had applied for school dinners, but these had been refused.

We were fortunately able to obtain and verify the income of each household and also the rent paid, and could therefore calculate the exact amount per head available to provide food, warmth, clothing, cleansing materials, and other necessities of life. This varied from 1*s.* 4*d.* to 4*s.* 6*d.*, and averaged 2*s.* 5½*d.* per week.

It might be objected that although 2*s.* 5½*d.* is a very small sum to provide all necessities, some of the persons concerned were very small children whose needs may have been much less than those of an adult or older child. Accordingly use was made of a table given by E. P. Cathcart and A. M. T. Murray in their report to the Medical Research Council (Spec. Rep. Ser. No. 151, 1931), and the "man never pay his fee. He is a mongrel dog who had suffered for years from corneal ulcers. He has not had one now for four years and bounds upstairs to talk to me while I see the lodger, a maternity nurse with angina pectoris. She is happy now because last month her landlady had a baby daughter and she nurses the baby occasionally; but the dog is very jealous.

The morning round takes me seven miles out through hedge-lined lanes past young lambs in one field and the herd of a model dairy in another, to a combined poultry and fruit farm. The owner fears she has cancer as she has found a "lump." It turns out to be so but I do not tell her. As she refuses operation I can only try to persuade her to see a surgeon so that my responsibility will be shared. On the way back I call on Mrs. A. and am glad to be rid of the key which has been weighing down my pocket all the morning. I let myself in, taking the loaf of bread and bottle of milk which have been left on the doorstep to the kitchen. Mrs. A. is in bed with a sore-throat, temperature, and some painful spots on her legs. She says she has only stayed in bed to save my time and is very distressed to be told she must remain there and that her daughter will have to leave work and come home to look after her and the rest of the family. After four short visits I come to the last for the morning. This is to a wealthy woman who has had a slight chill, and being very fearful of her health wants to know if it will be safe for her to go to a theatre to-night. This visit takes longer than any other although it is the most trivial. The pros and cons are argued and I urge her to go, which I know she had intended from the first, or she would not have telephoned for me.

This is a specimen morning and might be varied by giving gas for teeth extraction; anæsthetics for minor operations; or very rarely by doing a post-mortem or giving evidence at court. Once my partner had to go to town to choose a baby from an adoption society for a childless patient.

THE AFTERNOON

The afternoon is spent in finishing the round which usually takes till 4 or 5 P.M. in the winter, but may be quite free in the summer. On one afternoon a week we do tonsil and adenoid operations for the education committee; another is taken up by operations; and a third for consultations. My partner holds two surgeries a week in a village to which a number of our better-to-do patients have moved out and where a far-sighted builder is putting up villas as fast as he can.

The evening surgery is usually larger than the morning one as patients in work are only free to come then. In winter there may be 24 or more cases which means at least 2½ to 3 hours work, but in summer I have usually finished in 1½ hours. A day such as this is calm but sometimes everything is upset, as by a midwifery case coming off in the middle of surgery hours, or an accident call from the police.

A CHANGING BACKGROUND

It is not claimed that such a day has any special features distinguishing it from that of general practice elsewhere, except perhaps in its adaptation to a changing background. Fourteen years on the urban fringe have brought changes to the doctor's work as well as to the life of the people and the look of the district. My partner and I run our surgery in a 300-year-old wooden house, which is now practically the only old building in a town of modern shops and flats, and which is quite dwarfed by the giant trams passing to the market-place. Gone is the ancient cedar-tree which had been a landmark for miles, and the Tudor house with royal associations and underground passages to rectory and church. Gone is a fine old red-brick mansion and its handsome wrought-iron gates, which have been removed to one of the universities; in its place is a housing estate with paved streets and roofs of houses all hideously alike. Here and there in the district i is still possible to see red-tiled roofs overgrown wit moss. Occasionally one finds beautiful oak panellin in a coal office, or a four-poster bed filling a smal bedroom to capacity, but these discoveries are rar like the text-book case in a doctor's day.

The population, too, has changed. The better-o people are yearly moving further away from th encroaching sea of small villas, with its concomitant the 'buses, trams, and coaches, and only those remai whose profession or business makes it a necessity t live near town—a few perhaps for the sake of school for the children. Because of this the practitione has to work harder for the same income. Two visit must be paid instead of one for the same fee, but i does not mean that the hours are twice as lon because houses are now much closer together an as the patient is often as busy as the doctor ther is less ceremony and waste of time in small tal Until the last few years we only had a few pensione and club patients, but the number of the latter ha been swelled considerably since the spread unemployment. If this is to continue a system insurance for dependants would benefit doctors much as patients. Amongst other changes is t growth of the telephone system. It is now qui a rare event to hear the night bell, for call box are numerous and the public expert. Midwife cases are fewer, partly owing to the fall in birth-rat and partly to the inconvenience and publicity "rooms" in a house shared with other famili For this reason many mothers prefer admission a lying-in hospital.

Practice on the urban fringe affords varied oppo tunities for spending one's leisure. For the studio there are post-graduate courses or meetings medical societies which can be regularly attend without putting extra work on one's partner. is quite possible to act as clinical assistant at out-patient department during the afternoon an to be back for the surgery in the evening. F the sportsman there is easy access to Twickenha Lord's, or Wimbledon, with golf, hockey, tenni and swimming at his own back door. Those wh like town life may attend first nights or sympho concerts, while for the country lover there are other joys, not half an hour from home.

Altogether a good place to live and work in.

THE SERVICES

ROYAL NAVAL MEDICAL SERVICE

Surg. Capt. L. M. Morris is placed on the retd. list.

The following appointments are notified: Surg. Comdr. F. C. Hunot to *Ganges*, for R.N. Sick Quarters, Shotley. Surg. Lt.-Comdrs. R. W. Higgins to *President*, for course; D. A. Newbery to *Pembroke*, for R.N.B., Chatham, and to *Renown*; and T. B. Lynagh to *Dolphin*. Surg. Lt. W. J. M. Sadler to *Pembroke*, for R. M. Infirmary, Deal.

ROYAL NAVAL VOLUNTEER RESERVE

Surg. Lt. G. H. Sellars to *Renown*.

ROYAL ARMY MEDICAL CORPS

Capt. E. H. Hall, from the secd. list, is restd. to the estab.

J. N. Concannon to be Lt. (on prob.).

TERRITORIAL ARMY

J. E. Morrison (late Offr. Cadet Edin. Univ. Contgt., Sen. Div., O.T.C.) to be Lt.

INDIAN MEDICAL SERVICE

Lt.-Col. (Bt. Col.) E. C. Hodgson to be Col.

Capt. M. Rodrigues relinquishes his temp. commn.

NAVAL MEDICAL COMPASSIONATE FUND

A meeting of the subscribers of the above fund will be held at 3 P.M. on April 19th next, at the Medical Department of the Navy, Admiralty, S.W., to elect six directors of the fund.

My chief reason for writing to you is that a short ime ago I came across an instrument that to me was unique, one that checks its own readings with an ordinary sphygmomanometer and anyone could earn to use successfully in a few minutes.

Briefly, it is as follows. There is the usual armlet o which is attached an ordinary manometer—not a mercurial one, unfortunately. A bracelet with an efficient tambour for the brachial artery is provided. A stethoscope is also supplied, and this one couples up with the tambour by means of a Y-piece. Coupled up with the manometer by a rubber tube is an oscillometer; on this there is, of course, an interrupter. According to the oscillations of the needle, one can read off *on the manometer* the three pressures—systolic, mean, and diastolic. The figures on the oscillometer mean nothing apart from allowing one to measure the size of the deflections.

The chief value of the instrument is, in my opinion, the ease with which one can estimate the mean pressure; the systolic and diastolic can be estimated by any manometer. It is made at the Laboratoire du Detensyl at Nice, the British agents being Continental Laboratories, Ltd. It is very well got up, and is carried in a light leather case, and the price is low—£3. I am, Sir, yours faithfully,

A. GRAHAM-STEWART.

Ulster-place, N.W., March 18th, 1933.

THE INTIMATE NATURE OF NERVOUS ACTIVITY

To the Editor of THE LANCET

SIR,—Your leading article (March 18th, p. 589), written, no doubt, with high authority, contains some statements which are difficult for the non-expert reader to understand. It is said that the passage of a nervous impulse "is followed at once by a refractory period . . . Hence summation of impulses is impossible—for at the moment during which one impulse is occupying the wire another cannot be added to it." Surely it is not suggested that summation is, or would be, produced by the *simultaneous* passage of a number of impulses along a nerve fibre. It was shown by Keith Lucas that, if a region of decrement—that is, a region in which conduction is difficult—is introduced into the course of a nerve-fibre, nervous impulses undergo a progressive diminution in intensity in their passage through that region, until eventually they may be extinguished. But, if a nervous impulse manages to survive its passage through the region of decrement, it emerges on the other side in full intensity regardless of the strength of the stimulus which originated it, or of the amount of diminution which it has undergone. Further, the passage of a nervous impulse is followed by a period during which conductivity is diminished (the "refractory period"), and this, in turn, is followed by a period during which conductivity is increased (the "supernormal phase.") If successive nervous impulses are timed so that each one after the first falls within the refractory period of the one which preceded it, a complete block may be established so that no impulses are able to pass through the region of decrement. But, if the impulses are timed so that each one arrives during the period of increased conductivity which follows the preceding one, it becomes eventually possible for impulses to pass through the region of decrement, and, as already noted, they emerge on the other side in full intensity. This, surely, is what is meant by the "summation" of nervous impulses.

There is a strong presumption that the same processes occur in the case of the nerve-cell. It is true that in Keith Lucas's experiments the region of decrement in nerve-fibre was produced by artificial means. It is probable that the nerve-cell is more susceptible than the nerve-fibre to natural diminution or increase of conductivity, possible, as you suggest, by the action of hormones or "humoral stimuli." And it is more than probable that the natural regions of variable conductivity in the nervous system are situated mainly at the synapses and junctional tissues. But it is not at all evident (to the uninitiated) that "the nature of the processes in those two parts of neural tissue (the nerve-fibre and the nerve-cell) is different." One would also like to know whether there is any evidence that *an* impulse arriving at *the same* ganglion cell may either arrest activity or stimulate it: and, lastly, why inhibition is not "comparable with the refractory phase of nerve transmission"?

These remarks are not made in any spirit of captious criticism. Keith Lucas, one of the most brilliant scientists that I have ever known, had a shrewd conviction that the processes of conduction in the central and in the peripheral nervous system would be found to be fundamentally of the same nature. If this be true, there is good reason to hope that much may yet be learnt from the comparatively simple study of the processes in peripheral nerve. "If the central nervous system involves processes which are entirely unknown in peripheral nerve, then the analysis of peripheral conduction loses a great deal of its interest and the problem of central conduction becomes infinitely more formidable" (Keith Lucas).

It will be noted that Prof. Hill's work (quoted in your article) is concerned entirely with processes occurring in peripheral nerve.

I am, Sir, yours faithfully,

A. S. BLUNDELL BANKART.

London, W., March 21st, 1933.

PUBLIC HEALTH SERVICES

Ministry of Health on Local Expenditure

THE comments of the Minister of Health on certain sections of the report of the Committee on Local Expenditure[1] have been issued in Circular 1311,[2] addressed to local authorities. The general soundness of the principles on which the committee based their concrete proposals, and indeed of many of the proposals, is not questioned, but the Minister points out certain considerations which must not be ignored. The most important of these is that the public health service cannot be static; some measure of development and new expenditure is inevitable as fresh needs become manifest. Outstanding instances, he says, include maternity and child welfare, in respect of which few authorities have yet established a complete service; and in some remaining areas, where this is desirable on public health grounds and also feasible, the appropriation of poor-law infirmaries. In all such matters of development the need for economy must be weighed against the urgency of the suggested public health development. Among the recommendations of the committee to which local authorities are asked to give special attention are those advocating better coöperation in regard to infectious diseases hospitals, the more careful selection of patients sent to sanatoriums, the shortening of the routine period of isolation for uncomplicated cases of scarlet of digestive functions have been the only definite symptoms. Each had been examined clinically by several doctors. Gastro-intestinal function had been investigated chemically and radiologically, and the symptoms had been attributed to "functional" causes. After many months had elapsed, and different doctors had been consulted, the underlying basis of the symptoms—viz., pulmonary tuberculosis—was revealed by radiographic examination of the chest. On admission the blood sedimentation-rate was in each case appreciably increased above normal, and examination of the radiograms of the chest showed that the pulmonary disease was at least of several months' duration. It would appear probable that, had the first clinical examination been completed by an estimation of the sedimentation-rate, a toxæmic cause for the symptoms would have been definitely established, and radiographic examination of the chest recommended many months before it was actually done.

---

[1] See THE LANCET, 1932, ii., 1238.

[2] H.M. Stationery Office. 2s. 6d.

In conclusion, owing to the fact that a number of patients who have had serofibrinous pleurisy develop active pulmonary tuberculosis within a few years, attention should be paid to the sedimentation-rate during convalescence from the pleural effusion; this in particular to determine the length of convalescence required, and to regulate the patient's activities. Further, such patients should be warned to return for examination should they notice any departure from normal health, and sedimentation estimations will be found of value in these periodic examinations. My experience suggests that in the majority of cases where pulmonary tuberculosis develops after pleural effusion, the sedimentation-rate has not settled to normal, and that, in spite of this indication of the smouldering of the disease, the patient's activities have been insufficiently limited.

I am, Sir, yours faithfully,
HILARY ROCHE.

The British Sanatorium, Montana, March 16th, 1933.

THE COCKTAIL IN HYPOGLYCÆMIA

To the Editor of THE LANCET

SIR,—In the leading article on Spontaneous Hypoglycæmia in THE LANCET of March 11th (p. 533) it is suggested that the wide popularity of the cocktail before a meal is in part due to the relief of hypoglycæmia which it brings. This may give rise to the impression that it is the alcohol in the cocktail that "does the trick." Recent work by Edkins, Murray, and Hunt points to the fact that alcohol tends to produce a hypo- rather than a hyper-glycæmic condition. The two former workers have shown (*Jour. of Physiol.*, 1931 and 1932) that in normal human subjects alcohol with glucose decreases the degree and duration of hyperglycæmia, and that small doses of alcohol given to normal human beings lower the blood-sugar slightly. T. C. Hunt (THE LANCET, 1930, i., 121), dealing with alcohol given to diabetics, refers to experiments by others showing that alcohol tends to reduce rather than increase blood-sugar, and speaks of the action of alcohol as "such insulin-like action." There may be differences of opinion with regard to the value of a cocktail, but it should be clearly understood that whilst the glucose in a drink might possibly help, the alcohol (and in a cocktail it is present in a high percentage) will more likely increase than decrease the hypoglycæmia.

I am, Sir, yours faithfully,
COURTENAY C. WEEKS.

Beckenham, March 15th, 1933.

TREATMENT OF ENLARGED TONSILS IN CHILDREN

To the Editor of THE LANCET

SIR,—I have read the article by Mr. T. B. Layto in your issue of March 11th with some surprise The conclusion Mr. Layton arrives at is that the grea indication for operation is the history of recurrin follicular tonsillitis. This however, he states, rarel occurs in small children. Therefore removal o tonsils in children up to 5, 6, 7, 8 years of age shoul not be done unless it can possibly be helped.

He says, however, that instead of developin recurring tonsillitis these children are subject t "droplet infection giving them an inflammation o the upper respiratory tract," and that later o tonsils which are primarily filters for holding organism and factories for the production of immune bodie instead of resisting invasion become themselves th cause of trouble and are a source of sepsis, but tha in spite of this they should not be removed unless the rare complication of recurring tonsillitis should occur. This amounts to saying that the child is to keep up to 12 years of age a septic focus, giving rise to a chronic infection both local and general, because the lymphoid tissue in the pharynx (of which the tonsil is only a part) is necessary to the child's development. As a school medical officer I see hundreds of children every year, and in conjunction with many of my colleagues in other areas I am firmly convinced that the conclusions above arrived at are not supported, judging by the beneficial results one sees from the effect of early operation on children with enlarged septic tonsils. As school medical officers who advocate operation appear to have come under some criticism in the Report of the Chief Medical Officer of the Board of Education for 1931 I have written a fairly full account of this subject for my committee in my report for 1932.

The conclusions I put forward are: (1) lymphoid tissue is primarily protective; (2) this tissue when exercising its protective function becomes enlarged; (3) if the infection is overcome the swollen tissue will again subside; (4) if the resistance of the tissue and the individual is low, enlargement will persist; (5) the persistence of enlargement means the presence of a septic focus; (6) chronically enlarged tonsils must have lost any beneficial action they may have ever possessed and must be regarded as a source of danger immediate and remote; (7) such septic foci ought to be removed. This is no attack on a normal structure of the body but upon a diseased organ.

The particular point I wish to emphasise is that it is high time the medical profession threshed this matter out and came to some agreement, as otherwise our differences are likely to be a source of derision among the lay public. To operate or not, that is the question; and one answer only can be correct.

I am, Sir, yours faithfully,
W. W. JEUDWINE, M.D.,

March 20th, 1933. School Medical Officer, Newport, I.W.

OSCILLOMETRY AND THE "MEAN" PRESSURE

To the Editor of THE LANCET

SIR,—I was greatly interested in your annotation on this subject. I feel sure that the estimation of this mean pressure is of much greater value than has hitherto been realised. French workers have laid stress on this for some time now, and in this country Dr. J. F. Halls Dally has done the same. With the Pachon type of instrument I have never been particularly happy—possibly my own faulty technique.

y chief reason for writing to you is that a short ime ago I came across an instrument that to me as unique, one that checks its own readings with n ordinary sphygmomanometer and anyone could arn to use successfully in a few minutes.

Briefly, it is as follows. There is the usual armlet which is attached an ordinary manometer—not a ercurial one, unfortunately. A bracelet with an fficient tambour for the brachial artery is provided. stethoscope is also supplied, and this one couples p with the tambour by means of a Y-piece. Coupled p with the manometer by a rubber tube is an oscillo-eter; on this there is, of course, an interrupter. ccording to the oscillations of the needle, one can ad off *on the manometer* the three pressures—ystolic, mean, and diastolic. The figures on the scillometer mean nothing apart from allowing one measure the size of the deflections.

The chief value of the instrument is, in my opinion, he ease with which one can estimate the mean ressure; the systolic and diastolic can be estimated y any manometer. It is made at the Laboratoire u Detensyl at Nice, the British agents being Continental Laboratories, Ltd. It is very well got up, nd is carried in a light leather case, and the price is w—£3. I am, Sir, yours faithfully,

A. GRAHAM-STEWART.

Ulster-place, N.W., March 18th, 1933.

THE INTIMATE NATURE OF NERVOUS ACTIVITY

To the Editor of THE LANCET

SIR,—Your leading article (March 18th, p. 589), ritten, no doubt, with high authority, contains ome statements which are difficult for the non-xpert reader to understand. It is said that the assage of a nervous impulse "is followed at once by refractory period . . . Hence summation of npulses is impossible—for at the moment during hich one impulse is occupying the wire another annot be added to it." Surely it is not suggested hat summation is, or would be, produced by the *imultaneous* passage of a number of impulses along a erve fibre. It was shown by Keith Lucas that, if a egion of decrement—that is, a region in which onduction is difficult—is introduced into the course f a nerve-fibre, nervous impulses undergo a progres-ive diminution in intensity in their passage through hat region, until eventually they may be extinguished. ut, if a nervous impulse manages to survive its assage through the region of decrement, it emerges n the other side in full intensity regardless of the trength of the stimulus which originated it, or of the mount of diminution which it has undergone. urther, the passage of a nervous impulse is followed by a period during which conductivity is diminished (the "refractory period"), and this, in turn, is followed by a period during which conductivity is increased (the "supernormal phase.") If successive nervous impulses are timed so that each one after the first falls within the refractory period of the one which preceded it, a complete block may be established so that no impulses are able to pass through the region of decrement. But, if the impulses are timed so that each one arrives during the period of increased conductivity which follows the preceding one, it becomes eventually possible for impulses to pass through the region of decrement, and, as already noted, they emerge on the other side in full intensity. This, surely, is what is meant by the "summation" of nervous impulses.

There is a strong presumption that the same processes occur in the case of the nerve-cell. It is true that in Keith Lucas's experiments the region of decrement in nerve-fibre was produced by artificial means. It is probable that the nerve-cell is more susceptible than the nerve-fibre to natural diminution or increase of conductivity, possible, as you suggest, by the action of hormones or "humoral stimuli." And it is more than probable that the natural regions of variable conductivity in the nervous system are situated mainly at the synapses and junctional tissues. But it is not at all evident (to the uninitiated) that "the nature of the processes in those two parts of neural tissue (the nerve-fibre and the nerve-cell) is different." One would also like to know whether there is any evidence that *an* impulse arriving at *the same* ganglion cell may either arrest activity or stimulate it; and, lastly, why inhibition is not "comparable with the refractory phase of nerve transmission"?

These remarks are not made in any spirit of captious criticism. OBITUARY

ARTHUR COOKE, M.B., B.Ch. Oxf., F.R.C.S. Eng.

WE announced last week the death of Mr. Arthur ooke, surgeon to and surgeon in charge of the phthalmological department at Addenbrooke's ospital, Cambridge. This occurred on Monday, arch 13th, at his house, Grove Lodge, Cambridge, fter a brief illness, the sudden termination to which as unexpected.

Arthur Cooke was the son of Henry James Cooke, Bradford, and was in his 65th year. He was ducated at Giggleswick and New College, Oxford, d after taking honours in the Natural Science chools proceeded for his medical training to the London Hospital. He graduated M.B., B.Ch. Oxf. in 1895 and almost immediately took up practice in Cambridge as surgical partner to a well-known firm. During the war this partnership was dissolved and afterwards Mr. Cooke practised as a consultant. In 1898 he was made an M.A. Camb. and in the same year obtained the diploma of F.R.C.S. Eng.

MR. COOKE

Prior to the war Cooke was a major in the Territorials, and at the outbreak ostilities he served on the staff of the First Eastern eral Hospital. He soon went to France where he attached as a surgeon to various military hospitals, at the close of hostilities was a Lieut.-Colonel in R.A.M.C. At the end of the war he became sident of a joint organisation of the Y.M.C.A. the C.E.Y.M.S., and was responsible at Cambridge the formation of a panel of blood donors, composed members of the Y.M.C.A., which was attached to lenbrooke's and which still functions.

o Addenbrooke's Cooke was a devoted servant. became assistant surgeon to the institution nearly years ago, and having already specialised in thalmic work he was placed in charge of the thalmic department of the hospital on the retirement of the late George Wherry. On becoming surgeon to the hospital he was appointed teacher urgery at the University, and at various times d as an examiner for the medical degree. He also one of the most active movers for the recent nsion of the hospital. As a member of the eal and propaganda committees and an active ker on various subcommittees, he spoke assiduously many centres in the county in support of the ement, and last year he saw the realisation of of his principal objects—namely, the completion e new eye wards.

colleague writes of Arthur Cooke and his hospital k in words which may be quoted in full. "Above hat he achieved," he says, "Arthur Cooke had lities which bound him to all with whom he came ontact. It would be difficult to find a more loyal, energetic, and enthusiastic colleague on a hospital staff. As senior surgeon to the hospital and surgeon in charge of the eye department he did the work of two men, and it was only his boundless keenness that made this possible. He never spared himself and certainly never seemed to want to. At the end of a long out-patient morning, the way in which he would apply himself with zest to the examination and discussion of a fresh case was characteristic of all his work. He rarely appeared tired and always seemed to enjoy his work so that to consult him was a pleasure. His surgical technique reached a very high standard and this was maintained up to the time of his death. Perhaps he excelled most in gastric surgery, and some of his colleagues will always remember the faultless technique displayed at a particular gastrectomy which he performed about three months ago. In spite of an enormous amount of routine work he found time to read widely and keep up to date, and was continually improving both his own methods and the work of the hospital by meticulous attention to detail. In this respect he remained always young and a stimulus to all who worked with him. In addition to his hospital work he had a very large practice as a consulting surgeon. On the administrative side his personality and charm smoothed over many difficulties. He always seemed to know exactly how far the opposition would allow him to go. If he were held up temporarily his tact and friendliness usually took him a good deal further ultimately. This power was one of the biggest factors which brought to completion the extensive scheme for enlarging Addenbrooke's, and it is probable that the raising of the £85,000 obtained for this purpose would never have been attempted but for his leadership and charity. In the face of a great loss it is pleasant to think that he saw the hospital of his dreams, in buildings and equipment at any rate, standing almost complete before he died."

The activities referred to in the quotation above should be enumerated. Cooke was a member and ex-president of the Cambridge Medical Society and an active supporter of the work of the B.M.A., at one of whose annual meetings he had been president of the surgical section. He was chairman of the house committee of the Evelyn nursing-home, and consulting surgeon to the Papworth Village Settlement, the Rous Memorial Hospital at Newmarket, and the Royston Cottage Hospital. He was also a distributor under Crane's Charity, a fund which assists undergraduates of the University in the payment of medical and nursing fees, and had interested himself in the life insurance of the students. He was the author of a sound elementary text-book on surgery, and of various contributions to medical journals.

In private life Arthur Cooke was a man of varied activities. At Oxford he obtained his blue for cross-country running, and both there and at the London Hospital was a prominent footballer. He was a fine skater, president of the University skating club and medallist of the National Skating Association. He had been captain of more than one golf club, he sailed his boats regularly on a Norfolk Broad, and was among the earliest drivers of a motor-car in the neighbourhood.

Mr. Arthur Cooke married in 1891 Lucy, only daughter of the late Mr. John Collyer of Edgbaston, and leaves a widow, a daughter, and two sons; his eldest son was a victim in the *Vanguard* disaster at fever, the treatment of mild cases of scarlet fever at home, the practice of terminal disinfection, and the reservation of institutional treatment to those who cannot be treated otherwise.

Birth- and Death-rates in Northern Ireland

Although, according to the report of its Registrar-General,[3] the birth-rate of Northern Ireland in 1931 was, with one exception, the lowest recorded since 1901, it still enjoys the distinction of being the highest in the British Isles. At 20·5 per 1000 of the estimated population it is some 30 per cent. higher than the present rate of England and Wales (the comparison is of crude rates, but the proportion of the population in the two countries that is made up of women at the child-bearing ages does not differ appreciably, and measurement of the rates as births per 1000 women aged 15 to 45 years would give approximately the same result). In 1901–05 the birth-rate in England and Wales was 28·2 per 1000 living at all ages, and save for the exceptional post-war period it has practically never ceased to fall; by 1926–30 it had fallen as low as 16·7 per 1000, or 59 per cent. of its value at the beginning of the century. In Northern Ireland, on the other hand, reading from one of the diagrams included in this report, the rate in 1901–05 was about 25 per 1000—i.e., *below* the English rate; by 1926–30 it had declined to only 21 per 1000 and was therefore still over 80 per cent. of its value at the beginning of the century. For the years 1928–31 it has remained practically stationary at 20 to 21 per 1000. One possible explanation of this relatively high rate is the restrictive influences of Catholic principles, but in opposition to this it will be remembered that W. T. Russell found, in his careful study of Irish fertility,[4] that the fertility in the counties of Antrim and Down, including the borough of Belfast, had declined only 8 per cent. during the 40 years 1871–1911 as compared with 30 per cent. in rural Wales; and in these two counties the Catholic population, he concluded, comprised at the utmost only 25 per cent. of the total. From 1928 to 1931 this report of the Registrar-General shows that the highest birth-rates of Northern Ireland are to be found in the two county boroughs, Belfast and Londonderry (as the calculation is based upon the populations at the census of 1926 these rates would be overstated if there has been any expansion of these areas in the last five years).

Turning from the birth-rates to the death-rates it will be noticed that the latter for Northern Ireland compare in one respect very curiously with those of England and Wales. Comparison of the standardised rates for all causes shows that the males of the two countries do not differ very appreciably in their mortality; in 1931 the Northern Ireland rate was 11·7 per 1000 and the England and Wales rate was 11·4; for the five years 1927–31 the rate in Northern Ireland was 12·0 per 1000, in England and Wales 11·6. The males suffer a slightly higher rate of mortality in Northern Ireland, but the difference in the last few years is quite slight. Females in Northern Ireland, on the other hand, show an appreciably higher rate than their cousins over the water. In 1931 the standardised rate for females was 11·2 per 1000 in Northern Ireland, 9·2 in England and Wales; in 1927–31 it was 11·4 in the former compared with 9·3 in the latter. Whereas the ratio of the female to the male death-rate is only about 81 per cent. in England and Wales, it is about 95 per cent. in Northern Ireland. In fact, calculation of death-rates at ages (on the basis of population at the 1926 census) from the absolute numbers of deaths set out in this report shows that in 1931 the female mortality was appreciably higher than the male mortality at ages 15 to 45, and at most other ages differed from the male mortality by considerably less than is found in England and Wales. According to the rather limited data available in this report—i.e., for the one year 1931—females compared with males suffered unduly high death-rates in Northern Ireland from influenza, tuberculosis of the respiratory system, bronchitis, cerebral hæmorrhage, embolism and thrombosis, and chronic endocarditis and valvular disease. This report only provides the raw materials and offers no clue to the origin of this very noticeable feature of the mortality. Perhaps it should be sought, at least in part, in the proportion of women occupied in the linen mills.

The tuberculosis death-rate, as a whole, has declined quite as steadily in Northern Ireland as in England and Wales, but its level is still appreciably above tha of the latter country among young adults. Between the ages of 15 and 25 tuberculous diseases caused, in 1931, more than 500 deaths in every 1000. The crude cancer death-rate, on the other hand, is appreciably below that of England and Wales, but as 8 per cent. of all deaths in Northern Ireland were in 193 uncertified, and in allocation of cause of death 11 per cent. of all deaths were ascribed to senility, there can be little doubt but that the true rate is understated. During this century there has been a slight increase in the population (in contradistinction to the continual fall in the nineteenth century), but 1931 is the first year in the history of Northern Ireland as a separate administrative unit in which there has been recorded a net migration movement inwards.

INFECTIOUS DISEASE

IN ENGLAND AND WALES DURING THE WEEK ENDE
MARCH 11TH, 1933

Notifications.—The following cases of infectiou disease were notified during the week:—Small-pox, 15 (last week 9); scarlet fever, 1846; diphtheria, 839; enteric fever, 25; acute pneumonia (primary or influenzal), 1299 (last three weeks 2228, 1436, 1362); puerperal fever, 43; puerperal pyrexia, 101; cerebro-spinal fever, 74; acute poliomyelitis, 3; encephalitis lethargica, 13; continued fever, 2 (Northwich R.D., Chester, and St. Thomas R.D., Devon); dysentery, 21; ophthalmia neonatorum, 98. No case of cholera, plague, or typhus fever was notified during the week.

The notifications of acute pneumonia, primary or influenzal were still below the expected number by 31 per cent. in England and Wales and 20 per cent. in the County of London.

The number of cases in the Infectious Hospitals of the London County Council on March 14th–15th was as follows: Small-pox, 52 under treatment, 3 u week 52 and 2 respectively); scarlet f 1581; enteric fever, 8; measles, 302; puerperal fever, 23 (plus 10 babies); 231; poliomyelitis, 2; “other diseases,” 403. At S Margaret's Hospital there were 18 babies (plus 12 mothers with ophthalmia neonatorum.

Deaths.—In 118 great towns, including London there was no death from small-pox or enteric fever 35 (0) from measles, 6 (2) from scarlet fever, 44 (1 from whooping-cough, 29 (5) from diphtheria, 54 (1 from diarrhœa and enteritis under 2 years, and 157 (2 from influenza. The figures in parentheses are those for London itself.

No great town reported more than 8 deaths from influenza. The column of typhoid and paratyphoid fevers is blank. Eight deaths from measles occurred at Liverpool, 3 each Birmingham, Cardiff, and Newport. Whooping-cough accounted for 4 deaths each at West Ham and St. Helens.

The number of stillbirths notified during the week was 286 (corresponding to a rate of 41 per 1000 total births), including 49 in London.

the subject, [illegible] at the matter was very ortant. The Government would oppose the ond reading of this Bill.

he Bill was talked out.

Essex County Council Bill

he Essex County Council Bill (which provides the licensing of establishments in the county for sage and special treatment, and exempts establishts carried on by medical practitioners) was a second time in the House of Lords on Thursday, ch 16th, and was referred to a Select Committee.

HOUSE OF COMMONS

WEDNESDAY, MARCH 15TH

Tuberculosis in the Navy

Bertram Falle asked the First Lord of the Admiralty number of naval ratings invalided during the year 1st to Dec. 31st, 1932; the total number invalided tuberculosis during this period; and the number ided with tuberculosis whose disability was accepted ttributable to service.—Sir Bolton Eyres-Monsell d: The number of naval ratings and Royal Marines ided during the year 1932 was 979. The number ided during that period with pulmonary tuberculosis 199, and in 148 of these cases pensions were granted e attributable scale.

Smell of Sewage at Chiswick

Mitchell asked the Minister of Health whether he inquired into the complaints received from residents in wick with regard to the odour arising from the Chiswick ge works; and, if so, whether he proposed to take any in the matter.—Mr. Shakespeare (Parliamentary tary to the Ministry of Health) replied: My right hon. d is investigating these complaints and is in close with the council as to the measures to be taken. hoped that a remedy will shortly be found.

THURSDAY, MARCH 16TH

Health Insurance Medical Benefit

Banfield asked the Minister of Health whether he aware that in June next many unemployed persons d be in arrears as members of their approved societies the National Health Insurance Acts; that sums up to would have to be paid to clear these arrears; that in y cases payment of these arrears would not entitle the ns concerned to health benefits on account of not g been employed for a considerable time in an insurable pation; and that, owing to the complexity of the law, y of them were ignorant of their position; and whether would take steps to avoid the hardship which would .—Sir E. Hilton Young replied: The cases to which hon. Member refers arise under the provisions of the onal Health Insurance Act, 1932. These were fully ined when the Bill was before the House and all ed persons were informed of the changes by a leaflet d at the end of last year. All possible steps are being n to ease the position for the insured persons affected, arrangements have been made under which arrears to unemployment may be redeemed by instalments y time from now to the end of November next.

Rural Housing

Percy Hurd asked the Minister of Health whether ontribution of £1 per house payable by a county council Section 34 (2) of the Housing Act, 1930, towards the ision of a house for a member of the agricultural population in a rural district applied to the case of rehousing under arance or improvement scheme; what in that event the total weekly rent equivalent of the assistance inable under the Act for slum clearance; and whether s would be taken to make this position more widely n among county and district authorities.—Sir E. on Young replied: The reply to the first and third of the question is in the affirmative. For each three-oomed house provided under the Act the total of the ributions under the Act is approximately equivalent weekly sum of 5*s*. If the house is in an agricultural h the weekly equivalent is 5*s*. 6*d*.

Voluntary Contributors

David Grenfell asked the Minister of Health whether, nnexion with any forthcoming extension of voluntary ributions to national health insurance, and in view of the numbers of previous contributors who have been forced ave insurable occupations, he would consider giving em an opportunity to regain membership by payment oluntary contributions, as was provided in the Act of , for the provision of widows' and orphans' old age ion benefit to insured contributors.—Sir E. Hilton Young replied: No extension of the scope of voluntary insurance under the National Health Insurance Acts is in prospect, and therefore the remainder of the question does not arise. The persons to whom the hon. Member refers have for the most part already had an opportunity of becoming voluntary contributors under existing legislation.

MONDAY, MARCH 20TH

Death at Wrestling Contest

Mr. Clyde Wilson asked the Home Secretary whether his attention had been drawn to a fatality which occurred at an all-in wrestling contest at Sheffield, and the fact that similar contests were taking place in many parts of the country; and whether he would amend the law so as to enable local licensing authorities to regulate and control this form of entertainment.—Sir J. Gilmour replied: I have seen a reference to this contest in the press and I am making inquiry into the circumstances. I have no information that similar contests are frequent and I am not at present in a position to say whether any amendment of the law is necessary.

TUESDAY, MARCH 21ST

Milk for Expectant Mothers

Miss Rathbone asked the Minister of Health whether he was aware that analysis of the reports of the medical officers of health showed that only about half of the county councils and about a fourth of the borough councils exercised their power to provide milk for expectant mothers during the last three months of pregnancy and during lactation; and whether, in view of the high maternal mortality-rate and the privation being suffered by many mothers owing to their husbands' unemployment, he could take steps to urge on local authorities that they should all put this power into operation.—Mr. Shakespeare (Parliamentary Secretary to the Ministry of Health) said that information available to the Department indicated that such provision was made by at least 80 per cent. of the county and borough councils. There was much variation in the use that was made of the milk, but the Minister of Health did not think that the issue of a circular, on the general provision made, would be useful. Action was taken in individual areas where his right hon. friend was satisfied that it was necessary.

Chemical Treatment of Sewage

Mr. Kirkwood asked the Secretary for Scotland whether, in view of the complaints of the Clydebank Town Council and other local authorities regarding the action of the Glasgow Corporation in suspending, for reasons of economy, the chemical treatment of sewage entering the river Clyde at Dalmuir, he would request the Glasgow Corporation to reconsider the decision, in view of the danger to public health caused by the suspension of chemical treatment.—Mr. Skelton (Parliamentary Under-Secretary of State for Scotland) said that the Department of Health for Scotland had received no complaints regarding the action of the Glasgow Corporation in suspending the chemical treatment of sewage entering the river Clyde from the sewage works at Dalmuir, and he was informed that the medical officer of health of Glasgow was of opinion that there had been no danger to public health arising from the action taken. The matter was, however, considered by the Corporation on the 16th inst., when they approved a recommendation that provision should be made in their next year's estimates for the resumption of the chemical treatment of the sewage at the sewage works as from June 1st, 1933.

Vaccination and Death Certificates

Mr. Groves asked the Minister of Health how many death certificates were received during 1932 on which vaccination or vaccinia was mentioned as a cause of death; and the ages of the persons to whom those certificates referred.—Sir E. Hilton Young (Minister of Health) said that three such certificates were received in 1932. The ages of the deceased persons were 3 months, 5 months, and 6 months, respectively. In addition, there were five cases in which the practitioner had entered vaccinia or vaccination as one of the causes of death, but where in the course of the customary inquiries it was ascertained that neither vaccinia nor vaccination had contributed to the fatal issue, and the original certificate was withdrawn.

Milk Marketing

Mr. Leonard asked the Secretary for Scotland whether the report covering the inquiry into the Milk Marketing (Scotland) scheme had been prepared; and whether it was intended to publish it, and when.—Sir G. Collins (Secretary of State for Scotland) said that the answer to the first part of the question was in the affirmative. He had considered the report and hoped to be in a position to submit the scheme to Parliament at an early date; but he did not propose to publish the report.

Scapa Flow. The funeral service at Great St. Mary's Church, Cambridge, was attended by a great concourse of his professional and University colleagues, the representatives of many colleges, and friends.

MONTAGU LOMAX, M.R.C.S. Eng., L.R.C.P. Edin.

THE death is announced at Windlesham House, Shoreham-on-Sea, on Friday last, March 17th, of Dr. Montagu Lomax, who was associated prominently some years ago with the National Society for Lunacy Law Reform. He received his medical education at Edinburgh and St. Bartholomew's Hospital, and obtained his qualification in 1883. He was in practice for a time in New Zealand and was honorary medical officer to a hospital at Canterbury. Later he was assistant medical officer at Prestwich Asylum, b was not a regular member of the asylum medic service. He was however in temporary employm at two asylums during the war, and his life in th institutions impelled him to write a book entitl "Experiences of an Asylum Doctor." This sensatio book played a part in the institution of a departme committee appointed to inquire into the administ tion of the mental hospitals, but Dr. Lomax decli to give evidence personally before the committ On the appearance, however, of the report of t Committee he wrote a reply to it which appeared a pamphlet. The report was admitted on all hands be a fair and well-reasoned document in which cert legitimate criticisms of the administration found th place, and in so doing supported some of Dr. Loma statements, but his general allegations were refuted.

PARLIAMENTARY INTELLIGENCE

NOTES ON CURRENT TOPICS

Pharmacy and Poisons Bill

IN the House of Lords on March 16th the Pharmacy and Poisons Bill was agreed to on Report.

Health in the Villages

In the House of Commons on March 15th, on a motion calling attention to the plight of rural industries, Dr. O'DONOVAN said that if village life and village industries were to prosper there must be a fostering care on the part of the Government of the village labourer's wife. There could be nothing more disheartening than for a village labourer's wife to come to London and see the lavish social services at the disposal of her sister in the city, and to compare that with the impoverished social services at the disposal of the village labourer's wife. They could see arising in every city expensive buildings, staffed by an expensive body of experts for maternity and sickness, but in the country village the country doctor suffered in contrast with the panel practitioner in the town. The village midwife, too, worked under great difficulties and her returns hardly paid for her existence. To ask rural life to prosper under these conditions was to ask a lot, and he was sure that the Government must give a care to the return to the country of some of the money they took from the rural areas in the form of social services comparable to those received by town dwellers. It might be difficult, but difficult problems should be the test of good administration. If village life was to prosper there must be a complete culture; and in addition to the village parson they must have a first-class village teacher and parish doctor, and, he thought, a squire. There must be leaders in the social, medical, clerical, and teaching world, and then civilisation in the country would be complete and be able to stand against the false blandishments of town life. When men decayed in the villages the country could not prosper. He therefore supported the terms of the motion which asked the Government to give a care to village rural life.

Major ELLIOT (Minister of Agriculture) said that he appreciated the necessity that the services which were available for the town dweller should to some extent be available for the country dweller also. Efforts must be made to see that the rural housewife had access to sources of clean water, and that when she was bearing children she had the same services as those afforded to her sisters in the towns and living nearer to the great centres of medical research and education. The encouragement of rural industries and the maintenance of a pride in village life were, he said, fundamental to the policy of the Government. If they could make life in the country healthy, tolerable, and cultured, they would f people returning there.

General Exchequer Contributions Bill

In the House of Commons on March 16th t Local Government (General Exchequer Contrib tions) Bill was read the third time.

Shop Assistants' Hours

On March 17th in the House of Commons M MORGAN JONES moved the second reading of t Shops Acts (1912 to 1928) Amendment Bill. He sa that in 1930 a Bill limiting shop assistants hou to not more than 48 per week was given a secon reading in the House of Commons and referred to Select Committee, which heard a large number witnesses and presented a report. Many of th Committee's conclusions were embodied in th present Bill. Clause 1 laid down the general princip of a 48-hour week and provided that no young pers might work longer, but that shop assistants over years of age might work more than 48 hours per wee if a local board, composed of employers and employe had agreed to overtime employment and a local ord was in force. The Secretary of State was give power under Clause 6 to fix hours of overtime emplo ment where there was substantial disagreement the local board.

Mr. MITCHESON moved:

> That this House, while recognising the undesirabili of shop assistants working excessive hours, declines to gi a second reading to a Bill which would not only invol local authorities in increased expenditure in securing i enforcement, but would also add to the existing burde on industry by hampering business and increasing the co of distribution, and would be bound to lead either to increase in retail prices or to a reduction in the wages shop assistants.

Mr. HACKING (Under Secretary, Home Office replying for the Government, said that in practi the majority of adults in shops were only workin between 48 and 60 hours a week—an average approximately 54 hours a week. The Governme had sympathy with shop assistants, but this Bill woul entail expenditure on local authorities and on th National Exchequer which could not be afforde at the present time. But apart from the expens the question arose whether the measure was reall desirable. By passing the Bill the House might we damage the taxpayer and the ratepayer withou offering much, if any, benefit to the shop assistan themselves. The Government did not desire, howeve to take up a completely *non-possumus* attitude i regard to the employment of young persons in shop under 18. The present old Act gave inadequat protection to these young persons. The Governmen were at this moment giving close attention to tha aspect of the question, and while he could give n pledge as regarded the introduction of legislatio e subject, at the matter was very tant The Government would oppose the d reading of this Bill. e Bill was talked out.

Essex County Council Bill

e Essex County Council Bill (which provides e licensing of establishments in the county for ge and special treatment, and exempts establish- s carried on by medical practitioners) was second time in the House of Lords on Thursday, 16th. and was referred to a Select Committee.

HOUSE OF COMMONS

WEDNESDAY, MARCH 15TH

Tuberculosis in the Navy

BERTRAM FALLE asked the First Lord of the Admiralty umber of naval ratings invalided during the year 1st to Dec. 31st, 1932; the total number invalided tuberculosis during this period and the number ded with tuberculosis whose disability was accepted ributable to service.—Sir BOLTON EYRES MONSELL l The number of naval ratings and Royal Marines ded during the year 1932 was 979 The number ded during that period with pulmonary tuberculosis 9), and in 148 of these cases pensions were granted e attributable scale.

Smell of Sewage at Chiswick

MITCHELL asked the Minister of Health whether he quired into the complaints received from residents in ck with regard to the odour arising from the Chiswick e works; and, if so, whether he proposed to take any n the matter.—Mr. SHAKESPEARE (Parliamentary ary to the Ministry of Health) replied: My right hon is investigating these complaints and is in close with the council as to the measures to be taken. oped that a remedy will shortly be found.

THURSDAY, MARCH 16TH

Health Insurance Medical Benefit

BANFIELD asked the Minister of Health whether he ware that in June next many unemployed persons be in arrears as members of their approved societies the National Health Insurance Acts, that sums up to ould have to be paid to clear these arrears; that in cases payment of these arrears would not entitle the s concerned to health benefits on account of not g been employed for a considerable time in an insurable ation; and that, owing to the complexity of the law, of them were ignorant of their position; and whether ould take steps to avoid the hardship which would —Sir E HILTON YOUNG replied: The cases to which on. Member refers arise under the provisions of the nal Health Insurance Act, 1932. These were fully ned when the Bill was before the House and all d persons were informed of the changes by a leaflet l at the end of last year All possible steps are being to ease the position for the insured persons affected, arrangements have been made under which arrears o unemployment may be redeemed by instalments time from now to the end of November next.

Rural Housing

PERCY HURD asked the Minister of Health whether ntribution of £1 per house payable by a county council Section 34 (2) of the Housing Act, 1930, towards the ion of a house for a member of the agricultural popula- n a rural district applied to the case of rehousing under rance or improvement scheme: what in that event the total weekly rent equivalent of the assistance nable under the Act for slum clearance; and whether s would be taken to make this position more widely n among county and district authorities—Sir E. N YOUNG replied: The reply to the first and third of the question is in the affirmative For each three- omed house provided under the Act the total of the ibutions under the Act is approximately equivalent weekly sum of 5*s* If the house is in an agricultural h the weekly equivalent is 5*s* 6*d*.

Voluntary Contributors

DAVID GRENFELL asked the Minister of Health whether, nnexion with any forthcoming extension of voluntary ibutions to national health insurance, and in view of the numbers of previous contributors who have been forced ave insurable occupations, he would consider giving em an opportunity to regain membership by payment oluntary contributions, as was provided in the Act of , for the provision of widows' and orphans' old age on benefit to insured contributors—Sir E HILTON YOUNG replied: No extension of the scope of voluntary insurance under the National Health Insurance Acts is in prospect, and therefore the remainder of the question does not arise The persons to whom the hon Member refers have for the most part already had an opportunity of becoming voluntary contributors under existing legislation.

MONDAY, MARCH 20TH

Death at Wrestling Contest

Mr. CLYDE WILSON asked the Home Secretary whether his attention had been drawn to a fatality which occurred at an all-in wrestling contest at Sheffield, and the fact that similar contests were taking place in many parts of the country; and whether he would amend the law so as to enable local licensing authorities to regulate and control this form of entertainment—Sir J. GILMOUR replied: I have seen a reference to this contest in the press and I am making inquiry into the circumstances. I have no information that similar contests are frequent and I am not at present in a position to say whether any amendment of the law is necessary.

TUESDAY, MARCH 21ST

Milk for Expectant Mothers

Miss RATHBONE asked the Minister of Health whether he was aware that analysis of the reports of the medical officers of health showed that only about half of the county councils and about a fourth of the borough councils exercised their power to provide milk for expectant mothers during the last three months of pregnancy and during lactation; and whether, in view of the high maternal mortality-rate and the privation being suffered by many mothers owing to their husbands' unemployment, he could take steps to urge on local authorities that they should all put this power into operation.—Mr. SHAKESPEARE (Parliamentary Secretary to the Ministry of Health) said that information available to the Department indicated that such provision was made by at least 80 per cent. of the county and borough councils. There was much variation in the use that was made of the milk, but the Minister of Health did not think that the issue of a circular, on the general provision made, would be useful. Action was taken in individual areas where his right hon friend was satisfied that it was necessary.

Chemical Treatment of Sewage

Mr. KIRKWOOD asked the Secretary for Scotland whether, in view of the complaints of the Clydebank Town Council and other local authorities regarding the action of the Glasgow Corporation in suspending, for reasons of economy, the chemical treatment of sewage entering the river Clyde at Dalmuir, he would request the Glasgow Corporation to reconsider the decision, in view of the danger to public health caused by the suspension of chemical treatment—Mr. SKELTON (Parliamentary Under-Secretary of State for Scotland) said that the Department of Health for Scotland had received no complaints regarding the action of the Glasgow Corporation in suspending the chemical treatment of sewage entering the river Clyde from the sewage works at Dalmuir, and he was informed that the medical officer of health of Glasgow was of opinion that there had been no danger to public health arising from the action taken. The matter was, however, considered by the Corporation on the 16th inst., when they approved a recommendation that provision should be made in their next year's estimates for the resumption of the chemical treatment of the sewage at the sewage works as from June 1st, 1933

Vaccination and Death Certificates

Mr. GROVES asked the Minister of Health how many death certificates were received during 1932 on which vaccination or vaccinia was mentioned as a cause of death; and the ages of the persons to whom those certificates referred —Sir E. HILTON YOUNG (Minister of Health) said that three such certificates were received in 1932. The ages of the deceased persons were 3 months, 5 months, and 6 months, respectively. In addition, there were five cases in which the practitioner had entered vaccinia or vaccination as one of the causes of death, but where in the course of the customary inquiries it was ascertained that neither vaccinia nor vaccination had contributed to the fatal issue, and the original certificate was withdrawn

Milk Marketing

Mr. LEONARD asked the Secretary for Scotland whether the report covering the inquiry into the Milk Marketing (Scotland) scheme had been prepared; and whether it was intended to publish it, and when —Sir G. COLLINS (Secretary of State for Scotland) said that the answer to the first part of the question was in the affirmative He had considered the report and hoped to be in a position to submit the scheme to Parliament at an early date; but he did not propose to publish the report.

Scapa Flow. The funeral service at Great St. Mary's Church, Cambridge, was attended by a great concourse of his professional and University colleagues, the representatives of many colleges, and friends.

MONTAGU LOMAX, M.R.C.S. Eng., L.R.C.P. Edin.

THE death is announced at Windlesham House, Shoreham-on-Sea, on Friday last, March 17th, of Dr. Montagu Lomax, who was associated prominently some years ago with the National Society for Lunacy Law Reform. He received his medical education at Edinburgh and St. Bartholomew's Hospital, and obtained his qualification in 1883. He was in practice for a time in New Zealand and was honorary medical officer to a hospital at Canterbury. Later he was assistant medical officer at Prestwich Asylum
was not a regular member of the asylum m
service. He was however in temporary emplo
at two asylums during the war, and his life in
institutions impelled him to write a book e
"Experiences of an Asylum Doctor." This sens
book played a part in the institution of a depart
committee appointed to inquire into the admi
tion of the mental hospitals, but Dr. Lomax d

place, and in so doing supported some of Dr. L
statements, but his general allegations were ref

PARLIAMENTARY INTELLIGENCE

NOTES ON CURRENT TOPICS

Pharmacy and Poisons Bill

IN the House of Lords on March 16th the Pharmacy and Poisons Bill was agreed to on Report.

Health in the Villages

In the House of Commons on March 15th, on a motion calling attention to the plight of rural industries, Dr. O'DONOVAN said that if village life and village industries were to prosper there must be a fostering care on the part of the Government of the village labourer's wife. There could be nothing more disheartening than for a village labourer's wife to come to London and see the lavish social services at the disposal of her sister in the city, and to compare that with the impoverished social services at the disposal of the village labourer's wife. They could see arising in every city expensive buildings, staffed by an expensive body of experts for maternity and sickness, but in the country village the country doctor suffered in contrast with the panel practitioner in the town. The village midwife, too, worked under great difficulties and her returns hardly paid for her existence. To ask rural life to prosper under these conditions was to ask a lot, and he was sure that the Government must give a care to the return to the country of some of the money they took from the rural areas in the form of social services comparable to those received by town dwellers. It might be difficult, but difficult problems should be the test of good administration. If village life was to prosper there must be a complete culture; and in addition to the village parson they must have a first-class village teacher and parish doctor, and, he thought, a squire. There must be leaders in the social, medical, clerical, and teaching world, and then civilisation in the country would be complete and be able to stand against the false blandishments of town life. When men decayed in the villages the country could not prosper. He therefore supported the terms of the motion which asked the Government to give a care to village rural life.

Major ELLIOT (Minister of Agriculture) said that he appreciated the necessity that the services which were available for the town dweller should to some extent be available for the country dweller also. Efforts must be made to see that the rural housewife had access to sources of clean water, and that when she was bearing children she had the same services as those afforded to her sisters in the towns and living nearer to the great centres of medical research and education. The encouragement of rural industries and the maintenance of a pride in village life were, he said, fundamental to the policy of the Government. If they could make life in the country healthy, tolerable, and cultured, they woul
people returning there.

General Exchequer Contributions Bill

In the House of Commons on March 1
Local Government (General Exchequer Co
tions) Bill was read the third time.

Shop Assistants' Hours

On March 17th in the House of Commo
MORGAN JONES moved the second reading
Shops Acts (1912 to 1928) Amendment Bill.
that in 1930 a Bill limiting shop assistant
to not more than 48 per week was given a
reading in the House of Commons and refer
Select Committee, which heard a large nun
witnesses and presented a report. Many
Committee's conclusions were embodied
present Bill. Clause 1 laid down the general p
of a 48-hour week and provided that no young
might work longer, but that shop assistants
years of age might work more than 48 hours p
if a local board, composed of employers and em
had agreed to overtime employment and a loc
was in force. The Secretary of State was
power under Clause 6 to fix hours of overtime
ment where there was substantial disagreem
the local board.

Mr. MITCHESON moved:

> That this House, while recognising the undes
> of shop assistants working excessive hours, declines
> a second reading to a Bill which would not only
> local authorities in increased expenditure in secu
> enforcement, but would also add to the existing
> on industry by hampering business and increasing
> of distribution, and would be bound to lead eith
> increase in retail prices or to a reduction in the
> shop assistants.

Mr. HACKING (Under Secretary, Home
replying for the Government, said that in
the majority of adults in shops were only
between 48 and 60 hours a week—an ave
approximately 54 hours a week. The Gove
had sympathy with shop assistants, but this Bill
entail expenditure on local authorities and
National Exchequer which could not be a
at the present time. But apart from the e
the question arose whether the measure was
desirable. By passing the Bill the House mig
damage the taxpayer and the ratepayer
offering much, if any, benefit to the shop ass
themselves. The Government did not desire, ho
to take up a completely *non-possumus* attit
regard to the employment of young persons in
under 18. The present old Act gave inad
protection to these young persons. The Gover
were at this moment giving close attention t
aspect of the question, and while he could g
pledge as regarded the introduction of legis

London Homœopathic Hospital

At last week's annual meeting it was reported that the extensions had been completed at a cost of £21.633, and the total number of beds increased to 200. There was a deficit on the year of £2582.

A Children's Hostel

The Queen last week opened the new hostel and nursing school of the National Children Adoption Association at Sydenham Hill, which has accommodation for 40 babies and 20 nurses.

St. Andrew's Hospital, Dollis Hill

Last year this hospital, which is chiefly for the professional and middle-classes, received 1253 in-patients. More than 420 out-patients, accidents, and other urgent cases were dealt with, although the hospital has no special out-patients' department. The accumulated deficit of nearly £3000 was paid off by an anonymous gift, but the total liability, including the debt on the first portion of the nurses' home, the new pavilion, &c., is about £9250.

New Hospital at Lahore

Lady Willingdon recently opened the final portion of the new Lahore hospital for women and children, which is named after her. The building has been under construction since 1925, and has been opened in sections; it has cost £90,000. There are 64 beds, and in its design and equipment the hospital is the most modern in India; last year there were *1800* in-patients. Last week's ceremony was the opening of the main operating block, fitted with an air-conditioning plant which dispenses with fans in summer and fires in winter.

Royal Free Hospital

At the annual meeting last week Lord Riddell, the president, stated that last year the hospital treated 5903 in-patients and 50,515 out-patients, including children attending the dental clinic. Thanks to windfalls income exceeded expenditure by about £8000, but there is an overdraft on general accounts exceeding £30,000, and maintenance costs £100,000 a year. The dental clinic has made great progress, and the opening of the whole of the wards for tonsil, adenoid, ear, and throat cases, which will add another 25 beds, is now contemplated. An arrangement has been made to provide £12,000 a year for ten years for the maintenance of the dental clinic.

Progress of Cremation

The setting up of a National Council for the Disposition of the Dead was announced at the annual meeting of the Cremation Society in London on March 15th, when it was stated that the need for an authoritative body representative of all interests concerned has long been felt, especially in view of the increasing difficulties of local authorities in finding land suitable for cemeteries. The annual report of the Society stated that during the past year two new new crematoria had been opened, bringing the total in the country to 24, while the number of cremations had increased by 21 per cent., giving a total of 6315. The number of cremations had trebled in the last ten years and the society was convinced, from the ever-increasing demand for information received from municipal and other authorities, that the advance would be more rapid in the near future. The facilities for cremation at reduced fees offered by most cremation authorities to those insured under the National Health Insurance Acts, and their dependants, had brought cremation within the reach of many who might have been deterred from it from reasons of economy, or who were under the inpression that cremation was more expensive than earth burial. Apart from questions of transport the cost of cremation compares favourably, it is stated, with ordinary burial.
